CURRENT Medical Diagnosis & Treatment on AccessMedicine

Looking for the latest diabetes recommendations? Go to AccessMedicine.com/CMDT where you'll find this guidance as well as coverage of more than 1,000 diseases and disorders!

CURRENT Medical Diagnosis & Treatment 2026
Current Medical Diagnosis & Treatment 2026
Part 32. Diabetes Mellitus & Hypoglycemia

CURRENT Medical Diagnosis & Treatment (CMDT) on AccessMedicine gives you all the trusted book content in a searchable format plus expanded topic coverage, videos, audio clips, more images, and exclusive online-only chapters.

How will CMDT on AccessMedicine help you in your clinical practice?

- The **"Year in Review"** informs you on more than 100 of the most notable clinical changes over the last 12 months
- Search and navigation tools will expedite your clinical search
- Multimedia allows you to experience the sights and sounds of clinical conditions

Discover the above and more at **www.AccessMedicine.com/CMDT**

Purchasers of the book receive access to the e-chapters as noted in the table of contents. An AccessMedicine subscription includes the digitally searchable version of CMDT.

Quick Medical Diagnosis & Treatment

Quick Medical Diagnosis & Treatment 2026
QUICK
2026
LANGE
Diabetes Mellitus, Type 2

Over 960 diseases and conditions at your fingertips!

Quick Medical Diagnosis & Treatment is distilled from the trusted, best-selling annual guide to adult internal medicine–CURRENT Medical Diagnosis & Treatment.

Organized alphabetically, topics are bulleted for concise and at-a-glance use in a busy clinical setting.

Each disease is structured to highlight:
- Essentials of diagnosis
- Symptoms, signs, and differential diagnosis
- Laboratory tests, imaging studies, and diagnostic procedures
- Medications, surgery, and therapeutic procedures
- Complications, prognosis, when to refer, and when to admit
- References to clinical guidelines, must-know studies, and helpful online resources

Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each medication they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used medications.

This book was set in Minion Pro by KnowledgeWorks Global Ltd.
The editors were Kay Conerly, Jennifer Bernstein, and Sylvia Choi.
The production supervisor was Jeffrey Herzich.
The digital production manager was Priscilla Beer.
Project management was provided by Radhika Jolly at KnowledgeWorks Global Ltd.
The copyeditors were Greg Feldman, Kathryn Whitley, Allison Scerbo, and Kerri Fitzgerald.
The index was prepared by Susan Hunter.

This book is printed on acid-free paper.

McGraw Hill books are available at special quantity discounts to use as premiums and sales promotions, or for use in corporate training programs. To contact a representative, please visit the Contact Us pages at www.mhprofessional.com.

YEAR IN REVIEW:
KEY CLINICAL UPDATES IN *CMDT* 2026

1. Disease Prevention & Health Promotion 1
Michael Pignone, MD, MPH

2. Common Symptoms 15
Paul L. Nadler, MD, &
Ralph Gonzales, MD, MSPH

3. Preoperative Evaluation & Perioperative Management 42
Hugo Q. Cheng, MD

4. Geriatric Disorders 52
Leah J. Witt, MD, Rossana Lau-Ng, MD,
Tina R. Sadarangani, PhD, RN, ANP-C, GNP-BC,
FAAN, & G. Michael Harper, MD

5. Palliative Care & Pain Management 69
Kara E. Bischoff, MD, Sarah Nouri, MD, MPH,
Michael W. Rabow, MD, Ann Cai Shah, MD,
Lawrence Poree, MD, MPH, PhD, &
Karin Sinavsky, MD, MS

6. Dermatologic Disorders 100
Nathan W. Rojek, MD, & Scott Worswick, MD

7. Disorders of the Eyes & Lids 165
Jacque L. Duncan, MD, Neeti B. Parikh, MD, &
Gerami D. Seitzman, MD

8. Otolaryngology Disorders 199
Elliott D. Kozin, MD, & Lawrence R. Lustig, MD

9. Pulmonary Disorders 240
Rime Abbas, MD, Mazen El Ali, MD,
Meghan E. Fitzpatrick, MD, &
Belinda Rivera-Lebron, MD, MS, FCCP

10. Coronary Artery Disease, Valvular Disease, & Other Key Topics in Cardiology 313
Todd Kiefer, MD

11. Heart Failure & Cardiomyopathy 386
Christopher B. Granger, MD

12. Disorders of Cardiac Rhythm 406
Kevin P. Jackson, MD

13. Systemic Hypertension 426
Michael Sutters, MD, MRCP (UK)

14. Blood Vessel & Lymphatic Disorders 455
Warren J. Gasper, MD, James C. Iannuzzi, MD, MPH,
& Meshell D. Johnson, MD

15. Blood Disorders 483
Lloyd E. Damon, MD, &
Charalambos Babis Andreadis, MD, MSCE

16. Disorders of Hemostasis, Thrombosis, & Antithrombotic Therapy 528
Andrew D. Leavitt, MD, &
Erika Leemann Price, MD, MPH

17. Gastrointestinal Disorders 562
Kenneth R. McQuaid, MD

18. Liver, Biliary Tract, & Pancreas Disorders 656
Elliot B. Tapper, MD, FAASLD, &
Lawrence S. Friedman, MD

19. Breast Disorders 716
Armando E. Giuliano, MD, FACS, FRCSEd, &
Sara A. Hurvitz, MD, FACP

20. Women's Health Issues 742
Brigid M. Dolan, MD, MEd, &
Judith Walsh, MD, MPH

21. Gynecologic Disorders 748
Jill Brown, MD, MPH, MHS, FACOG, &
Katerina Shvartsman, MD, FACOG

22. Obstetrics & Obstetric Disorders 778
Vanessa L. Rogers, MD, & Scott W. Roberts, MD

23. Rheumatologic, Immunologic, & Allergic Disorders 804

Jinoos Yazdany, MD, MPH, Rebecca L. Manno, MD, MHS, Teresa K. Tarrant, MD, & Mildred Kwan, MD, PhD

24. Electrolyte & Acid-Base Disorders 861

Nayan Arora, MD, FASN, & J. Ashley Jefferson, MD, FRCP

25. Kidney Disease 889

Tonja C. Dirkx, MD, & Tyler B. Woodell, MD, MCR

26. Urologic Disorders 928

Mathew Sorensen, MD, MS, FACS, Marah C. Hehemann, MD, & Brian Jordan, MD

27. Nervous System Disorders 954

Vanja C. Douglas, MD, & Michael J. Aminoff, MD, DSc, FRCP

28. Psychiatric Disorders 1033

Kristin S. Raj, MD, Nolan R. Williams, MD, & Charles DeBattista, DMH, MD

29. Disorders of the Pituitary, Thyroid, & Adrenal Glands 1075

Paul A. Fitzgerald, MD

30. Disorders of Parathyroid Glands & Bone Metabolism 1128

Anne Schafer, MD, & Paul A. Fitzgerald, MD

31. Male Hypogonadism & Gynecomastia, Hirsutism & Virilization 1147

Paul A. Fitzgerald, MD

32. Diabetes Mellitus & Hypoglycemia 1156

Savitha Subramanian, MD, Amy Eby, MD, & Umesh Masharani, MB, BS

33. Lipid Disorders 1199

Michael J. Blaha, MD, MPH

34. Nutrition, Nutritional Disorders, & Obesity 1210

Katherine H. Saunders, MD, Leon I. Igel, MD, FACP, FTOS, DABOM, & Sarah Fink, RD, CDN, CNSC

35. Common Problems in Infectious Diseases & Antimicrobial Therapy 1230

Monica Fung, MD, MPH, Katherine Gruenberg, PharmD, MAEd, & Peter V. Chin-Hong, MD

36. HIV Infection & AIDS 1274

Monica Gandhi, MD, MPH, & Matthew A. Spinelli, MD, MAS

37. Viral & Rickettsial Infections 1315

John Szumowski, MD, MPH, Tyler Brehm, MD, Jishna Shrestha, MBBS, & Wayne X. Shandera, MD

38. Bacterial & Chlamydial Infections 1401

Kelly A. Johnson, MD, MPH, & Emma D. Bainbridge, MD, MPH

39. Spirochetal Infections 1441

Ina Park, MD, MS

40. Protozoal & Helminthic Infections 1458

Philip J. Rosenthal, MD

41. Mycotic Infections 1494

Stacey R. Rose, MD, FACP, FIDSA, & Richard J. Hamill, MD, FIDSA

42. Disorders Related to Environmental Emergencies 1508

Jacqueline A. Nemer, MD, FACEP, & Marianne A. Juarez, MD

43. Poisoning 1523

Craig Smollin, MD

44. Cancer 1547

Sunny Wang, MD, Tiffany O. Dea, PharmD, BCOP, Elliot B. Tapper, MD, FAASLD, Lawrence S. Friedman, MD, Carling Ursem, MD, Kenneth R. McQuaid, MD, & Marc A. Dall'Era, MD

45. Genetic & Genomic Disorders 1608

Reed E. Pyeritz, MD, PhD

46. Orthopedic Disorders & Sports Medicine 1619

Anthony Luke, MD, MPH, & C. Benjamin Ma, MD

47. Sexual & Gender Minority Health 1655

Patricia A. Robertson, MD, Nicole Rosendale, MD, Kevin L. Ard, MD, MPH, Kenneth H. Mayer, MD, & Mitzi Hawkins, MD

48. Substance Use Disorders 1677

J. Janet Ho, MD, MPH, FASAM, Jessica Ristau, MD, Soraya Azari, MD, Julian A. Mitton, MD, MPH, & Meshell D. Johnson, MD

The following chapters are available online without subscription at www.accessmedicine.com/CMDT

e1. Anti-infective Treatment: Antibiotic, Antifungal, & Antiviral Agents

Katherine Gruenberg, PharmD, MAEd, & Emily Kaip, PharmD

e2. Diagnostic Testing & Medical Decision-Making

Chuanyi Mark Lu, MD

e3. Information Technology in Patient Care

Russ Cucina, MD, MS

e4. Podiatric Disorders

Monara Dini, DPM, & Charles B. Parks, DPM

e5. Appendix: Therapeutic Drug Monitoring, Pharmacogenetic Tests, Laboratory Reference Intervals, & Commonly Used Blood Specimen Collection Tubes

Chuanyi Mark Lu, MD

Index 1705

Authors

Rime Abbas, MD
Clinical Assistant Professor, Division of Pulmonary, Allergy, Critical Care, and Sleep Medicine, Department of Medicine, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania
Pulmonary Disorders

Michael J. Aminoff, MD, DSc, FRCP
Distinguished Professor Emeritus, Department of Neurology, University of California, San Francisco
Nervous System Disorders

Charalambos Babis Andreadis, MD, MSCE
Professor of Clinical Medicine, Division of Hematology/Oncology, Department of Medicine, University of California, San Francisco
Blood Disorders

Kevin L. Ard, MD, MPH
Faculty, Division of Infectious Diseases, Massachusetts General Hospital; Medical Director, National LGBTQIA+ Health Education Center, Fenway Institute; Assistant Professor of Medicine, Harvard Medical School, Boston, Massachusetts
Sexual & Gender Minority Health

Nayan Arora, MD, FASN
Associate Professor of Medicine, Division of Nephrology, Oregon Health and Science University, Portland, Oregon
Electrolyte & Acid-Base Disorders

Soraya Azari, MD
Physician Specialist, San Francisco Department of Public Health (SFDPH); Professor of Medicine, University of California, San Francisco, Zuckerberg San Francisco General and Trauma Center
Substance Use Disorders

Emma D. Bainbridge, MD, MPH
Assistant Clinical Professor, Division of Infectious Diseases, Department of Medicine, University of California, San Francisco
Bacterial & Chlamydial Infections

Kara E. Bischoff, MD
Associate Professor and Associate Division Chief for Outpatient Palliative Care, University of California, San Francisco
Palliative Care & Pain Management

Michael J. Blaha, MD, MPH
Professor of Medicine, Division of Cardiology, Department of Medicine; Director of Clinical Research, Ciccarone Center for the Prevention of Cardiovascular Disease; Johns Hopkins University School of Medicine, Baltimore, Maryland
Lipid Disorders

Tyler Brehm, MD
Infectious Diseases Fellow, Baylor College of Medicine, Houston, Texas
Viral & Rickettsial Infections

Jill Brown, MD, MPH, MHS, FACOG
Associate Professor, Department of Gynecologic Surgery and Obstetrics, Uniformed Services University of the Health Sciences, Bethesda, Maryland
Gynecologic Disorders

Mandy Brown, PharmD
Associate Clinical Professor, School of Pharmacy, University of California, San Francisco
Drug References

Hugo Q. Cheng, MD
Clinical Professor of Medicine, Division of Hospital Medicine, Department of Medicine, University of California, San Francisco
Preoperative Evaluation & Perioperative Management

Peter V. Chin-Hong, MD
Associate Dean for Regional Campuses, Professor of Medicine, Division of Infectious Diseases, Department of Medicine, University of California, San Francisco
Common Problems in Infectious Diseases & Antimicrobial Therapy

Russ Cucina, MD, MS
Professor of Hospital Medicine, Department of Medicine; Vice President, Genetic and Genomic Services and Chief Health Information Officer, UCSF Health System; University of California, San Francisco
CMDT on AccessMedicine—Information Technology in Patient Care

Marc A. Dall'Era, MD
Professor of Urology, Department of Urologic Surgery, UC Davis Health, University of California, Davis
Cancer

Lloyd E. Damon, MD
Professor Emeritus of Hematology, Division of Hematology/Oncology, Department of Medicine, University of California, San Francisco
Blood Disorders

Tiffany O. Dea, PharmD, BCOP
Oncology Pharmacist, Veterans Affairs Health Care System, San Francisco, California; Adjunct Professor, Thomas J. Long School of Pharmacy and Health Sciences, Stockton, California
Cancer

Charles DeBattista, DMH, MD
Professor of Psychiatry and Behavioral Sciences, Department of Psychiatry and Behavioral Sciences; Director, Depression Clinic and Research Program; Director of Medical Student Education in Psychiatry, Stanford University School of Medicine, Stanford, California
Psychiatric Disorders

Monara Dini, DPM
Associate Clinical Professor of Orthopedics, Department of Orthopedic Surgery, University of California, San Francisco
CMDT on AccessMedicine —Podiatric Disorders

Tonja C. Dirkx, MD
Chief, Nephrology Section, Veterans Affairs Portland Health Care System; Associate Professor of Medicine, Division of Nephrology, Department of Medicine, Oregon Health & Science University, Portland, Oregon
Kidney Disease

Brigid M. Dolan, MD, Med
Associate Professor of Medicine and Medical Education, Division of General Internal Medicine, Departments of Medicine and Medical Education, Northwestern University Feinberg School of Medicine
Women's Health Issues

Vanja C. Douglas, MD
Sara & Evan Williams Foundation Endowed Neurohospitalist Chair, Professor of Clinical Neurology, Department of Neurology, University of California, San Francisco
Nervous System Disorders

Jacque L. Duncan, MD
Chair and Distinguished Professor, Department of Ophthalmology, University of California, San Francisco
Disorders of the Eyes & Lids

Amy Eby, MD
Clinical Assistant Professor, Division of Internal Medicine, University of Washington, Seattle, Washington
Diabetes Mellitus & Hypoglycemia

Mazen El Ali, MD
Clinical Assistant Professor of Medicine, Division of Pulmonary, Allergy and Critical Care Medicine, Department of Medicine; Director, Sleep Medicine Fellowship Program, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania
Pulmonary Disorders

Sarah Adler Fink, RD, CDN, CNSC
Dietetic Internship Program Coordinator, Department of Food and Nutrition, New York-Presbyterian Hospital, New York, New York
Nutrition, Nutritional Disorders, & Obesity

Paul A. Fitzgerald, MD
Clinical Professor of Medicine, Division of Endocrinology, Department of Medicine, University of California, San Francisco
Disorders of the Pituitary, Thyroid, & Adrenal Glands; Disorders of Parathyroid Glands & Bone Metabolism; Male Hypogonadism & Gynecomastia, Hirsutism & Virilization

Meghan E. Fitzpatrick, MD
Assistant Professor of Medicine, Division of Pulmonary and Critical Care Medicine, Department of Medicine, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania
Pulmonary Disorders

Lawrence S. Friedman, MD
Professor of Medicine, Harvard Medical School; Professor of Medicine, Tufts University School of Medicine, Boston, Massachusetts; The Anton R. Fried, MD, Chair, Department of Medicine, Newton-Wellesley Hospital, Newton, Massachusetts; Assistant Chief of Medicine, Massachusetts General Hospital, Boston
Liver, Biliary Tract, & Pancreas Disorders; Cancer

Monica Fung, MD, MPH
Associate Professor, Division of Infectious Diseases, Department of Medicine, University of California, San Francisco
Common Problems in Infectious Diseases & Antimicrobial Therapy

Monica Gandhi, MD, MPH
Professor, Division of HIV, ID, and Global Medicine, San Francisco General Hospital; University of California, San Francisco
HIV Infection & AIDS

Warren J. Gasper, MD
Associate Professor of Clinical Surgery, Division of Vascular and Endovascular Surgery, Department of Surgery, University of California, San Francisco
Blood Vessel & Lymphatic Disorders

Armando E. Giuliano, MD, FACS, FRCSEd
Professor of Surgery, Linda and Jim Lippman Chair in Surgical Oncology; Director, Surgical Oncology; Associate Director, Cedars-Sinai Cancer Center, Los Angeles, California
Breast Disorders

Ralph Gonzales, MD, MSPH
Professor of Medicine, Division of General Internal Medicine, Department of Medicine; Associate Dean, Clinical Innovation and Chief Innovation Officer, UCSF Health; University of California, San Francisco
Common Symptoms

Christopher B. Granger, MD
Fred Cobb, MD Distinguished Professor of Medicine, Professor of Nursing, Division of Cardiology, Duke University Medical Center Duke Clinical Research Institute, Durham, North Carolina
Heart Failure & Cardiomyopathy

Katherine Gruenberg, PharmD, MAEd
Associate Professor of Clinical Pharmacy, School of Pharmacy, University of California, San Francisco
Common Problems in Infectious Diseases & Antimicrobial Therapy; CMDT on AccessMedicine—Anti-Infective Treatment: Antibiotic, Antifungal, & Antiviral Agents

Richard J. Hamill, MD, FIDSA
Section of Infectious Diseases, Department of Medicine, Baylor College of Medicine Staff Physician, Infectious Diseases Section, Michael E. DeBakey VA Medical Center Houston, TX
Mycotic Infections

G. Michael Harper, MD
Professor, Division of Geriatrics, Department of Medicine, University of California, San Francisco School of Medicine; San Francisco Veterans Affairs Health Care System, San Francisco, California
Geriatric Disorders

Mitzi Hawkins, MD
Assistant Professor, Obstetrics, Gynecology & Reproductive Sciences, University of California, San Francisco
Sexual & Gender Minority Health

Marah C. Hehemann, MD
Assistant Professor, Department of Urology, University of Washington, Seattle, Washington
Urologic Disorders

J. Janet Ho, MD, MPH, FASAM
Associate Professor, University of California, San Francisco
Substance Use Disorders

Sara A. Hurvitz, MD, FACP
Professor of Medicine, Smith Family Endowed Chair in Women's Health; Head, Division of Hematology and Oncology, University of Washington Department of Medicine; Senior Vice President, Clinical Research Division, Fred Hutchinson Cancer Center
Breast Disorders

James C. Iannuzzi, MD, MPH
Associate Professor of Surgery, Division of Vascular and Endovascular Surgery, Department of Surgery, University of California, San Francisco
Blood Vessel & Lymphatic Disorders

Leon I. Igel, MD, FACP, FTOS, DABOM
Clinical Assistant Professor of Medicine, Division of Endocrinology, Diabetes and Metabolism, Department of Medicine, Weill Cornell Medical College, New York, New York; Chief Medical Officer, FlyteHealth, New Canaan, Connecticut
Nutrition, Nutritional Disorders, & Obesity

Kevin P. Jackson, MD
Associate Professor of Medicine, Division of Cardiology, Department of Medicine; Director of Electrophysiology Lab, Duke University Hospital, Duke University Medical Center, Durham, North Carolina
Disorders of Cardiac Rhythm

J. Ashley Jefferson, MD, FRCP
Professor of Medicine, Division of Nephrology, Department of Medicine; Section Head, Nephrology, University of Washington Medical Center, Seattle, Washington
Electrolyte & Acid-Base Disorders

HIV Infection & AIDS

Savitha Subramanian, MD
Professor of Medicine, Division of Metabolism, Endocrinology and Nutrition, University of Washington, Seattle, Washington
Diabetes Mellitus & Hypoglycemia

Michael Sutters, MD, MRCP (UK)
Attending Nephrologist, Virginia Mason Medical Center, Seattle, Washington
Systemic Hypertension

John Szumowski, MD, MPH
Associate Clinical Professor, Division of Infectious Diseases, Department of Medicine, San Francisco VA Medical Center and University of California, San Francisco
Viral & Rickettsial Infections

Elliot B. Tapper, MD, FAASLD
Associate Professor and Chief, Hepatology Division of Gastroenterology and Hepatology, University of Michigan, Ann Arbor, Michigan
Liver, Biliary Tract, & Pancreas Disorders; Cancer

Teresa K. Tarrant, MD
Associate Professor, Department of Medicine, Division of Rheumatology and Immunology, Duke University Health System, Durham, North Carolina
Rheumatologic, Immunologic, & Allergic Disorders

Carling Ursem, MD
Assistant Professor, Division of Hematology and Oncology, Department of Medicine, University of California, San Francisco; Staff Physician, Veterans Affairs Health Care System, San Francisco
Cancer

Judith Walsh, MD, MPH
Professor of Clinical Medicine, Division of General Internal Medicine, Women's Health Center of Excellence, University of California, San Francisco
Women's Health Issues

Sunny Wang, MD
Professor of Clinical Medicine, Division of Hematology/Oncology, University of California, San Francisco; Chief of Hematology/Oncology, San Francisco Veterans Affairs Health Care System
Cancer

Nolan R. Williams, MD
Associate Professor of Psychiatry and Behavioral Sciences (Major Labs & Translational Neuroscience Incubator) and, by courtesy, of Radiology (Neuroimaging and Neurointervention); Director, Brain Stimulation Laboratory; Director, Interventional Psychiatry Clinical Research, Department of Psychiatry and Behavioral Sciences, Stanford University
Psychiatric Disorders

Leah J. Witt, MD
Associate Professor, Division of Geriatrics and Division of Pulmonary, Critical Care, Allergy and Sleep Medicine, Department of Medicine, University of California, San Francisco
Geriatric Disorders

Tyler B. Woodell, MD, MCR
Associate Professor of Medicine, Division of Nephrology-Hypertension, Department of Medicine, University of California, San Diego
Kidney Disease

Scott Worswick, MD
Clinical Associate Professor of Dermatology, Department of Dermatology, Keck School of Medicine, University of Southern California
Dermatologic Disorders

Jinoos Yazdany, MD, MPH
Alice Betts Endowed Professor, Department of Medicine, University of California, San Francisco; Chief of Division of Rheumatology, Zuckerberg San Francisco General Hospital
Rheumatologic, Immunologic, & Allergic Disorders

Preface

CURRENT Medical Diagnosis & Treatment 2026 (CMDT 2026) is the 65th edition of this single-source reference for practitioners of adult medicine in both hospital and ambulatory settings. The book emphasizes the practical features of clinical diagnosis and patient management in all fields of internal medicine and in specialties of interest to primary care practitioners and to subspecialists who provide general care.

The editors of *CMDT* have committed to a thorough examination of our content to remove biased language, research, and recommendations. Since 2020, we have been pursuing an ongoing, formal process of review and revision in an effort to recognize and correct biases and to promote equity in our book and thus in the practice of medicine. While we, the editors, take this on as our responsibility, we also invite readers to share with us any *CMDT* content that they find problematic or biased. Please email comments to CMDT@mheducation.com.

We have tried to describe populations used in the studies that form the basis of the information in *CMDT* and use appropriate language where we can (eg, persons of sub-Sahara African descent, rather than African Americans). We continue, however, to use terms from original sources when study populations are broad.

INTENDED AUDIENCE FOR *CMDT*

House officers, medical students, and all other health professions learners will find the descriptions of diagnostic and therapeutic modalities, with citations to the current literature, of everyday usefulness in patient care.

Internists, family physicians, hospitalists, nurse practitioners, physician associates, and all primary care providers of adult medicine will appreciate *CMDT* as a ready reference and refresher text. Physicians in other specialties, pharmacists, and dentists will find the book a useful basic medical reference text. Nurses, nurse practitioners, and physician associates will welcome the format and scope of the book as a means of quickly referencing medical diagnosis and treatment modalities.

Patients and their family members who seek information about the nature of specific diseases and their diagnosis and treatment may also find this book to be a valuable resource.

NEW IN THIS EDITION OF *CMDT*

The ***"Year in Review: Key Clinical Updates in CMDT 2026"*** highlights what the editors consider to be the most significant clinical changes over the last year, providing page numbers and reference citations for easy access. This tool is meant to get users "current" quickly but does not reflect all the changes since the last edition.

OUTSTANDING FEATURES OF *CMDT*

- Medical advances up to time of annual publication
- Detailed presentation of internal medicine disciplines, plus key primary care topics
- At-a-glance format, facilitating efficient use in any practice setting
- Coverage of more than 1000 diseases and disorders
- Specific disease prevention information
- Easy access to medication dosages, with trade names indexed and updated in each annual edition
- Recent references, with unique identifiers (PubMed, PMID numbers) for rapid downloading of article abstracts and, in some instances, full-text reference articles

BONUS E-CHAPTERS, *CMDT* ON ACCESSMEDICINE

Five ***e-chapters*** listed in the Table of Contents can be accessed at **www.AccessMedicine.com/CMDT**. These online-only chapters (available without the need for subscription) include

- Anti-Infective Chemotherapeutic & Antibiotic Agents
- Diagnostic Testing & Medical Decision-Making
- Information Technology in Patient Care
- Podiatric Disorders
- Appendix: Therapeutic Drug Monitoring, Laboratory Reference Intervals, & Commonly Used Blood Specimen Collection Tubes

ACKNOWLEDGMENTS

We wish to thank our authors for participating once again in the annual updating of this important book. We are especially grateful to Patrycja Ashley, MD, Eva H. Clark, MD, PhD, Lindy P. Fox, MD, Maahum A. Haider, MD, MPH, Susan S. Philip, MD, MPH, Roth Sethi, MD, and Kanade Shinkai, MD, who are passing the baton this year. We have all benefited from their clinical wisdom and commitment.

Many students and physicians have contributed useful suggestions to this and previous editions, and we are grateful. We continue to welcome comments and recommendations for future editions via email at CMDT@mheducation.com.

Maxine A. Papadakis, MD
Michael W. Rabow, MD
Kenneth R. McQuaid, MD
Paul L. Nadler, MD
Erika Leemann Price, MD, MPH

San Francisco, California

COMMONLY USED ACRONYMS & ABBREVIATIONS

AAA	Abdominal aortic aneurysm
ABG	Arterial blood gas
ACE	Angiotensin-converting enzyme
ACS	Acute coronary syndrome
ACTH	Adrenocorticotropic hormone
AKI	Acute kidney injury
ALT	Alanine aminotransferase
ANA	Antinuclear antibodies
ARB	Angiotensin receptor blocker
AST	Aspartate aminotransferase
ATN	Acute tubular necrosis
BMI	Body mass index
BNP	B-type natriuretic peptide
BPH	Benign prostatic hypertrophy
BUN	Blood urea nitrogen
CAD	Coronary artery disease
CBC	Complete blood count
CDC	Centers for Disease Control and Prevention
CHD	Coronary heart disease
CI	Confidence interval
CKD	Chronic kidney disease
CNS	Central nervous system
COPD	Chronic obstructive pulmonary disease
COVID-19	Coronavirus disease 2019
CRP	C-reactive protein
CSF	Cerebrospinal fluid
CT	Computed tomography or computed tomographic
CVD	Cardiovascular disease
CVP	Central venous pressure
CXR	Chest radiograph
DLCO	Diffusing capacity for carbon monoxide
DOAC	Direct-acting oral anticoagulant
DSM-5	*Diagnostic Statistical Manual,* 5e
DVT	Deep venous thrombosis
ECG	Electrocardiogram; electrocardiography
EF	Ejection fraction
eGFR	Estimated glomerular filtration rate
ELISA	Enzyme-linked immunosorbent assay
ESKD	End-stage kidney disease
ESR	Erythrocyte sedimentation rate
FEV$_1$	Forced expiratory volume in 1 second
FSH	Follicle-stimulating hormone
FVC	Forced vital capacity
GERD	Gastroesophageal reflux disease
GFR	Glomerular filtration rate
GI	Gastrointestinal
GLP-1	Glucagon-like peptide-1
HCC	Hepatocellular carcinoma
HDL	High-density lipoprotein
HF	Heart failure
HPV	Human papillomavirus
HRCT	High-resolution computed tomography
IBD	Inflammatory bowel disease
ICD-11	International Classification of Diseases, 11e
ICU	Intensive care unit
INR	International normalized ratio
IUD	Intrauterine device
LD	Lactate dehydrogenase
LDL	Low-density lipoprotein
LH	Luteinizing hormone
LR	Likelihood ratio
LV	Left ventricle or left ventricular
LVEDP	Left ventricular end-diastolic pressure
LVEF	Left ventricular ejection fraction
LVH	Left ventricular hypertrophy
MAO	Monoamine oxidase inhibitor
MI	Myocardial infarction
MMR	Measles, mumps, rubella
MRI	Magnetic resonance imaging
NIH	National Institutes of Health
NSAIDs	Nonsteroidal anti-inflammatory drugs
nSTEMI	Non–ST-segment elevation myocardial infarction
OCD	Obsessive-compulsive disorder
PCR	Polymerase chain reaction
PE	Pulmonary embolism
PEF	Peak expiratory flow
PET	Positron emission tomography
PFTs	Pulmonary function tests
PPI	Proton pump inhibitor
PSA	Prostate-specific antigen
RBC	Red blood cell
RCT	Randomized controlled trial
RSV	Respiratory syncytial virus
RV	Right ventricle or right ventricular
RVH	Right ventricular hypertrophy
SGLT-2	Sodium-glucose cotransporter-2
SIADH	Syndrome of inappropriate antidiuretic hormone
SLE	Systemic lupus erythematosus
SSRI	Selective serotonin reuptake inhibitor
STEMI	ST-segment elevation myocardial infarction
STI	Sexually transmitted infection
TLC	Total lung capacity
TNF	Tumor necrosis factor
TSH	Thyroid-stimulating hormone
UA	Urinalysis
US FDA	United States Food and Drug Administration
USPSTF	United States Preventive Services Task Force
UTI	Urinary tract infection
VTE	Venous thromboembolism
WBC	White blood cell
WHO	World Health Organization

YEAR IN REVIEW: KEY CLINICAL UPDATES IN *CMDT* 2026

Entries presented in the Year in Review are curated by the editors as being extremely impactful to daily clinical practice. These highlighted entries are only a fraction of all the updates included across this edition of *CMDT*.

Topic	Page Number	Key New Advances Affecting Clinical Practice*
CHAPTER 1: DISEASE PREVENTION & HEALTH PROMOTION		
Prevention of Infectious Diseases	4	The Advisory Committee on Immunization Practices has updated their recommendations, including: • A second dose of 2024–2025 COVID-19 vaccine for adults ages 65 years and older and for those ages 6 months to 64 years who are moderately or severely immunocompromised. • MenB-4C (Bexsero®) administered as a 2-dose series (0 and 6 months) for young adults aged 16–23 years for the prevention of serogroup B meningococcal disease and as a 3-dose series for persons aged ≥ 10 years at increased risk for serogroup B meningococcal disease. • Pneumococcal vaccination for all adults aged 50 years and older. • Two doses of recombinant zoster vaccine (RZV) to prevent shingles and related complications in adults aged ≥ 50 years and for adults aged ≥ 19 years who are or will be immunodeficient or immunosuppressed.
CHAPTER 2: COMMON SYMPTOMS		
Acute Headache	37	• MRI is the modality of choice for evaluation of headache in pregnant patients and supported as safe by the American College of Radiology. *Griege T et al. Ann Emerg Med. [PMID: 38597849]*
Dysuria	40	• A double-blind randomized placebo-controlled trial across 99 primary care centers examined the use of D-mannose for protection against recurrent UTIs and found no benefit. *Hayward G et al. JAMA Intern Med. [PMID: 38587819]*
	40	• A systematic review of six randomized controlled trials found methenamine hippurate to be as effective as antibiotic prophylaxis in reducing recurrent UTIs. *Kale S et al. Curr Opin Urol. [PMID: 37337660]*
CHAPTER 3: PREOPERATIVE EVALUATION & PERIOPERATIVE MANAGEMENT		
Cardiac Risk Assessment & Reduction in Noncardiac Surgery	43	The 2024 American College of Cardiology and American Heart Association guideline: • Emphasizes that ischemia evaluation by stress testing or coronary CT angiography is primarily indicated to exclude high risk coronary anatomy such as left main coronary artery disease, rather than to identify undiagnosed CAD or assess risk. • Recommends measuring BNP or NT-proBNP in selected patients who have both elevated risk based on a prediction tool and limited functional capacity. Patients with normal biomarker measurements, defined as BNP < 92 ng/L or NT-proBNP < 300 ng/L, generally have acceptable cardiac risk and do not require additional risk stratification testing. *Thompson A et al. Circulation. [PMID: 39316661]*
CHAPTER 6: DERMATOLOGIC DISORDERS		
Pruritus	159	• Nemolizumab (IL-31 inhibitor) and dupilumab (IL-4/13 inhibitor) are each approved to treat prurigo nodularis. *Liao V et al. Br J Dermatol. [PMID: 38345154]*

*See chapter for further details and references.

(continued on following page)

Topic	Page Number	Key New Advances Affecting Clinical Practice*
CHAPTER 7: DISORDERS OF THE EYES & LIDS		
Blepharitis	174	• Topical antimicrobials targeting staphylococcal or *Demodex* mite overgrowth can be helpful. Lotilaner 0.25% solution, the first therapy approved to treat *Demodex* mite blepharitis, is applied twice daily for 6 weeks. *Davey PG et al. Healthcare (Basel). [PMID: 39120190]*
	174	• Oral antibiotics (tetracyclines and macrolines) may be helpful in patients with rosacea.
Conjunctivitis	167	• A single low-concentration ocular betadine wash commonly preceded by a drop of ophthalmic anesthesia (administered by an eye care specialist) may expedite recovery from viral conjunctivitis. *Vats S et al. Rom J Ophthalmol. [PMID: 39464754]*
Infectious Keratitis	176	• Extending oral antiviral therapy for 12 months is recommended to reduce recurrence rates and duration of pain in herpes zoster ophthalmicus. *Davis AR et al. Eye Contact Lens. [PMID: 30844951]*
Retinal Disorders Associated with Systemic Diseases	188	• Patients with hypertension should have routine retinal examinations for retinopathy. *Wang Z et al. J Stroke Cerebrovasc Dis. [PMID: 39227002]*
CHAPTER 9: PULMONARY DISORDERS		
Chronic Obstructive Pulmonary Disease	256	• In patients with COPD and diabetes there is emerging evidence for possible benefit from GLP-1 receptor agonists and SGLT-2 inhibitors in reducing exacerbation rates. *Foer D et al. Am J Respir Crit Care Med. [PMID: 37647574]*
Cystic Fibrosis	261	• Triple modulator therapy with elexacaftor/tezacaftor/ivacaftor is recommended for patients ≥ 2 years of age with two copies of the ΔF508 mutation, or one copy of the ΔF508 regardless of the other *CFTR* allele. • Dual modulator therapy (tezacaftor/ivacaftor) is recommended for children 1 to < 2 years old, and ivacaftor monotherapy for those as young as 1 month old. *Green DM et al. Pediatrics. [PMID: 38577740]*
Pulmonary Hypertension	293	• Patients with Group 1 PAH and low/intermediate risk based on initial risk assessment should be initiated on dual combination therapy with an ERA plus PDE5I. Following reassessment at 3–4 months, if the patient is not at low risk, additional therapy should be added, such as a prostacyclin or activin-signaling inhibitor, or switching from PDE5I to sGCS. • High-risk patients with Group 1 PAH should be started on combination therapy of continuous prostacyclin infusion (IV/SC) with ERA and PDE5I. Following a short-term interval reassessment, if the risk is not improved, add an activin-signaling inhibitor and consider lung transplant referral. *Chin KM et al. Eur Respir J. [PMID: 39209476]*
CHAPTER 10: CORONARY ARTERY DISEASE, VALVULAR DISEASE, & OTHER KEY TOPICS IN CARDIOLOGY		
Coronary Heart Disease (Atherosclerotic CAD, Ischemic Heart Disease)	347	• A 2024 large, randomized trial demonstrated that routine colchicine administration to patients presenting with a myocardial infarction and undergoing percutaneous coronary intervention did *not* reduce the composite endpoint of cardiovascular death, stroke, myocardial infarction, or coronary revascularization over 3 years of follow-up. *Jolly SS et al. N Engl J Med. [PMID: 39555823]*
Tricuspid Regurgitation	340	• Randomized clinical trial data in 2025 demonstrated an improvement in quality-of-life outcomes and improved heart failure symptoms in patients treated with transcatheter tricuspid valve replacement compared with standard medical therapy. *Hahn RT et al. N Engl J Med. [PMID: 39475399]*

---

*See chapter for further details and references.

Topic	Page Number	Key New Advances Affecting Clinical Practice*
CHAPTER 11: HEART FAILURE & CARDIOMYOPATHY		
Heart Failure	394	• The GLP-1 receptor agonist semaglutide and the dual acting agonist of GLP-1 and glucose-dependent insulinotropic polypeptide receptors tirzepatide improve HF symptoms and exercise function in patients with heart failure and obesity. *Kosiborod MN et al. Lancet. [PMID: 39222642]; Lincoff AM et al. N Engl J Med. [PMID: 37952131]; Packer M et al. N Engl J Med. [PMID: 39555826]*
Restrictive Cardiomyopathy	405	• Two medications that stabilize transthyretin—tafamidis and acoramidis—are approved by the FDA to treat ATTR cardiomyopathy. Both medications reduced the composite of all-cause mortality and cardiovascular hospitalizations in clinical trials. *Gillmore JD et al. N Engl J Med. [PMID: 38197816]*
CHAPTER 13: SYSTEMIC HYPERTENSION		
Drug Therapy: Current Antihypertensive Agents	445	• Aprocitentan, an endothelin receptor antagonist, is FDA-approved for treatment of resistant hypertension, adding a fourth-line alternative to spironolactone for patients receiving maximal doses of a RAS inhibitor, calcium channel blocker, and thiazide diuretic. *Naseralallah L et al. Blood Press. [PMID: 39520722]*
Treatment of Hypertension in Diabetes	447	• The impact of more aggressive blood pressure lowering in patients with type 2 diabetes with increased cardiovascular risk was re-evaluated in the BROAD study performed in China. Intensive treatment resulted in a mean systolic pressure of 121.6 mm Hg, compared to 140.4 mm Hg in the standard treatment group. For the primary outcome, which was a composite of non-fatal stroke, non-fatal myocardial infarction, treatment or hospitalization for heart failure, or death from cardiovascular causes, the hazard ratio was 0.79 in the intensive treatment group compared to the standard treatment group with no significant difference in adverse effects. *Bi Y et al. N Engl J Med. [PMID: 39555827]*
CHAPTER 14: BLOOD VESSEL & LYMPHATIC DISORDERS		
Chronic Occlusive Disease: Aorta & Iliac Arteries	456	• Programs that include behavior modification have demonstrated improvements in sustained walking distance and patients' ability to cope with their disease. *Canonico ME et al. Curr Cardiol Rep. [PMID: 38696099]; Thangada ND et al. Curr Cardiol Rep. [PMID: 38722492]*
Shock	481	• Subgroup analysis of the APROCCHSS trial in 2024 showed a significant reduction in 90-day mortality in patients with septic shock from CAP (39% vs 51%) who were administered low-dose corticosteroids. Thus, for ICU patients with septic shock from CAP, the recommended dosing is hydrocortisone 50 mg IV every 6 hours plus fludrocortisone 50 mcg by mouth or nasogastric tube daily for 7 days. *Heming et al. Lancet Respir Med. [PMID: 38310918]*
CHAPTER 15: BLOOD DISORDERS		
Hodgkin Lymphoma	518	• The checkpoint inhibitor nivolumab, when added to AVD (Nivo-AVD), can produce superior response rates to A-AVD and is being increasingly used for high-risk patients with stage III or IV disease or with stage II disease and a large mediastinal or other bulky mass or systemic inflammation. *Herrera AF et al. N Engl J Med. [PMID: 39413375]*

*See chapter for further details and references.

(continued on following page)

Topic	Page Number	Key New Advances Affecting Clinical Practice*
Myelodysplastic Neoplasms	510	• The novel telomerase inhibitor imetelstat has been approved to treat adults with low- to intermediate-1 risk MDS with transfusion-dependent anemia and erythropoietin levels above 500 U/L. Imetelstat can result in more than 24 weeks of freedom from red blood cell transfusions or anemia symptoms for 28% of patients and is generally well tolerated except for manageable cytopenias and liver abnormalities. *Lennox AL et al. Clin Transl Sci. [PMID: 39555853]*
Paroxysmal Nocturnal Hemoglobinuria	493	• An oral complement factor B inhibitor (iptacopan) is also now FDA-approved as well as a complement factor D inhibitor (danicopan; as an add-on to those with an inadequate response to eculizumab or ravulizumab). *Waheed A et al. Blood Rev. [PMID: 38071133]*
Polycythemia Vera	504	• Ropeginterferon alfa-2b, a novel interferon, is approved as first-line therapy for patients without symptomatic splenomegaly, with 53% of patients achieving a complete hematologic response and with improved disease burden at 3 years' follow-up.
		• A novel hepcidin mimetic peptide, rusfertide, has shown great promise as another adjunctive treatment to phlebotomy with 60% of patients reaching the target hemoglobin level compared to 17% on placebo. *Kremyanskaya M et al. N Engl J Med. [PMID: 38381675]*
Primary Myelofibrosis	506	• Momelotinib is the first inhibitor of JAK1 and JAK2 shown to also inhibit activin A receptor type 1 (ACVR1), a key regulator of iron homeostasis, and has demonstrated improvements in splenomegaly, constitutional symptoms, and anemia in myelofibrosis. *Verstovsek S et al. Blood Adv. [PMID: 37042865]*
Sickle Cell Anemia & Related Syndromes	496	• Allogeneic hematopoietic cell transplant (ie, from another person as the donor) is potentially curative in younger patients with SS disease but with treatment-related morbidity and mortality as competing considerations. *Bhalla N et al. Front Med (Lusanne). [PMID: 36910492]*
CHAPTER 16: DISORDERS OF HEMOSTASIS, THROMBOSIS, & ANTITHROMBOTIC THERAPY		
Antithrombotic Therapy	557	• Patients undergoing surgery for cancer may transition to prophylactic doses of rivaroxaban or apixaban after an initial 7- to 10-day period of LMWH or unfractionated heparin. Prophylaxis may be continued for up to 4 weeks in patients undergoing major open or laparoscopic abdominal or pelvic cancer surgery with risk factors such as limited mobility, obesity, or history of VTE. *Key NS et al. J Clin Oncol. [PMID: 37075273]*
	558	• The 2024 EVE study suggested that dose-reduced apixaban (2.5 mg twice daily rather than 5 mg twice daily) after an initial 6 months of therapeutic anticoagulation carried a similar risk of recurrence but did not lower the incidence of bleeding in patients with cancer-associated VTE. *McBane R et al. J Thromb Haemost. [PMID: 38537780]*
Congenital Disorders of Coagulation	541	• New non-factor products for both hemophilia A and B with and without inhibitors include a class of rebalancing agents that inhibit tissue factor pathway inhibitor (TFPI), the first of which, marstacimab, received FDA approval in 2024. *Mahlangu J et al. Br J Haematol. [PMID: 36220152]*
CHAPTER 17: GASTROINTESTINAL DISORDERS		
Peptic Ulcer Disease	607	• Updated 2024 American College of Gastroenterology (ACG) treatment guidelines provide a strong recommendation for use of bismuth-based quadruple therapy (BQT) as the preferred first-line empiric therapy for *H pylori* infection. *Chey WD et al. Am J Gastroenterol. [PMID: 39626064]*

*See chapter for further details and references.

Topic	Page Number	Key New Advances Affecting Clinical Practice*
Ulcerative Colitis	640	• Among patients who failed prior treatment with biologic agents, the clinical response rates at 12 weeks following intravenous guselkumab versus placebo was 62% and 28%, respectively; following mirikizumab versus placebo was 56% and 31%, respectively; following intravenous risankizumab (180 or 360 mg) versus placebo was 65% and 36%; and following intravenous ustekinumab versus placebo at 8 weeks were 52% and 26%, respectively. Among all treatment responders who entered long-term maintenance treatment with subcutaneous injections every 8 weeks, clinical remission at 1 year was significantly higher with guselkumab (45–50%,) ustekinumab (45%), mirikizumab (51%), or risankizumab (57–61%) than with placebo (14–27%).
CHAPTER 18: LIVER, BILIARY TRACT, & PANCREAS DISORDERS		
Autoimmune Hepatitis	675	• In some clinical settings, mycophenolate mofetil is used as first-line therapy in place of azathioprine. *Snijders RJALM et al. J Hepatol. [PMID: 38101756]*
Primary Biliary Cholangitis	689	• Seladelpar (10 mg orally once daily), a PPAR-δ agonist, and elafibranor (80 mg orally once daily), a PPAR-α/δ agonist, were recently approved for use in patients without response to or intolerance of ursodiol with biochemical response rates in RCTs of 42–47% higher than placebo. *Hirschfield GM et al. N Engl J Med. [PMID: 38381664]; Kowdley KV et al. N Engl J Med. [PMID: 37962077]*
CHAPTER 19: BREAST DISORDERS		
Carcinoma of the Female Breast	727	• Taxane-based regimens have not been evaluated extensively; however, data suggest they may be safe for women with pregnancy- and postpartum-associated breast cancer. Trastuzumab should not be given during pregnancy. *Ferrigno Guajardo AS et al. J Natl Cancer Inst. [PMID: 38059798]; Lefrere H et al. Clin Cancer Res. [PMID: 37449970]; Mumtaz A. Transl Breast Cancer Res. [PMID: 39184929]; Roesch E et al. JCO Oncol Pract. [PMID: 39383485]*
	728	• A novel antibody-drug conjugate, trastuzumab deruxtecan, has demonstrated efficacy in metastatic breast cancer with normal "low" levels of expression of HER2, leading to the need to classify breast cancers based on whether they are "HER2-low" on immunohistochemical assay. *Kang S et al. Cancer Res Treat. [PMID: 38291745]*
	736	• Inavolisib, a selective inhibitor of the α isoform of the p110 subunit of PI3K, was shown to improve progression-free survival when added to fulvestrant and palbociclib in patients with *PIK3CA*-mutated breast cancer that relapsed during or within 12 months of completion of adjuvant hormonally targeted therapy. *Turner NC et al. N Engl J Med. [PMID: 39476340]*
	737	• HR-positive breast cancer phase III studies (RIGHT choice and PADMA) have indicated that the use of first-line CDK4/6i plus endocrine therapy should be tried before chemotherapy even in the presence of life- or organ-threatening visceral metastases. *Loibl S et al. PADMA study, 2024 San Antonio Breast Cancer Symposium, LB1-03; Lu YS et al. J Clin Oncol. [PMID: 38771995]*
	739	• Surgery to reconnect lymphatics in the axilla to correct lymphedema is being studied, with several studies showing decrease in lymphedema rates from the traditional 25–30% down to 5–10%. *Donahue PMC et al. Breast Cancer Res Treat. [PMID: 37103598]; McEvoy MP, Feldman S. Adv Surg. [PMID: 39089787]; Pagliara D et al. J Clin Med. [PMID: 38256688]; Sharifi N et al. Surg Oncol. [PMID: 39208532]; Shen A et al. Ann Surg Oncol. [PMID: 37725224]; Whitworth P et al. J Cancer Surviv. [PMID: 35947288]*

---

*See chapter for further details and references.

(continued on following page)

Topic	Page Number	Key New Advances Affecting Clinical Practice*
CHAPTER 20: WOMEN'S HEALTH ISSUES		
Amenorrhea	**744**	• With hypothalamic amenorrhea, if menses do not resume with 6–12 months of lifestyle efforts, supplementation with estrogen and cyclic progesterone, such as transdermal estradiol 100 mcg continuous use and micronized progesterone 200 mcg for 12 days of each month, should be considered to support bone health until menses resume. *Practice Committee of the American Society for Reproductive Medicine. Fertil Steril. [PMID: 38456861]; Saadedine M et al. Mayo Clin Proc. [PMID: 37661145]*
Menopause	**746**	• Although fezolinetant has not been directly compared to other treatments of vasomotor symptoms, a network meta-analysis found that a dose of fezolinetant 45 mg daily is equivalent to all HT regimens and that it is more efficacious than all non-HT regimens. When prescribing, liver function tests should be measured at baseline and then every 3 months for the first 9 months of treatment.
CHAPTER 21: GYNECOLOGIC DISORDERS		
Abortion	**765**	• Rh immune globulin should be given to Rh-negative women following abortion at or beyond 12 weeks' gestation. *ACOG Clinical Practice Update. Obstet Gynecol. [PMID: 39255498]*
Polycystic Ovary Syndrome	**756**	• Patients who are unable to reduce body weight with lifestyle modifications may benefit from use of glucagon-like peptide-1 (GLP-1) receptor agonists to lower body weight, improve metabolic parameters, and normalize menstrual cycles. *Bader S et al. Women's Health (Lond). [PMID: 38444070]*
CHAPTER 22: OBSTETRICS		
Maternal Hepatitis B & C Carrier State	**800**	• All pregnant persons should be screened for HBsAg during every pregnancy. If not previously done, the patient should have a triple-panel screen (HBsAg, Anti-HBs, and total antibody to hepatitis B core antigen [total anti-HBc]). *Badell ML et al. Am J Obstet Gynecol. [PMID: 38141870]*
Syphilis, Gonorrhea, & *Chlamydia Trachomatis* Infection	**801**	• Because of increasing rates of congenital syphilis, all women should be tested for syphilis as part of their routine prenatal care at their initial visit, in the third trimester, and at delivery. *ACOG. Practice Advisory. April 2024.*
Urinary Tract Infection	**798**	• Nitrofurantoin (100 mg orally twice daily), amoxicillin (500 mg orally three times daily), and cephalexin (250 mg orally four times daily) are acceptable medications for 5–7 days. *ACOG Clinical Consensus No. 4: Urinary Tract Infection in Pregnant Individuals: Correction. [PMID: 39601712]*
CHAPTER 23: RHEUMATOLOGIC, IMMUNOLOGIC, & ALLERGIC DISORDERS		
Adult Still Disease	**818**	• Early use of biologic therapies targeting IL-1 (anakinra or canakinumab) or IL-6 (tocilizumab or sarilumab) improves outcomes and reduces the need for long-term corticosteroids. *Bindoli S et al. Ann Rheum Dis. [PMID: 39317415]; Fautrel B et al. Ann Rheum Dis. [PMID: 39317417]*
Granulomatosis with Polyangiitis	**840**	• If there is an intolerance or contraindication to methotrexate, mycophenolate mofetil can be used as a second-line induction therapy for non-severe disease. *Hellmich B et al. Ann Rheum Dis. [PMID: 36927642]*

*See chapter for further details and references.

Topic	Page Number	Key New Advances Affecting Clinical Practice*
Immune-Mediated Inflammatory Myopathies	831	• All patients with immune-mediated inflammatory myopathies should be referred for physical therapy and encouraged to participate in an exercise program. This is a foundational treatment of IBM and a key component of therapeutic interventions for all patients with myositis. *Jensen KY et al. Rheumatol Int. [PMID: 39192022]*
Osteoarthritis	806	• In a randomized, double-blind trial of individuals with obesity and pain from knee osteoarthritis, semaglutide resulted in greater reductions in body weight and pain compared to placebo. *Bliddal H et al. N Engl J Med. [PMID: 39476339]*
Sjögren Disease	833	• Nipocalimab, a monoclonal antibody with high affinity to block FcRn and reduce levels of circulating immunoglobulin G, was granted Breakthrough Therapy designation by the FDA in 2024 for patients with moderate to severe Sjögren disease. *Gandolfo S et al. Lancet Rheumatol. [PMID: 38723653]*
Systemic Lupus Erythematosus	822	• ACR guidelines recommend combination therapy to further improve renal response, including: (1) adding a calcineurin inhibitor (voclosporin or tacrolimus) to mycophenolate mofetil in patients with significant proteinuria (≥ 3 g/day) since these drugs can more rapidly reduce proteinuria, or (2) adding belimumab to mycophenolate mofetil or cyclophosphamide in those with lower levels of proteinuria.
Takayasu Arteritis	837	• Antiplatelets therapy is recommended for patients with active Takayasu arteritis or critical cranial or vertebrobasilar involvement. *Tawakol A et al. Circ Cardiovasc Imaging. [PMID: 39561226]*
CHAPTER 24: ELECTROLYTE & ACID-BASE DISORDERS		
Hyperkalemia	872	• SGLT-2 inhibitors have emerged as an option for decreasing the risk of chronic hyperkalemia with angiotensin and mineralocorticoid antagonists. *Massicotte-Azarniouch D et al. Kidney Int Rep. [PMID: 37441466]*
CHAPTER 25: KIDNEY DISORDERS		
Chronic Kidney Disease	904	• In patients with CKD and anemia, KDIGO guidelines recommend offering iron supplementation if serum ferritin is below 500 ng/mL and iron saturation is less than 30%. *Stevens P et al. Kidney Int. [PMID: 38490803]*
	904	• Daprodustat, a hypoxia-inducible factor prolyl hydroxylase inhibitor, has emerged as an alternative to ESAs in treating anemia; however, it is not widely available to date. *Johnson H et al. Ann Pharmacother. [PMID: 38616529]*
	905	• GLP-1 agonists have emerged as a promising class of medications to help slow disease progression in patients with diabetes. *Perkovic V et al. N Engl J Med. [PMID: 38785209]; Taber-Hight E et al. Kidney Int. [PMID: 37926421]*
Nephritic Spectrum Glomerular Diseases	913	• Iptacopan, which inhibits factor B in the alternative pathway of complement, has been shown to reduce proteinuria without increasing risk of infection. *Perkovic V et al. N Engl J Med. [39453772]*
	914	• For induction therapy for lupus nephritis, revised 2024 practice guidelines call for a combination of corticosteroids in combination with one of the following: (1) mycophenolate mofetil; (2) intravenous cyclophosphamide; (3) belimumab (anti-B cell therapy) with either mycophenolate or cyclophosphamide; or (4) mycophenolate mofetil with a calcineurin inhibitor. *Kidney Disease: Improving Global Outcomes (KDIGO) Lupus Nephritis Work Group. Kidney Int. [PMID: 38182286]*

*See chapter for further details and references.

(continued on following page)

Topic	Page Number	Key New Advances Affecting Clinical Practice*
CHAPTER 26: UROLOGIC DISORDERS		
Benign Prostatic Hyperplasia	953	• Angioembolization of the bilateral prostatic arteries has been shown to reduce prostate volume, and recent data shows some relief of urinary symptoms. *Bhatia S et al. J Vasc Interv Radiol. [PMID: 39532156]*
Urinary Stone Disease	939	• Several large recent studies of the novel anti-diabetic medications SGLT-2 inhibitors and GLP-1 agonists have demonstrated their safety in patients with kidney stones, with convincing evidence that SGLT-2 inhibitors reduce the risk of stones by nearly 40%. *Paik JM et al. JAMA Intern Med. [PMID: 38285598]*
CHAPTER 27: NERVOUS SYSTEM DISORDERS		
Headache	956	• Transcutaneous supraorbital neurostimulation, single-pulse transcranial magnetic stimulation, and non-invasive vagus nerve stimulation reduced headache frequency as reflected in a meta-analysis of RCTs and are approved in the United States. *Chen Y et al. Acta Neurol Belg. [PMID: 37184609]*
Intracranial & Spinal Mass Lesions	985	• Grade 2 IDH-mutant astrocytomas and oligodendrogliomas may be treated with the IDH inhibitor vorasidenib (40 mg once daily orally), which prolongs progression-free survival. *Mellinghoff IK et al. N Eng J Med. [PMID: 37272516]; Swensen SN et al. Curr Treat Options Oncol. [PMID: 39612163]*
Myopathic Disorders	1029	• Vamorolone (6 mg/kg once daily; maximum daily dose 300 mg) is a novel oral corticosteroid approved for patients ≥ 2 years of age. It is as effective as prednisone but with fewer adverse effects. *Dang UJ et al. Neurology. [PMID: 38508835]*
	1029	• Givinostat (22.2 to 53.2 mg twice daily based on body weight) is an oral histone deacetylase inhibitor approved for patients > 6 years of age. In an RCT, it slowed decline over 72 weeks compared with placebo. *Mercuri E et al. Lancet Neurol. [PMID: 38508835]*
Polyneuropathies & Mononeuritis Multiplex	1015	• In a meta-analysis of RCTs, scrambler therapy, which consists of transcutaneous electrical nerve stimulation at multiple simultaneous sites, appears to be effective for neuropathic pain. *Smith TJ et al. N Engl J Med. [PMID: 37437145]*
	1017	• Cryotherapy, or covering the hands and feet with cold gloves and stockings before, during, and after neurotoxic chemotherapy infusion, prevented neuropathy and improved quality of life in a meta-analysis of randomized trials. *Tai HY et al. Support Care Cancer. [PMID: 38955817]*
	1018	• Cohort studies suggest an association of GBS with adenovirus vector SARS-CoV-2 vaccines but not with mRNA vaccines. *Censi S et al. J Neurol. [PMID: 38233678]*
	1019	• Weekly subcutaneous injection of efgartigimod alfa and hyaluronidase-qvfc (1008 mg/11,200 units), a neonatal Fc receptor blocker, reduced the risk of relapse in CIDP in a randomized trial and is approved in the United States. *Allen JA et al. Lancet Neurol. [PMID: 39304241]*
	1020	• Hydrocortisone injections medial to the anterosuperior iliac spine often relieve symptoms temporarily, while ultrasound-guided hydro-dissection with 5% dextrose or surgical nerve decompression may provide more lasting relief of meralgia paresthetica symptoms. *Xu H et al. Pain Physician. [PMID: 39621981]*
	1021	• If there is poor motor recovery, surgical treatments such as tendon transfer may improve function in sciatic and fibular (common peroneal) nerve palsies. *Klifto KM et al. J Plast Reconstr Aesthet Surg. [PMID: 34801427]*

*See chapter for further details and references.

Topic	Page Number	Key New Advances Affecting Clinical Practice*
CHAPTER 28: PSYCHIATRIC DISORDERS		
Autism Spectrum Disorders	1067	• Probiotics have demonstrated some efficacy in improving behavioral symptoms. *Soleimanpour S et al. J Psychiatr Res. [PMID: 39265200]*
Disorders of Aggression	1070	• For less acute treatment, community-based programs as well as cognitive bias modification interventions can be useful in decreasing aggressive behaviors. *Jiang S et al. Trauma Violence Abuse. [PMID: 38293961]*
	1070	• Omega-3 fatty acid supplementation has demonstrated efficacy in reducing aggressive behavior. *Raine A et al. Aggress Violent Behav. [PMID: 38911617]*
Mood Disorders (Depression & Mania)	1064	• There is strong evidence for tamoxifen, typically a breast cancer treatment, in treatment of mania. Its mechanism may be in inhibition of protein kinase C. *Huang W et al. Mol Psychiatry. [PMID: 39191865]*
Obsessive-Compulsive Disorder & Related Disorders	1039	• There is growing evidence for the use of acceptance and commitment therapy, another behavioral therapy, in reducing OCD symptoms. *Evey KJ et al. Behav Ther. [PMID: 37863582]*
Personality Disorders	1047	• There is a growing body of evidence for noninvasive brain stimulation techniques, such as transcranial magnetic stimulation, for treatment of some symptoms of borderline personality disorder, such as mood dysregulation and impulsivity. *Lisoni J et al. Expert Rev Neurother. [PMID: 38349069]*
Schizophrenia Spectrum Disorders	1054	• There is emerging evidence for the use of transcranial magnetic stimulation for psychosis, which has limited side effects. *Poorganji M et al. Schizophr Res. [PMID: 37844414]*
Sleep-Wake Disorders	1068	• Moderate aerobic exercise and mind-body exercises have demonstrated efficacy in improving sleep. *Xu M et al. Sleep Med Rev. [PMID: 38006755]*
Somatic Symptom Disorders	1040	• There is recent evidence for the efficacy of intensive psychodynamic therapy administered in the ER to reduce somatic symptoms and reduce ER usage. *Town JM et al. J Psychosom Res. [PMID: 39241562]*
CHAPTER 29: DISORDERS OF THE PITUITARY, THYROID, & ADRENAL GLANDS		
Cushing Syndrome (Hypercortisolism)	1119	• Patients with metastatic ACTH-secreting neuroendocrine tumors that are avid for DOTATATE on PET imaging may be treated with peptide receptor radionuclide therapy (PRRT) with a radioisotope-tagged octreotide analogue. *Boehm E et al. Endocr Oncol. [PMID: 39649117]*
Hyperprolactinemia	1085	• Aripiprazole may be added to conventional dopamine agonist therapy to optimally reduce high PRL levels caused by antipsychotics or antidepressants. *Ma K et al. Expert Opin Drug Saf. [PMID: 39411853]*
Thyroid Cancer	1109	• Larger papillary thyroid cancers (1–4 cm) that are intrathyroidal and nonmetastatic are typically treated with hemithyroidectomy; however, active surveillance is increasingly employed for larger papillary thyroid cancers with low-risk characteristics. *Altshuler B et al. J Clin Endocrinol Metab. [PMID: 38349208]*
Thyroid Eye Disease	1104	• Statin medications appear to reduce the risk of thyroid eye disease by 80% in patients with newly diagnosed Graves disease and should be considered as an off-label adjuvant treatment. *HSU GC-Y et al. Ophthalmol Ther. [PMID: 38581604]*

*See chapter for further details and references.

(continued on following page)

Topic	Page Number	Key New Advances Affecting Clinical Practice*
Thyroid Nodules & Multinodular Goiter	1106	• Autonomously functioning thyroid nodules can cause subclinical or overt hyperthyroidism that can be reversed by RFA. *Dhanasekaran M et al. J Endocr Soc. [PMID: 39502476]*
CHAPTER 30: DISORDERS OF PARATHYROID GLANDS & BONE METABOLISM		
Hypoparathyroidism & Pseudo-hypoparathyroidism	1130	• FDA-approved in 2024 for the treatment of adults with hypoparathyroidism, palopegteriparatide is a long-acting prodrug of PTH (1-34) that patients self-administer subcutaneously daily. It is an option for patients with difficulty maintaining stable serum and urinary calcium levels with calcium and vitamin D preparations.
Osteoporosis & Osteopenia	1138	• Because of the very rare but serious potential side effects of cumulative doses of antiresorptive therapy (including atypical fractures of the femur, osteonecrosis of the jaw), the benefit and risk of bisphosphonate treatment is reassessed after approximately 3 years of IV bisphosphonate or 4–5 years of oral bisphosphonate therapy. If the patient is deemed to be at continued high risk of fracture as assessed by repeat DXA bone densitometry and evaluation or the current clinical history, continued bisphosphonate therapy for a total of 8–10 years may be appropriate. Alternatively, if risk is more moderate, a bisphosphonate "drug holiday" may be pursued. *Black DM et al. Bone. [PMID: 34920168]*
	1139	• Denosumab must be given on-schedule, without the "drug holidays" applied to bisphosphonate therapy. Once started, denosumab should either be continued indefinitely, or transitioned to another antiresorptive agent (eg, a bisphosphonate), with the intensity and duration of the other therapy dependent on the duration of the denosumab treatment. *Sølling AS et al. Curr Osteoporos Rep. [PMID: 36564572]*
Paget Disease of Bone (Osteitis Deformans)	1143	• In some patients, biochemical remission will be achieved with a single dose of zoledronic acid. If the serum alkaline phosphatase level rises above normal or increases more than 25% above the nadir level, the infusion may be repeated. *Ayalon-Dangur I et al. Endocrine. [PMID: 38555314]*
Rickets & Osteomalacia	1142	• Serum levels of 25-OHD should be monitored, and the dosage of vitamin D adjusted to achieve and maintain, a goal level of at least 20 ng/mL in the general population and 30–60 ng/mL in those with metabolic bone disease. *Demay MB et al. J Clin Endocrinol Metab. [PMID: 38828931]*
CHAPTER 31: MALE HYPOGONADISM & GYNECOMASTIA, HIRSUTISM & VIRILIZATION, TURNER SYNDROME		
Hirsutism & Virilization	1155	• Crinecerfont, a corticotropin releasing factor pituitary receptor antagonist, is used for treating hirsutism and virilization in women with congenital adrenal hyperplasia (21-hydroxylase deficiency). At a dose of 100 mg twice daily, it dramatically decreases androstenedione production. Patients may experience fatigue that usually improves with time and glucocorticoid replacement optimization. *Auchus RJ et al. N Engl J Med. [PMID: 38828955]*

*See chapter for further details and references.

Topic	Page Number	Key New Advances Affecting Clinical Practice*
CHAPTER 32: DIABETES MELLITUS & HYPOGLYCEMIA		
Chronic Complications of Diabetes: Cardiovascular Complications	1184	The ADA recommends: • Lowering systolic blood pressure to < 130 mm Hg and diastolic pressure to < 80 mm Hg in patients with diabetes. • Screening asymptomatic adults for HF by measuring b-type natriuretic peptide or N-terminal pre-BNP and, if abnormal, obtaining an echocardiogram so that treatment can be prescribed to lower risk of progression to stage C symptomatic HF. • Lowering LDL-C with statins to < 55 mg/dL for individuals with diabetes and known ASCVD due to very high-risk status of these individuals. If LDL-C goal is not attained, addition of ezetimibe, bempedoic acid, and/or PCSK9 inhibitor therapy is indicated. • Lowering LDL-C to < 70 mg/dL for those with diabetes without ASCVD. • Screening individuals annually for peripheral arterial disease with a history and physical examination, and if there are positive signs or symptoms, referring for non-invasive arterial vascular ultrasound studies. If a foot ulcer is present with abnormal non-invasive testing, immediate referral for vascular evaluation is warranted. Doppler ultrasonography should be repeated every 5 years if initial testing is normal. *American Diabetes Association Professional Practice Committee. Diabetes Care. [PMID: 39651970]*
Prevention	1159	• Several large RCTs have demonstrated that lifestyle intervention with a decreased calorie meal plan is highly effective in preventing or delaying the onset of type 2 diabetes and decreasing cardiometabolic risk. *American Diabetes Association Professional Practice Committee. Diabetes Care. [PMID: 39651971]*
	1160	• Results in 2024 from the SURMOUNT-1 trial demonstrated that a 3-year treatment with tirzepatide at 5 mg, 10 mg, and 15 mg doses reduced the risk of developing type 2 diabetes by 94% in individuals with pre-diabetes and obesity or overweight. Participants who took tirzepatide had weight reduction of up to 20% that was sustained over 3 years and the risk of progression to type 2 diabetes was markedly lower compared to placebo. No medication is yet approved by the US FDA, though, to prevent the development of type 2 diabetes. *Jastreboff AM et al. N Engl J Med. [PMID: 39536238]*
Technology for Individuals with Diabetes	1163	• Several randomized controlled studies using real-time CGM have demonstrated improvement in A1C and reduction in hypoglycemia when worn consistently. *Ajjan RA et al. Nat Rev Endocrinol. [PMID: 38589493]*
Treatment: Medical Nutrition Therapy	1164	• MNT, when delivered by a registered dietitian, is highly beneficial to persons living with diabetes. MNT is associated with A1C reduction of 1.0–1.9% for persons with type 1 diabetes and 0.3–2.0% for those with type 2 diabetes.
CHAPTER 33: LIPID DISORDERS		
Lipid Fractions & the Risk of Coronary Heart Disease	1200	• As of 2024, the National Lipid Association recommends one-time screening of the entire adult population and recommends cascade screening in family members of those with severe hypercholesterolemia, including elevated lipoprotein(a). *Koschinsky ML et al. J Clin Lipidol. [PMID: 38565461]*
CHAPTER 34: NUTRITION, NUTRITIONAL DISORDERS, & OBESITY		
Obesity	1213	• In 2024, tirzepatide received an expanded indication for the treatment of moderate to severe obstructive sleep apnea in adults with obesity.

*See chapter for further details and references.

(continued on following page)

Topic	Page Number	Key New Advances Affecting Clinical Practice*
CHAPTER 36: HIV INFECTION & AIDS		
Complications	1291	• The NIH-sponsored international STOMP trial showed no efficacy of tecovirimat in mitigating severe disease with Clade 2 mpox, so this medication should no longer be used. *https://www.nih.gov/news-events/news-releases/ antiviral-tecovirimat-safe-did-not-improve-clade-i-mpox-resolution-democratic-republic-congo*
Prevention	1295	• As of 2025, the use of HIV RNA testing at follow-up visits is being debated, due to the potential for false positives (the positive predictive value of a positive HIV RNA is only 18.5%) and the challenges that frequent RNA testing poses for implementation of injectable cabotegravir in many settings. An isolated positive HIV RNA at cabotegravir PrEP follow-up, particularly if it is at the limit of detection (ie, < 20, but detected), should be repeated and the patient should be counseled that there is a higher probability of false positives than a true positive. • FDA approval of a new long-acting PrEP agent, biyearly subdermal lenacapavir (LEN), is expected in 2025, given the positive results reported from the PURPOSE-1 trial, which found 100% efficacy of lenacapavir among cisgender women (0 HIV infections with LEN vs. background HIV incidence of 2.4 per 100 person-years; 39 infections with F/TAF), and the PURPOSE-2 trial, finding 96% efficacy among cisgender gay, bisexual, and other men, transgender women, transgender men, and gender non-binary individuals compared to background HIV incidence. *Bekker LG et al. N Engl J Med. [PMID: 39046157]; Kelley CF et al. N Engl J Med. [PMID: 39602624]*
	1296	• One study presented at the 2024 AIDS conference demonstrated a large reduction in chlamydia and syphilis infections after initiating pre-exposure prophylaxis with daily doxycycline 100 mg in a pre/post study among 40 female sex workers in Japan. *Abe S et al. AIDS 2024. Munich, Germany.*
Treatment	1312	• The International Antiviral Society-USA and DHHS now recommend cabotegravir/rilpivirine among those at high risk of HIV progression who cannot take oral ART, with virus susceptible to both agents. For individuals with HIV resistant to rilpivirine, some clinicians are using cabotegravir and lenacapavir together off-label. A case series of 34 individuals using this regimen at four academic medical centers achieved high virologic suppression (94%). *Gandhi M et al. Open Forum Infect Dis. [PMID: 38628952]; Hickey MD et al. Clin Infect Dis. [PMID: 39367871]*
CHAPTER 37: VIRAL & RICKETTSIAL INFECTIONS		
Chikungunya Fever	1363	• The first chikungunya vaccine (Ixchiq -VLA 1533) was approved in the US in November 2023. It is recommended for adults ≥ 18 years traveling to endemic areas with outbreaks or evidence of chikungunya virus human transmission within the last 5 years. *Maure C et al. Vaccine. [PMID: 39467413]*
Epstein-Barr Virus & Infectious Mononucleosis	1327	• Recent work has demonstrated a potential mechanism (molecular mimicry) that suggests a causal link between EBV infection and some cases of multiple sclerosis. *Naughton P et al. Curr Opin Infect Dis. [PMID: 38529804]*

---

*See chapter for further details and references.

Topic	Page Number	Key New Advances Affecting Clinical Practice*
Erythroparvovirus Infections	1384	• Cidofovir and brincidofovir have been successfully used in some studies to inhibit B19 viral replication. Foscarnet has been used in one study in kidney transplant patients with red cell aplasia secondary to parvovirus B19 infection. Hydroxyurea and telbivudine (thymidine analog used in hepatitis B virus infection) have demonstrated effectiveness in in vitro studies. *Lopes TS et al. Arch Virol. [PMID: 38378929]*
	1384	• Pregnant and immunocompromised patients should be monitored for parvovirus B19 infection especially during outbreaks. *Dittmer FP et al. J Pers Med. [PMID: 38392573]*
Human Herpesviruses 6, 7, & 8	1329	• Although HHV-8-related malignancies are often associated with HIV infection, Kaposi sarcoma is also well described in solid organ transplant recipients and noted in other patient populations. Antiviral therapy targeting KSHV has not demonstrated efficacy in associated malignancies. *Kampouri E et al. Curr Opin Infect Dis. [PMID: 38726832]*
Measles	1331	• There are conflicting studies on the optimal timing of MMR vaccination—one suggested higher measles susceptibility in adults who received the vaccine before 15 months due to the impact of residual maternal antibodies. However, another study showed lower initial seroprotection rates after the first dose of MMR when given at 5–7 months, but no negative impact on the short-term responses to subsequent MMR vaccinations. *Vittrup DM et al. EClinicalMedicine. [PMID: 38292039]*
	1331	• Recent data suggests that the MMR vaccine is both safe and effective in children post-chemotherapy and hematopoietic stem cell transplant, as well as those post-liver and kidney transplant (notably, mean time post-transplant was 6.3 years and 73% were on low-level monotherapy for immunosuppression at time of vaccination). *Feldman AG et al. JAMA Netw Open. [PMID: 37824141]; Wang M et al. World J Pediatr. [PMID: 37087716]*
Molluscum Contagiosum	1383	• One meta-analysis found that berdazimer had a higher rate of clearance of lesions and decreased scarring. *Pera Calvi I et al. Pediatr Dermatol. [PMID: 37721050]*
Rabies	1340	• Although not currently routinely recommended, some centers suggest serologic testing for all over age 70 as inadequate titer levels have been seen in up to 6.5% of patients in this age group after the recommended 4-dose vaccine schedule, with appropriate levels reached after a fifth booster dose. *Itani O et al. Clin Infect Dis. [PMID: 37405484]*
Rocky Mountain Spotted Fever	1394	• Due to the slow turnaround of testing and risk of mortality, it is important to initiate empirical antibiotic therapy when a diagnosis of RMSF is being considered.
Seasonal Influenza	1374	• As of the 2024–2025 influenza season, quadrivalent vaccines are no longer recommended. *Grohskopf LA et al. MMWR Recomm Rep 2024;73(No. RR-5):1–25.*

*See chapter for further details and references.

(continued on following page)

Topic	Page Number	Key New Advances Affecting Clinical Practice*
Severe Acute Respiratory Syndrome—Coronavirus 2019 (SARS-CoV-2)	1365	• After population immunity from vaccines and natural infection, the highest viral load for SARS-CoV-2 was on day 4 of symptoms, with most of the current spread occurring during active symptoms. *Frediani JK et al. Clin Infect Dis. [PMID: 37768707]*
	1365	• Immunocompromised individuals may demonstrate prolonged viral shedding and can show a reduced response to vaccination, particularly persons who have received B-cell-depleting agents such as rituximab. *Razonable RR. Front Immunol. [PMID: 38756784]*
	1365	• In a large multinational cohort study of pregnant patients, COVID-19 is shown to be associated consistently with higher maternal morbidity and mortality including increased rates of preeclampsia and eclampsia, severe maternal infections, and maternal ICU admissions. While miscarriage rates are not increased, SARS-CoV-2 can rarely cause placentitis, which may lead to stillbirth. In addition, SARS-CoV-2 infection during pregnancy has been associated with preterm birth in some but not all studies. *Packer CH, Prabhu M. Clin Obstet Gynecol. [PMID: 38967474]*
	1367	• In general, *outpatients* with COVID-19 should not receive anticoagulant or antiplatelet therapy to prevent venous or arterial thrombosis unless other strong indications are present. Therapeutic anticoagulation with heparin has been recommended for *hospitalized* patients requiring supplemental oxygen (but **not** high-flow nasal cannula oxygen or non-invasive or mechanical ventilation) with elevated D-dimer and without increased bleeding risk. Prophylactic dose heparin is recommended for other persons hospitalized with COVID-19 who do not have another indication for therapeutic anticoagulation, including critically ill patients requiring high-flow nasal canula oxygen or non-invasive or mechanical ventilation. *Siegal DM et al. Blood Adv. [PMID: 39437977]*
	1368	• While it is common for symptoms such as mild fatigue to slowly resolve after COVID-19, some individuals report persistent symptoms and deficits for 3 months or more following infection ("long COVID"). *Ely EW et al. N Engl J Med. [PMID: 39083764]*
	1369	• Ensitrelvir, an oral SARS-CoV-2 3C-like protease inhibitor currently available in Japan, was found to reduce symptom duration by about 1 day compared to placebo among patients treated less than 72 hours of disease onset in the SCORPIO-SR trial. *Yotsuyanagi H et al. JAMA Netw Open. [PMID: 38335000]*
Varicella (Chickenpox) & Herpes Zoster (Shingles)	1324	• Children under 2 should be treated with acyclovir as the safety of valacyclovir has not been established for this age group. There is no consensus dosing for acyclovir for this age group.
	1325	• Duloxetine initiated during the initial outbreak of postherpetic neuralgia may reduce pain scores at 12 weeks, although randomized, *placebo-controlled* studies on this are lacking. *Zhao C et al. Clin Infect Dis. [PMID: 38015658]*
	1324	• Vaccine efficacy has ranged from 70–100% in different studies over a follow-up period of 2–7 years, with more rapidly waning efficacy seen in patients who only received one dose (48% by year 3). • The vaccine may be less efficacious in immunocompromised persons, as reported in patients taking corticosteroids at the time of immunization. *Proano DAE et al. Hum Vaccin Immunother. [PMID: 38838170]; Zerbo O et al. Ann Intern Med. [PMID: 38190712]*
Viral Hemorrhagic Fevers	1355	• The Pan American Health Organization (PAHO) issued an alert on July 17, 2024, about vertical transmission of the Oropouche virus with adverse pregnancy outcomes in Brazil.

*See chapter for further details and references.

Topic	Page Number	Key New Advances Affecting Clinical Practice*
CHAPTER 38: BACTERIAL AND CHLAMYDIAL INFECTIONS		
Meningococcal Meningitis	1420	• A pentavalent conjugate vaccine targeting serogroups A, C, W, Y, and B was approved for use in the United States in 2023. Use of the new pentavalent vaccine is recommended when both MCV4 and MenB vaccines are indicated. *Collins JP et al. MMWR Morb Mortal Wkly Rep. [PMID: 38635488]*
	1420	• Ciprofloxacin should not be used as prophylaxis if there have been two or more cases of invasive meningococcal disease due to ciprofloxacin-resistant strains and ≥ 20% of all reported cases are caused by ciprofloxacin-resistant strains in a local catchment area during a rolling 12-month period. *Berry I et al. MMWR Morb Mortal Wkly Rep. [PMID: 38329923]*
CHAPTER 39: SPIROCHETAL INFECTIONS		
Leptospirosis	1452	• A 2024 meta-analysis did not find that pre- or post-exposure prophylaxis reduced infection or all-cause mortality. *Win TZ et al. Cochrane Database Syst Rev. [PMID: 38483067]*
Syphilis	1444	• The American College of Obstetrics and Gynecology recommends screening three times during pregnancy: at the first prenatal visit, during the third trimester (eg, 28 weeks), and at delivery.
	1450	• The CDC released guidelines for the use of doxycycline as PEP for bacterial STIs in 2024. *Bachmann LH et al. MMWR Recomm Rep. 2024;73:2.*
CHAPTER 40: PROTOZOAL & HELMINTHIC INFECTIONS		
African Trypanosomiasis	1459	• Fexinidazole has replaced suramin and melarsoprol (previously first-line for early and CNS disease, respectively) for individuals over 6 years of age with body weight ≥ 20 kg. As the drug is effective for all disease stages, lumbar punctures are no longer routinely required. For younger children, recommendations remain to treat early disease with suramin. *Lindner AK et al. Lancet Infect Dis. [PMID: 39389073]*
CHAPTER 41: MYCOTIC INFECTIONS		
Aspergillosis	1505	• The National Comprehensive Cancer Network (NCCN) 2024 guidelines recommend posaconazole for patients with myelodysplastic syndrome or acute myeloid leukemia who are neutropenic, and for hematopoietic stem cell transplant recipients on immune suppressive therapy for acute graft-versus-host disease (GVHD). Mold-active triazole therapy is less strongly advised for patients with allogeneic hematopoietic stem cell transplants who are neutropenic. Prophylaxis is recommended until the underlying risk factor has been resolved (e.g., neutropenia or GHVD). Anti-mold prophylaxis is not universally recommended for patients with solid organ transplantation; rather, recommendations vary based on the type of transplantation (with lung being highest risk for invasive aspergillosis) and other clinical factors (such as the need for reoperation or renal replacement therapy in liver transplant recipients). *Baden LR et al. J Natl Compr Canc Netw. [PMID: 39536464]*
CHAPTER 44: CANCER		
Bladder Cancer	1593	• The antibody-drug conjugate enfortumab vedotin has replaced chemotherapy as the first-line agent in the metastatic setting. *Powles T et al. N Engl J Med. [PMID: 38446675]*
	1594	• The phase 3 Niagara trial demonstrated improved event-free and overall survival with neoadjuvant chemotherapy and perioperative durvalumab compared to chemotherapy alone for patients with muscle-invasive bladder cancer undergoing cystectomy. *Powles T et al. N Engl J Med. [PMID: 39282910]*

*See chapter for further details and references.

(continued on following page)

Topic	Page Number	Key New Advances Affecting Clinical Practice*
Carcinoma of the Pancreas & Ampulla of Vater	1564	• Although there were signals of risk in older studies, among patients with diabetes, GLP-1–based therapy is not associated with increased risk of pancreatic cancer up to 7 years later.
Colorectal Cancer	1576	• All new diagnoses of colorectal cancers should be evaluated for MMR/MSI status.
	1580	• In 2024, the FDA approved a "next-generation" multitarget stool DNA test (Cologuard Plus) for patients at average risk for CRC. In a randomized prospective study of asymptomatic adults undergoing colonoscopy, the next-generation test had higher sensitivity than FIT for colorectal cancer (93.9% versus 67.3%) and advanced precancerous lesions (43.4% versus 23.3%) but lower specificity for advanced precancerous lesions (90.6% versus 94.8%). *Imperiale TF et al. N Engl J Med. [PMID: 38477986]*
Esophageal Cancer	1569	• For adenocarcinomas without *HER2* overexpression that do have Claudin 18.2 expression, the addition of zolbetuximab to chemotherapy prolongs survival. For tumors that have expression of both PD-L1 and Claudin 18.2, the optimal regimen is unknown. *Shitara K et al. N Engl J Med. [PMID: 39282934]*
Gastric Adenocarcinoma	1571	• Perioperative immunotherapy for patients with dMMR/MSI-H localized tumors is a promising strategy. Hence, testing for either MMR or MSI status is recommended for all new gastric cancer diagnoses. *André T et al. J Clin Oncol. [PMID: 35969830]*
Lung Cancer	1556	• Amivantamab (an EGFR-MET bispecific antibody) with lazertinib (another third-generation EGFR TKI) is another FDA-approved option for first-line treatment for patients with sensitizing *EGFR* variants. *Cho BC et al. N Engl J Med. [PMID: 38924756]*
	1557	• In limited SCLC, thoracic radiation therapy is given *concurrently* with chemotherapy, and adjuvant immunotherapy with durvalumab (PD-L1 inhibitor) for 2 years post-chemoradiation is recommended and improves survival outcomes. *Cheng Y et al. N Engl J Med. [PMID: 39268857]*
Prostate Cancer	1586	• The American Society of Clinical Oncology (ASCO) published guidelines on the use of multigene panels for germline testing in men with prostate cancer. *Tung N et al. J Clin Oncol. [PMID: 38759122]*
Renal Cell Carcinoma	1596	• The LITESPARK-005 trial demonstrated superior progression-free survival with belzutifan over everolimus in non-VHL patients with progressive, previously treated advanced clear-cell RCC. Belzutifan is now FDA-approved for patients with VHL or metastatic clear-cell RCC following immunotherapy or VEGF-TKI therapy.
Testicular Cancers	1598–1599	• The Surgery in the Early Metastatic Seminoma (SEMS) trial demonstrated an 81% 2-year recurrence-free survival with low morbidity in men with low-volume retroperitoneal metastatic seminoma treated with surgery alone.
CHAPTER 46: ORTHOPEDICS & SPORTS MEDICINE		
Adhesive Capsulitis ("Frozen Shoulder")	1627	• Intraarticular PRP injections show at least equal benefits to a corticosteroid injection and, in one trial, showed early gain in range of motion. *Nudelman B et al. Arthroscopy. [PMID: 36708748]*

*See chapter for further details and references.

Topic	Page Number	Key New Advances Affecting Clinical Practice*
Carpal Tunnel Syndrome	1636	• A timed Phalen test is when the patient reports the time it takes to experience first symptoms up to 120 seconds. If the patient reports symptoms within 10 seconds or less, this test has a specificity of 96.8% and positive predictive value of 96.6% in predicting abnormal signs of nerve conduction. *Priya A et al. J Family Med Prim Care. [PMID: 39722997]*
	1636	• A systemic review and network meta-analysis examining different injections for CTS found that PRP injections to the carpal tunnel space had the best outcomes and longest results for symptom relief, followed by dextrose injections (prolotherapy), with corticosteroids providing only short-term benefits. *Yang FA et al. PLoS One. [PMID: 38753671]*
Dupuytren Contracture	1637	• A meta-analysis showed similar results in reducing long-term contracture among those treated with LF, PNF, and CCH. However, a multi-center RCT showed that LF performed better than CCH injections, with less contracture recurrence, but with more moderate and severe complications (complications were 5.1% with LF and 1.8% with CCH). *Shaheen MS et al. Plast Reconstr Surg. [PMID: 39451139]*
Eversion ("High") Ankle Sprains	1654	• Follow-up of athletes over 18 years showed that conservative treatment can be successful, although 27% of patients had radiographic signs of ankle arthritis, including some with heterotopic ossification. *Nussbaum ED. Am J Sports Med. [PMID: 39235770]*
Inversion Ankle Sprains	1653	• Proprioception and balance exercises (eg, "wobble board") can help restore function to the ankle, and there is moderate evidence that neuromuscular training can prevent future ankle sprains. There is strong evidence that bracing prevents ankle sprains; however, one study included in a meta-analysis made the effects of bracing non-significant. In general, ankle bracing is considered for recurrent sprains and is tolerable for most activities. *Wang F et al. Clin Rehabil. [PMID: 36630892]*
Knee Osteoarthritis	1652	• There is a potential dose-response relationship between platelet dose and PRP effectiveness for knee OA treatment; the suggested optimal threshold is > 10 billion platelets for favorable clinical outcomes. *Berrigan W et al. Curr Rev Musculoskelet Med. [PMID: 39331322]*
Lateral & Medial Epicondylosis (Tendinopathy)	1635	• A systematic review of PRP for tendinopathy reported a dose-related effect, with higher platelet concentrations demonstrating better outcomes, although the literature regarding tendinopathy is limited. Both leukocyte-rich and leukocyte-poor concentrations of PRP appeared to effectively treat lateral epicondylitis. *Berrigan W et al. Curr Rev Musculoskelet Med. [PMID: 39331322]*
Low Back Pain	1630	• Systematic reviews of studies of low to moderate quality suggest that various exercises used for pain and disability have short-term benefit with no major difference between types of exercises. Complementary therapies, such as Tai Chi, pilates, mindfulness-based stress reduction, core strengthening exercises and yoga, have shown benefit for chronic low back pain. Compared with conventional rehabilitation and no intervention, yoga and core or stabilization exercises were statistically significant in improving physical function in patients with chronic low back pain. *Li Y et al. Front Public Health. [PMID: 38035307]; Nicol V et al. J Clin Med. [PMID: 36836220]*
Rotator Cuff Tears	1625	• Corticosteroid injections should be minimized, especially if surgery is a consideration, since injection within 6 months of surgery is associated with a higher surgical revision rate after 3 years. • For traumatic massive tears, the best practice recommendation is surgical repair within 12 weeks of injury.

*See chapter for further details and references.

(continued on following page)

Topic	Page Number	Key New Advances Affecting Clinical Practice*
Shoulder Dislocation & Instability	1626	• The FARES (Fast, Reliable, and Safe) method is the least painful method of manually reducing an acutely dislocated shoulder, with success rates > 88.7%. *Gonai S et al. Am J Emerg Med. [PMID: 39442380]*
CHAPTER 47: SEXUAL AND GENDER MINORITY HEALTH		
Health Care for Gay & Bisexual Men	1670–1671	• Anal cytology, high-risk HPV testing, or both for screening of MSM without HIV is recommended in international consensus guidelines, beginning at age 45. If a screening test is negative, it should be repeated in 12–24 months depending upon the screening strategy used (cytology, high-risk HPV testing, or both). *Stier EA et al. Int J Cancer. [PMID: 38297406]*
Health Care for Transgender & Gender Diverse People	1672	• Progestins may be an effective anti-androgen, particularly cyproterone acetate, which is used widely outside the United States as the primary androgen blocker in feminizing regimens. *Szymczyk S et al. J Clin Med. [PMID: 39597939]*
CHAPTER 48: SUBSTANCE USE DISORDER		
Alcohol Use Disorder	1694	• A small non-randomized trial suggested that symptoms-triggered protocols were associated with lower readmission rates and reduced total dose of benzodiazepines, but with longer lengths of hospital stay.
Miscellaneous Drugs & Solvents	1703	• Treatment of nitrous oxide intoxication is with aggressive B_{12} supplementation (B_{12} 1000 mcg intramuscularly daily or every other day in the first week, followed by weekly for 4–8 weeks, then monthly). Concurrent megaloblastic anemia typically resolves in 6–8 weeks.
Opioid Use Disorders	1687	• In 2024, federal regulations changed to allow a greater role for provider judgment in making decisions about take-home methadone. A patient now can be eligible for up to 7 take-home doses after only 14 days of treatment.

*See chapter for further details and references.

Disease Prevention & Health Promotion

1

Michael Pignone, MD, MPH[1]

GENERAL APPROACH TO THE PATIENT

The medical interview serves several functions. It is used to collect information to assist in diagnosis (the “history” of the present illness), to understand patient values and goals, to assess and communicate prognosis, to establish a therapeutic relationship, and to reach agreement with the patient about further diagnostic procedures and therapeutic options. It also serves as an opportunity to influence patient behavior, such as in motivational discussions about smoking cessation or medication adherence. Interviewing techniques that promote shared decision making increase patient involvement and satisfaction. Effective clinician-patient communication and increased patient involvement can improve health outcomes.

Patient Adherence

For many illnesses, successful prevention and treatment depend on difficult fundamental behavioral changes, including altering diet, taking up exercise, giving up smoking, cutting down drinking, wearing masks to prevent infection, and adhering to complex medication regimens. *Adherence* is a common problem; up to 50% of patients fail to achieve full adherence, and one-third never take their medicines. Many patients with medical problems, even those with access to care, do not seek appropriate care or may drop out of care prematurely. Adherence rates for short-term, self-administered therapies are higher than for long-term therapies and are inversely correlated with the number of interventions, their complexity and cost, and the patient’s perception of overmedication.

As an example, in persons with HIV, adherence to antiretroviral therapy is a crucial determinant of treatment success. Studies have unequivocally demonstrated a close relationship between patient adherence and plasma HIV RNA levels, CD4 cell counts, and mortality. High adherence levels are needed to maintain virologic suppression. However, studies show that adherence varies over time, and inconsistent adherence is associated with incomplete viral suppression.

Patient reasons for suboptimal adherence include simple forgetfulness, being away from home, being busy, and changing daily routine. Other reasons include psychiatric disorders (depression or substance misuse), uncertainty about the effectiveness of treatment, lack of knowledge about the consequences of poor adherence, regimen complexity, and treatment side effects. The rising costs of medications, including generic medications, and the increase in patient cost-sharing burden have made adherence even more difficult, particularly for patients with lower incomes.

Patients seem better able to take prescribed medications than to adhere to recommendations to change their diet, exercise habits, or alcohol intake or to perform various self-care activities (such as monitoring blood glucose levels at home). For short-term regimens, adherence to medications can be improved by giving clear instructions. Writing out advice to patients, including changes in medication, may be helpful. Because low functional health literacy is common (*almost half of English-speaking US patients are unable to read and understand standard health education materials*), other forms of communication—such as illustrated simple text, videotapes, or oral instructions—may be more effective. Clinicians and health care delivery systems must provide culturally and linguistically appropriate health services.

To help improve adherence to long-term regimens, clinicians can work with patients to reach agreement on the goals for therapy, provide clear, concise information about the regimen, ensure understanding by using the “teach-back” method, counsel about the importance of adherence and how to organize medication-taking, reinforce self-monitoring, provide more convenient care, prescribe a simple dosage regimen for all medications (preferably no more than one or two doses daily), suggest ways to help in remembering to take doses (time of day, mealtime, alarms) and to keep appointments, prescribe lower-cost generic medications when available, and provide ways to simplify dosing (medication boxes). Single-unit doses supplied in foil wrappers can increase adherence but should be avoided for patients who have difficulty opening them. Medication boxes with compartments (eg, Medisets) that are filled weekly by the patient, caregiver, or pharmacy are useful. Devices can provide feedback to show patients whether they have taken doses as scheduled or to notify patients (or others) within a day if doses are skipped. Reminders, including cell phone text messages, are another effective means of encouraging adherence. The clinician can also enlist social support from family and friends, recruit an adherence monitor, provide a more convenient care environment with fewer barriers, and provide rewards and recognition for the patient's efforts to follow the regimen. Collaborative programs in which pharmacists help ensure adherence are also effective. Motivational interviewing techniques can be helpful when patients are ambivalent about their therapy.

---

[1] Dr. Pignone is a former member of the US Preventive Services Task Force (USPSTF). The views expressed in this chapter are his and not necessarily those of the USPSTF.

Adherence is also improved when a trusting clinician-patient relationship has been established and when patients actively participate in their care. Clinicians can improve patient adherence by inquiring about specific behaviors and barriers in a nonjudgmental manner. When asked, many patients admit to incomplete adherence with medication regimens, plans for giving up cigarette smoking, or engaging only in "safer sex" practices, offering an opportunity for joint problem-solving. Although difficult, sufficient time must be made available for communication.

Medication adherence can be assessed generally with a single question: "In the past month, how often did you take your medications as your clinician prescribed?" Other ways of assessing medication adherence include pill counts and refill records; monitoring serum, urine, or saliva levels of medications or metabolites; watching for appointment nonattendance and treatment nonresponse; and assessing predictable medication effects, such as weight changes with diuretics or bradycardia from beta-blockers. In some conditions, even partial adherence, as with medication treatment of hypertension and diabetes mellitus, improves outcomes compared with nonadherence; in other cases, such as HIV antiretroviral therapy or tuberculosis treatment, partial adherence may be *worse* than complete nonadherence.

Guiding Principles of Care

Ethical practices are called for in medical care at both the "micro" level of the individual patient-clinician relationship and the "macro" level of allocation of resources or the adoption of infection-reducing public health interventions. Ethical principles that guide the successful approach to diagnosis and treatment are honesty, beneficence, justice, avoidance of conflict of interest, and the pledge to do no harm. Increasingly, Western medicine involves partnership with patients in important decisions about medical care, eg, which colorectal screening test to obtain or which modality of therapy for breast cancer or how far to proceed with treatment attempts for patients who have end-stage illnesses (see Chapter 5).

The clinician's role does not end with diagnosis and treatment. The importance of the empathic clinician in helping patients and their families face serious illness and death cannot be overemphasized. *"To cure sometimes, to relieve often, and to comfort always"* is a French saying as apt today as it was five centuries ago—as is Francis Peabody's admonition: *"The secret of the care of the patient is in caring for the patient."* Training to improve mindfulness and enhance patient-centered communication increases patient satisfaction and may also improve clinician satisfaction.

HEALTH MAINTENANCE & DISEASE PREVENTION

Preventive medicine can be categorized as primary, secondary, or tertiary. *Primary prevention* aims to remove or reduce disease risk factors (eg, immunization, giving up or not starting smoking). *Secondary prevention* techniques promote early detection of disease or precursor states (eg, routine cervical Papanicolaou screening to detect carcinoma or dysplasia). *Tertiary prevention* measures are aimed at limiting the impact of established disease (eg, partial mastectomy combined with radiation therapy to remove and control localized breast cancer).

Table 1–1 shows leading causes of death in the United States for 2023 and Figure 1–1 compares leading causes of death in 1990, 2010, and 2021. The 2023 mortality data are notable for the reduction in COVID-19-related deaths relative to other leading causes of death. Recent increases in mortality and decreased life expectancy have been larger in the United States than in Western European countries; this discrepancy has been driven partially by differences in COVID-19 mortality as well as ongoing trends in other midlife preventable mortality, particularly deaths from heart disease, unintentional injuries (including overdoses), and liver disease.

Many effective preventive services are underutilized, and few adults receive all of the most strongly recommended services. Several methods, including the use of provider or patient reminder systems (including interactive patient health records), reorganization of care environments to reduce barriers, and possibly provision of financial incentives to clinicians (though this remains controversial), can increase utilization of preventive services, but such methods have not been widely adopted.

Woolf SH. Increasing mortality rates in the US, but not from COVID-19. JAMA. 2024;332:959. [PMID: 39207745]

PREVENTION OF INFECTIOUS DISEASES

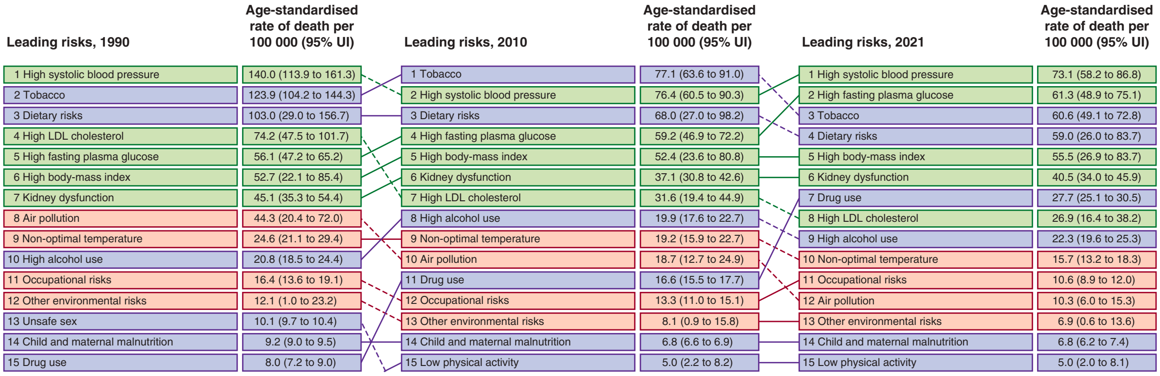
Much of the historic decline in the incidence and fatality rates of infectious diseases is attributable to public health measures—especially immunization, improved sanitation, nonpharmacologic interventions (eg, mask-wearing to prevent respiratory-transmissible conditions, improvements in indoor air quality), and better nutrition. This observation has been reinforced by the experience during the global COVID-19 pandemic.

Immunization remains the best means of preventing many infectious diseases. Recommended immunization schedules for children and adolescents can be found online at https://www.cdc.gov/vaccines/schedules/hcp/child-adolescent.html, and the schedule for adults is at https://www.cdc.gov/vaccines/schedules/hcp/adult.html (see also Chapters 35 and 37). In addition to the severe toll in morbidity and mortality from COVID-19, substantial morbidity and mortality continue to occur from vaccine-preventable diseases, such as hepatitis A, hepatitis B, influenza, and pneumococcal infections. *The high incidence and mortality rates from COVID-19 and other recent outbreaks of vaccine-preventable diseases in the United States highlight the need to better understand vaccine hesitancy or refusal and methods for mitigating it.*

The Advisory Committee on Immunization Practices recommendations for the following vaccines appear in Table 1–2: influenza; MMR; 23-valent pneumococcal; tetanus, diphtheria, and acellular pertussis; hepatitis B; HPV; RSV; meningococcal; mpox; and Zoster (shingles). Updated guidance for COVID-19 vaccination also is provided.

Persons traveling to countries where infections are endemic should take the precautions described in Chapter 35 and at https://wwwnc.cdc.gov/travel/destinations/list. Immunization registries—confidential, population-based, computerized information systems that collect vaccination data about all residents of a geographic area—can be used to increase and sustain high vaccination coverage.

Globally, COVID-19 has resulted in > 7.1 million deaths through November 2024, including > 1.2 million in the United States, according to WHO data. Estimates of total excess deaths from COVID-19 may be twice as high. In addition to its tremendous overall health impact, the COVID-19 pandemic has revealed and exacerbated profound inequities in health and health care. In the United States, the COVID-19 mortality rates are higher in Black, Latina/Latino, and American Indian patients compared with White patients. Currently, the CDC recommends that everyone aged 6 months and older stay up to date with COVID-19 vaccination (through receiving a primary series



Leading risks, 1990	Age-standardised rate of death per 100 000 (95% UI)	Leading risks, 2010	Age-standardised rate of death per 100 000 (95% UI)	Leading risks, 2021	Age-standardised rate of death per 100 000 (95% UI)
1 High systolic blood pressure	140.0 (113.9 to 161.3)	1 Tobacco	77.1 (63.6 to 91.0)	1 High systolic blood pressure	73.1 (58.2 to 86.8)
2 Tobacco	123.9 (104.2 to 144.3)	2 High systolic blood pressure	76.4 (60.5 to 90.3)	2 High fasting plasma glucose	61.3 (48.9 to 75.1)

▲ **Figure 1–1. Leading causes of death in 1990, 2010, and 2021 in the United States for all ages and sexes combined (causes are ranked by number of deaths in each year).** (Reproduced from GBD 2021 US Burden of Disease Collaborators. The burden of diseases, injuries, and risk factors by state in the USA, 1990-2021: a systematic analysis for the Global Burden of Disease Study 2021. *Lancet*. 2024;404:2314.)

Table 1–2. Advisory Committee on Adult Immunization Practices vaccine recommendations, 2024.

Vaccine	Recommendation	Comment
Influenza	Routine vaccination for all persons aged 6 months and older, including all adults. An alternative high-dose inactivated vaccine is available for adults aged 65 years and older.	When vaccine supply is limited, certain groups should be given priority, such as adults aged 50 years and older, individuals with chronic illness or immunosuppression, and pregnant women
COVID-19	Routine vaccination for all persons 19 and older. For previously unvaccinated persons: • 1 dose of updated (2024–2025 Formula) Moderna or Pfizer-BioNTech vaccine • 2-dose series of updated (2024–2025 Formula) Novavax at 0, 3–8 weeks For previously vaccinated with one or more doses of any COVID-19 vaccine: one dose of any updated (2024–2025 Formula) COVID-19 vaccine administered at least 8 weeks after the most recent COVID-19 vaccine dose. A second dose of 2024–2025 COVID-19 is recommended for adults aged 65 years and older and for ages 6 months to 64 years who are moderately or severely immunocompromised.	New addition of recommended second dosing for older adults and immunocompromised; option for third dose for immunocompromised as well
MMR	Two doses for adults at high risk for exposure and transmission (eg, college students, health care workers); otherwise, one dose for adults aged 18 years and older.	Physician documentation of disease is not acceptable evidence of MMR immunity
Meningococcal	MenB-4C (Bexsero) administered as a 2-dose series (0 and 6 months) for young adults aged 16–23 years based on shared clinical decision-making for the prevention of serogroup B meningococcal disease and as a 3-dose series at 0, 1–2, and 6 months when given to persons aged ≥ 10 years at increased risk for serogroup B meningococcal disease.	New recommendation
Mpox	Any person at risk for mpox infection: complete 2-dose series, 28 days apart. Risk factors for mpox infection include: • Persons who are gay or bisexual and other MSM, transgender, or nonbinary people who in the past 6 months have had a new diagnosis of at least 1 sexually transmitted disease; > 1 sexual partner; sex at a commercial sex venue; or sex in association with a large public event in a geographic area where mpox transmission is occurring • Persons who are sexual partners of persons described above • Persons who anticipate experiencing any of the situations described above	
Pneumococcal	One dose of PCV15 followed by PPSV23 *or* One dose of PCV20 or PCV21 For all adults aged 50 years and older plus those aged 19–64 years who are at increased risk.	New recommendation to start at age 50 years
Tdap	Routine use of a single dose of Tdap for adults aged 19–64 years.	Replaces next booster dose of Td vaccine
Hepatitis B	Two-, three-, or four-dose primary series recommended for all adults aged 19–59 years who have not been previously vaccinated or infected. Recommended for patients aged 60 years and over who are at increased risk or who wish to be vaccinated.	Prevents chronic hepatitis B and cirrhosis and their predispositions to HCC
HPV VLP	Routine HPV vaccination for children and adults aged 9–26 years. Shared decision making is recommended for unvaccinated individuals between 27 and 45 years of age (vaccine is not licensed for adults older than 45 years).	Prevents persistent HPV infections effectively and thus may impact rate of CIN II–III
RSV	Routine RSV vaccination (one dose) for pregnant persons at 32 weeks 0 days through 36 weeks 6 days gestation from September through January in most of the continental United States. Shared decision making for adults aged 60 and older. Those who are immunocompromised or who have chronic conditions are most likely to benefit.	
Zoster (shingles)	Two doses (2–6 months apart) of recombinant zoster vaccine to prevent shingles and related complications in adults aged ≥ 50 years and for adults aged ≥ 19 years who are or will be immunodeficient or immunosuppressed.	

CIN, cervical intraepithelial neoplasia; VLP, virus-like particle; MSM, men who have sex with men; PCV15, 15-valent pneumococcal conjugate; PCV20, 20-valent pneumococcal conjugate; PCV21, 21-valent pneumococcal conjugate; PPSV23, 23-valent pneumococcal polysaccharide; Td, tetanus and diphtheria toxoids; Tdap, tetanus, diphtheria, and five-component acellular pertussis.

and appropriate boosters) to help protect against COVID-19 (see Chapter 37 and Table 1–2) using one of the CDC-approved vaccines.

The USPSTF recommends **behavioral counseling** for adolescents and adults who are sexually active and at increased risk for STIs. Sexually active women aged 24 years or younger and older women who are at increased risk for infection should be **screened for chlamydia and gonorrhea**. Screening HIV-positive men or men who have sex with men for syphilis every 3 months is associated with improved syphilis detection.

The CDC recommends universal **HIV screening** of all patients aged 13–64, and the USPSTF recommends that clinicians screen adolescents and adults aged 15–65 years. Clinicians should integrate biomedical and behavioral approaches for HIV prevention. In addition to reducing sexual transmission of HIV, initiation of antiretroviral therapy reduces the risk for AIDS-defining events and death among patients with less immunologically advanced disease.

Daily **preexposure prophylaxis (PrEP)** with the fixed-dose combination of tenofovir disoproxil 300 mg and emtricitabine 200 mg (Truvada) should be considered for persons who are HIV-negative but at substantial risk for HIV infection. Studies of men who have sex with men suggest that PrEP is very effective in reducing the risk of contracting HIV. Patients taking PrEP should be encouraged to use other prevention strategies, such as consistent condom use, to maximally reduce their risk. **Postexposure prophylaxis (PEP)** with combinations of antiretroviral medications is widely used after occupational and nonoccupational contact and may reduce the risk of transmission by about 80%. PEP should be initiated within 72 hours of exposure.

Herpes zoster, caused by reactivation from previous varicella zoster virus infection, affects many older adults and persons with immune system dysfunction. The Advisory Committee on Immunization Practices recommends that the **herpes zoster subunit vaccine** (HZ/su; Shingrix) be used for the prevention of herpes zoster and related complications in immunocompetent adults aged 50 and older and in individuals who previously received Zostavax.

PREVENTION OF CARDIOVASCULAR DISEASE

Cardiovascular disease, including CHD and stroke, is the leading cause of death globally, with over 20 million deaths in 2021, nearly one-third of all deaths. Over three-quarters of all cardiovascular deaths occur in low- and middle-income countries; however, CHD and stroke remain top causes of death in the United States as well. Several risk factors increase the risk for coronary disease and stroke. These risk factors can be divided into those that are modifiable (eg, lipid disorders, hypertension, cigarette smoking) and those that are not (eg, age, sex, family history of early coronary disease). Impressive declines in age-specific mortality rates from heart disease and stroke were achieved in all age groups in North America from 1980 to 2015, in large part through improvement of modifiable risk factors: reductions in cigarette smoking, improvements in lipid levels, and more aggressive detection and treatment of hypertension. However, the past several years have seen a disturbing increase in cardiovascular deaths in the United States and a plateau in the reduction in cardiovascular mortality rates. This section considers the role of screening for cardiovascular risk and the use of effective therapies to reduce such risk. Key USPSTF recommendations for cardiovascular prevention are shown in Table 1–3. Guidelines encourage regular assessment of global cardiovascular risk in adults 40–79 years of age without known CVD using standard cardiovascular risk factors and in younger adults at increased risk. The role of nontraditional risk factors for improving risk estimation and therapeutic decision making remains unclear. However, current guidance recommends considering cardiovascular risk prevention within the context of cardiovascular-kidney-metabolic health.

Khan SS et al; American Heart Association. Novel prediction equations for absolute risk assessment of total cardiovascular disease incorporating cardiovascular-kidney-metabolic health: a scientific statement from the American Heart Association. Circulation. 2023;148:1982. [PMID: 37947094]

Abdominal Aortic Aneurysm

One-time screening for AAA by ultrasonography is recommended by the USPSTF (B recommendation) in men aged 65–75 years who have ever smoked. One-time screening for AAA is associated with a relative reduction in odds of AAA-related mortality over 12–15 years and a similar reduction in AAA-related ruptures. Women who have never smoked and who have no family history of AAA do not appear to benefit from such screening (D recommendation); the current evidence for women who have ever smoked or who have a family history of AAA is insufficient to assess the balance of risks versus benefits (I recommendation) (Table 1–3).

Cigarette Smoking

Cigarette smoking remains the most important cause of preventable morbidity and early mortality. In 2019, there were an estimated 7.69 million deaths in the world attributable

Table 1–3. Expert recommendations for cardiovascular risk prevention methods: USPSTF.[1]

Prevention Method	Recommendation/[Year Issued]
Screening for AAA	Recommends one-time screening for AAA by ultrasonography in men aged 65–75 years who have ever smoked. (B) Selectively offer screening for AAA in men aged 65–75 years who have never smoked. (C) Current evidence is insufficient to assess the balance of benefits and harms of screening for AAA in women aged 65–75 years who have ever smoked or have a family history of AAA. (I) Recommends against routine screening for AAA in women who have never smoked and have no family history of AAA. (D) [2019]
Aspirin use	The decision to initiate low-dose aspirin use for the primary prevention of CVD in adults aged 40–59 years who have a 10% or greater 10-year CVD risk should be an individual one. Evidence indicates that the net benefit of aspirin use in this group is small. Persons who are not at increased risk for bleeding and are willing to take low-dose aspirin daily are more likely to benefit. [C] Recommends against initiating low-dose aspirin use for primary prevention of CVD in adults aged 60 years or older. [D] [2022]
Blood pressure screening	Recommends screening for hypertension in adults aged 18 years or older with office blood pressure measurement. Recommends obtaining blood pressure measurements outside of the clinical setting for diagnostic confirmation before starting treatment. (A) [2021]
Serum lipid screening and use of statins for prevention	Recommends that clinicians prescribe a statin for primary prevention of CVD for adults aged 40–75 years who have one or more CVD risk factors (ie, dyslipidemia, diabetes, hypertension, or smoking) and an estimated 10-year risk of a cardiovascular event of 10% or greater. [B] Recommends that clinicians selectively offer a statin for primary prevention of CVD for adults aged 40–75 years who have one or more CVD risk factors (ie, dyslipidemia, diabetes, hypertension, or smoking) and an estimated 10-year risk of a cardiovascular event of 7.5% to < 10%. The likelihood of benefit is smaller in this group than in persons with a 10-year risk of 10% or greater. [C] Current evidence is insufficient to assess the balance of benefits and harms of initiating a statin for the primary prevention of CVD events and mortality in adults aged 76 years or older. [I] [2022]
Counseling about healthful diet and physical activity for CVD prevention	Recommends offering or referring adults with CVD risk factors to behavioral counseling interventions to promote a healthy diet and physical activity. (B) [2020] Recommends that primary care professionals individualize the decision to offer or refer adults without CVD risk factors to behavioral counseling interventions to promote a healthy diet and physical activity. (C) [2022]
Screening for diabetes mellitus	Recommends screening for prediabetes and type 2 diabetes in adults aged 35–70 years who have overweight or obesity. Clinicians should offer or refer patients with prediabetes to effective preventive interventions. (B) [2021]
Screening for smoking and counseling to promote cessation	Recommends that clinicians ask all adults about tobacco use, advise them to stop using tobacco, provide those who use tobacco behavioral interventions, and prescribe US FDA–approved pharmacotherapy to nonpregnant adults. (A) [2021]

[1] USPSTF recommendations available at http://www.uspreventiveservicestaskforce.org/BrowseRec/Index/browse-recommendations.

Recommendation A: The USPSTF strongly recommends that clinicians routinely provide the service to eligible patients. (The USPSTF found good evidence that the service improves important health outcomes and concludes that benefits substantially outweigh harms.)

Recommendation B: The USPSTF recommends that clinicians routinely provide the service to eligible patients. (The USPSTF found at least fair evidence that the service improves important health outcomes and concludes that benefits substantially outweigh harms.)

Recommendation C: The USPSTF makes no recommendation for or against routine provision of the service.

Recommendation D: The USPSTF recommends against routinely providing the service to asymptomatic patients. (The USPSTF found at least fair evidence that the service is ineffective or that harms outweigh benefits.)

Recommendation I: The USPSTF concludes that the evidence is insufficient to recommend for or against routinely providing the service.

to smoking and tobacco use (13.6% of all deaths worldwide); smoking is the second leading cause of disability-adjusted life-years lost overall and the leading cause among men. Cigarettes are responsible for one in every five deaths in the United States, or over 480,000 deaths annually. The most frequent causes of smoking-related deaths are cancer, CVD, and respiratory disease (COPD). The annual cost of smoking-related health care is about $240 billion in the United States, with another $372 billion in productivity losses. Fortunately, US smoking rates have been declining; in 2015, 15.1% of US adults were smokers, and by 2020, 12.5% were smokers. Global direct health care costs from smoking in 2012 were estimated at $422 billion, with total costs of > $1.4 trillion.

Although tobacco use constitutes one of the most serious common medical problems, it is undertreated. Of the estimated 28.8 million adult smokers (11.6% of the population) in 2022, 67% wanted to quit and 77% saw a health care provider in the past year. Of these, only 50% received advice or assistance. Several effective clinical interventions are available to promote smoking cessation, including counseling, pharmacotherapy, and a combination of the two.

Persons whose clinicians advise them to quit are 1.6 times as likely to attempt quitting. Use of evidence-based interventions is low: only one-third of persons used medication assistance and < 10% received evidence-based counseling, while only 5.3% used both.

More than half of smokers attempt to quit each year, but only 5–10% are successful. Factors associated with successful cessation include having a rule against smoking in the home, younger age, having a higher income, being insured, and having a higher education. Mental health counseling in the past year was also associated with successful smoking cessation.

Helpful counseling strategies are shown in Table 1–4. Additionally, a system should be implemented to identify smokers, and advice to quit should be tailored to the patient's level of readiness to change. *All patients trying to quit should be offered pharmacotherapy* (Table 1–5) *except those with medical contraindications, women who are pregnant or breastfeeding, and adolescents.* Weight gain occurs in most patients (80%) following smoking cessation. Average weight gain is 2 kg, but for some (10–15%), major weight gain—over 13 kg—may occur. Planning for the possibility of weight gain, and means of mitigating it, may help with maintenance of cessation.

Several pharmacologic therapies shown to be effective in promoting cessation are summarized in Table 1–5. Nicotine replacement therapy doubles the chance of successful quitting. The nicotine patch, gum, and lozenges are available over the counter, and nicotine nasal spray and inhalers are available by prescription. The sustained-release antidepressant drug bupropion (150–300 mg/day orally) is an effective smoking cessation agent and is associated with minimal weight gain, although seizures are a contraindication. It acts by boosting brain levels of dopamine and norepinephrine, mimicking the effect of nicotine. Varenicline, a partial nicotinic acetylcholine-receptor agonist, also has been shown to improve cessation rates; however, its adverse effects, particularly its effects on mood, are not completely understood and warrant careful consideration, although recent safety data have provided reassurance. A head-to-head trial found varenicline to be more effective than other pharmacologic therapies and all pharmacologic therapies to be more effective than placebo. Combination therapy is more effective than a single pharmacologic modality. The efficacy of e-cigarettes in smoking cessation has not been well evaluated, and some users may find them addictive. "E-cigarette or vaping use–associated lung injury" (EVALI) should prompt additional caution in the use of unregulated nicotine delivery devices for smoking cessation (see Chapter 9).

Clinicians should not show disapproval of patients who fail to stop smoking or who are not ready to make a quit attempt. Thoughtful advice that emphasizes the benefits of cessation and recognizes common barriers to success can increase motivation to quit and quit rates. An upcoming medical procedure or intercurrent illness or hospitalization may motivate even the most addicted smoker to quit.

Individualized or group counseling is very cost-effective, even more so than treating hypertension. Smoking cessation counseling by telephone ("quitlines") and text messaging have both proved effective. An additional strategy is to recommend that any smoking take place outdoors

Table 1–4. Inquiries to help in support of smoking cessation.

Component	Helpful Clinician Statements and Inquiries
Communicate your caring and concern	"I am concerned about the effects of smoking on your health… • and want you to know that I am willing to help you quit." • and so how do you feel about quitting?" • do you have any fears or ambivalent feelings about quitting?"
Encourage the patient to talk about the quitting process	"Tell me… • why do you want to quit smoking?" • when you tried quitting smoking in the past, what sort of difficulties did you encounter?" • were you able to succeed at all, even for a while?" • what concerns or worries do you have about quitting now?"
Provide basic information about smoking (eg, its addictive nature) and successful quitting (eg, nature and time course of withdrawal)	"Did you know that… • the nicotine in cigarette smoke is highly addictive?" • within a day of stopping, you will notice nicotine withdrawal symptoms, such as irritability and craving?" • after you quit, any smoking (even a single puff) makes it likely that you will fully relapse into smoking again?"
Encourage the patient to make a quit attempt	"I want to reassure you that… • as your clinician, I believe you are going to be able to quit." • many effective smoking cessation treatments are now available." • more than half the people who have *ever* smoked have now successfully quit."

Table 1–5. Medications for tobacco dependence and smoking cessation (categories listed in order of frequency of use).

Medication	Some Formulations	Usual Adult Dosage[1,2]
Nicotine Replacement Therapies (NRTs)		
Nicotine transdermal patch[3] – generic (NicoDerm CQ)	7, 14, 21 mg/24-h patches	1 patch/day
Nicotine polacrilex gum[3] – generic (Nicorette gum)	2, 4 mg/pieces	8–24 pieces/day[4,5]
Nicotine polacrilex lozenge[3,6] – generic (Nicorette lozenge)	2, 4 mg/lozenges	8–20 lozenges/day[4,7]
Nicotine oral inhaler – Nicotrol[8]	10 mg cartridges	4–16 cartridges/day
Nicotine nasal spray – Nicotrol NS	200 sprays/10 mL bottles (0.5 mg/spray)	2 sprays 8–40×/day (max 10 sprays/h)
Dopaminergic-Noradrenergic Reuptake Inhibitor		
Bupropion SR – generic	100, 150, 200 mg SR tablets[9]	150 mg orally once daily × 3 days, then 150 mg orally twice daily
Nicotinic Receptor Partial Agonist		
Varenicline tartrate – Chantix	0.5, 1 mg tablets	0.5 mg orally once daily × 3 days, then 0.5 mg twice daily on days 4–7, then 1 mg twice daily

SR, sustained-release.

[1] Dosage reductions may be needed for liver or kidney impairment.

[2] Patients should receive a minimum of 3–6 months of effective therapy. In general, the dosage of NRTs can be tapered at the end of treatment; bupropion SR and varenicline can usually be stopped without a gradual dosage reduction, but some clinicians recommend a taper.

[3] Available over the counter for persons ≥ 18 years old.

[4] Avoid eating or drinking within 15 minutes of using a gum or lozenge.

[5] A second piece of gum can be used within 1 hour. Continuously chewing one piece after another is not recommended.

[6] Also available in a mini-lozenge.

[7] Maximum of 5 lozenges in 6 hours or 20 lozenges/day. Use of > 1 lozenge at a time or continuously using one after another is not recommended.

[8] Not currently available from the manufacturer.

[9] Only the generic 150-mg SR tablets are FDA-approved as a smoking cessation aid.

Reprinted with special permission from The Medical Letter on Drugs and Therapeutics, July 15, 2019; Vol. 61(1576):106.

to limit the effects of passive smoke on housemates and coworkers. This can lead to smoking reduction and quitting.

Public policies, including higher cigarette taxes and more restrictive public smoking laws, have also been shown to encourage cessation, as have financial incentives directed to patients.

▶ Lipid Disorders

Higher LDL cholesterol concentrations and lower HDL levels are associated with an increased risk of CHD (see Chapter 33). Measurement of total and HDL cholesterol levels can help assess the degree of CHD risk. The best age to start screening is controversial, as is its frequency. Cholesterol-lowering therapy reduces the relative risk of CHD events, with the degree of reduction proportional to the reduction in LDL cholesterol achieved, at least at initial LDL levels > 100 mg/dL. The absolute benefits of screening for—and treating—abnormal lipid levels depend on the presence and level of other cardiovascular risk factors, including hypertension, diabetes mellitus, smoking, age, and sex (see Chapter 33). If other risk factors are present, atherosclerotic CVD risk is higher and the potential benefits of therapy are greater. Patients with known CVD are at higher risk and have larger benefits from reduction in LDL cholesterol. The optimal risk threshold for initiating statins for primary prevention remains somewhat controversial, although most guidelines now suggest statin therapy when 10-year atherosclerotic cardiovascular risk is > 10%. Use of a cardiovascular risk calculator can help inform decision making for primary prevention.

Evidence for the effectiveness of statin-type medications is better than for the other classes of lipid-lowering agents or dietary changes specifically for improving lipid levels. Multiple large, randomized, placebo-controlled trials have demonstrated important reductions in total mortality, major coronary events, and strokes with lowering levels of LDL cholesterol by statin therapy for patients with known CVD. Statins also reduce cardiovascular events for patients with diabetes mellitus. For patients with no previous history of cardiovascular events, meta-analyses have shown important reductions of cardiovascular events and all-cause mortality.

Antilipidemic monoclonal antibody agents (eg, evolocumab and alirocumab) lower LDL cholesterol by 50–60% by binding proprotein convertase subtilisin kexin type 9 (PCSK9), which decreases the degradation of LDL receptors. PCSK9 inhibitors also decrease Lp(a) levels. These medications are very expensive and so are often used mainly in high-risk patients when statin therapy does not reduce LDL cholesterol sufficiently at maximally tolerated doses or when patients are intolerant of statins. Few side effects have been reported with PCSK9 inhibitor use.

Guidelines for statin and PCSK9 therapy are discussed in Chapter 33.

Hypertension

The most recent data from the National Health and Nutrition Examination Survey estimated the adult prevalence of hypertension at 47.7%, using a 130/80 mm Hg threshold or current medication use. Less than 60% of persons were aware of their hypertension and about half were being treated, with only 20% being controlled at the 130/80 mm Hg threshold. These patterns have been stable over the past 10 years.

In every adult age group, higher values of systolic and diastolic blood pressure carry greater risks of stroke and HF. Systolic blood pressure is a better predictor of morbid events than diastolic blood pressure. Home monitoring is better correlated with target organ damage than clinic-based values. Clinicians can apply specific blood pressure criteria, such as those of the Joint National Committee or American Heart Association guidelines, along with consideration of the patient's cardiovascular risk and personal values, to decide at what levels treatment should be considered in individual cases.

Primary prevention of hypertension can be accomplished by strategies aimed at both the general population and special high-risk populations. The latter include persons with high-normal blood pressure or a family history of hypertension; Black persons; and individuals with various behavioral risk factors, such as physical inactivity; excessive consumption of salt, alcohol, or calories; and deficient intake of potassium. Effective interventions for primary prevention of hypertension include reduced sodium and alcohol consumption, weight loss, and regular exercise. Diets high in fresh fruits and vegetables and low in saturated fat and sugar-containing beverages are associated with lower blood pressure.

Improved identification and treatment of hypertension has been a major cause of the decline in stroke deaths as well as the reduction in incidence of HF-related hospitalizations; more recently, stalled progress in control of hypertension has led to slowing of improvements in cardiovascular outcomes. *Because hypertension is usually asymptomatic, screening is strongly recommended to identify patients for treatment.* Elevated office readings should be confirmed with repeated measurements, ideally from ambulatory monitoring or home measurements. Despite strong recommendations in favor of screening and treatment, hypertension control remains suboptimal. Several types of interventions, including telehealth applications, have been shown to be effective in increasing adherence and blood pressure control. An intervention that included both patient and provider education was more effective than provider education alone in achieving control of hypertension, suggesting the benefits of patient participation; another trial found that home monitoring combined with telephone-based nurse support was more effective than home monitoring alone for blood pressure control. Pharmacologic management of hypertension is discussed in Chapter 13.

Mikulski BS et al. Mobile health applications and medication adherence of patients with hypertension: a systematic review and meta-analysis. Am J Prev Med. 2022;62:626. [PMID: 34963562]

Chemoprevention

Regular use of low-dose aspirin (81–325 mg) can reduce cardiovascular events but increases GI bleeding and hemorrhagic stroke. The potential benefits of aspirin may exceed the possible adverse effects among middle-aged adults who are at increased cardiovascular risk, which can be defined as a 10-year risk of > 10%, and who do not have an increased risk of bleeding. However, a large trial in older healthy adults did not find clear benefit from aspirin for reduction of cardiovascular events and saw an increase in all-cause mortality with aspirin. Therefore, aspirin should *not* be routinely initiated in healthy adults over age 70.

NSAIDs may reduce the incidence of colorectal adenomas and polyps but may also increase heart disease and GI bleeding and thus are *not* recommended for colon cancer prevention in average-risk patients.

Antioxidant vitamin (vitamin E, vitamin C, and β-carotene) supplementation produced no significant reductions in the 5-year incidence of—or mortality from—vascular disease, cancer, or other major outcomes in high-risk individuals with CAD, other occlusive arterial disease, or diabetes mellitus.

US Preventive Services Task Force; Davidson KW et al. Aspirin use to prevent cardiovascular disease: US Preventive Services Task Force Recommendation Statement. JAMA. 2022;327:1577. [PMID: 35471505]

PREVENTION OF OSTEOPOROSIS

See Chapter 30.

Osteoporosis, characterized by low bone mineral density, is common and associated with an increased risk of fracture. The lifetime risk of an osteoporotic fracture is about 50% for women and 30% for men. Osteoporotic fractures can cause significant pain and disability. As such, research has focused on means of preventing osteoporosis and related fractures. Primary prevention strategies include calcium supplementation, vitamin D supplementation, and exercise programs. The effectiveness of calcium and vitamin D for fracture prevention remains controversial, particularly in noninstitutionalized individuals.

Screening for osteoporosis on the basis of low bone mineral density is recommended for women over age 65, based on indirect evidence that screening can identify women with low bone mineral density and that treatment of women with low bone density with bisphosphonates is effective in reducing fractures. However, real-world adherence to pharmacologic therapy for osteoporosis is low: one-third to one-half of patients do not take their medication as directed. Screening for osteoporosis is also recommended in younger women who are at increased risk. The effectiveness of screening in men has not been established. Bisphosphonates may increase the risk of certain uncommon, atypical types of femoral fractures and rare osteonecrosis of the jaw and are associated with some nonserious GI symptoms. As such, consideration of the benefits and risks of therapy, as well as the importance of consistent adherence, is important when deciding about screening.

PREVENTION OF PHYSICAL INACTIVITY

Lack of sufficient physical activity is the second most important contributor to preventable deaths, trailing only tobacco use. The US Department of Health and Human Services and the CDC recommend that adults (including older adults) engage in 150 minutes of moderate-intensity (such as brisk walking) or 75 minutes of vigorous-intensity (such as jogging or running) aerobic activity or an equivalent mix of moderate- and vigorous-intensity aerobic activity each week. In addition to activity recommendations, the CDC recommends activities to strengthen all major muscle groups (abdomen, arms, back, chest, hips, legs, and shoulders) at least twice a week.

Patients who engage in regular moderate to vigorous exercise have a lower risk of MI, stroke, hypertension, hyperlipidemia, type 2 diabetes mellitus, diverticular disease, and osteoporosis. Regular exercise may also have a positive effect on executive function in older adults.

In longitudinal cohort studies, individuals who report higher levels of leisure-time physical activity are less likely to gain weight. Conversely, individuals who are overweight are less likely to stay active. However, at least 60 minutes of daily moderate-intensity physical activity may be necessary to maximize weight loss and prevent significant weight regain. Moreover, adequate levels of physical activity appear to be important for the prevention of weight gain and the development of obesity.

Systematic reviews have consistently found that more intensive counseling interventions are more effective than brief interventions.

Several factors influence physical activity behavior, including personal, social (eg, family and work), and environmental (eg, access to exercise facilities and well-lit parks) factors.

PREVENTION OF OVERWEIGHT & OBESITY

Obesity is a true epidemic and public health crisis that both clinicians and patients must face. Obesity is associated with type 2 diabetes mellitus, hypertension, hyperlipidemia, cancer, osteoarthritis, CVD, obstructive sleep apnea, asthma, and (for more severe obesity) increased all-cause mortality. Risk assessment for overweight and obesity begins with determination of BMI, waist circumference for patients with a BMI of ≤ 35, presence of comorbid conditions, and a fasting blood glucose and lipid panel. Normal body weight is defined as a BMI of < 25, overweight is defined as a BMI of 25.0–29.9, and obesity is defined as a BMI > 30. Persons with a BMI of ≥ 40 have death rates from cancers that are 52% higher for men and 62% higher for women than the rates in men and women of normal weight.

Primary, secondary, and tertiary prevention of overweight and obesity involves both increasing physical activity and dietary modification to reduce caloric intake. Adequate levels of physical activity appear to be important for the prevention of weight gain and the development of obesity. Physical activity programs consistent with public health recommendations may promote modest weight loss (about 2 kg); however, the amount of weight loss for any one individual is highly variable.

Clinicians can help prevent and treat obesity by intensive, multicomponent interventions, often best delivered by a trained nutritionist. Patients engaged in such interventions learn to develop personalized eating plans to reduce energy intake, particularly by recognizing the contributions of unhealthy fats, concentrated carbohydrates, and large portion sizes (see Chapter 34). Patients typically underestimate caloric content, especially when consuming food away from home. Providing patients with caloric and nutritional information may help limit caloric intake as part of a multicomponent intervention.

Other treatment options for obesity include pharmacotherapy and surgery (see Chapter 34). Recent evidence has demonstrated the effectiveness of GLP-1 agonists in producing sustained weight loss. However, the high cost of these medications has limited their access, especially for patients with low incomes and limited or no health insurance coverage. Effective use of GLP-1 medications also requires assessment and intervention to ensure preservation of muscle mass.

Weight loss strategies using dietary, physical activity, or behavioral interventions can produce significant improvements in weight among persons with prediabetes and a significant decrease in diabetes incidence. Intensive lifestyle interventions including diet combined with physical activity are effective in achieving weight loss and reducing cardiometabolic risk factors among patients with severe obesity.

Bariatric surgical procedures, eg, adjustable gastric band, sleeve gastrectomy, and Roux-en-Y gastric bypass, are reserved for patients with severe obesity in whom BMI exceeds 40 or for patients with less severe obesity (with BMIs between 35 and 40) and high-risk comorbid conditions, such as life-threatening cardiopulmonary problems (eg, sleep apnea, obesity-hypoventilation syndrome, and obesity-related HF) or diabetes mellitus. In selected patients, surgery can produce substantial weight loss (10–159 kg) over 1–5 years, with rare, but sometimes serious, complications. Surgery also appears to be successful in improving glycemic control and reducing diabetes. Nutritional deficiencies are one complication of bariatric surgical procedures and close monitoring of a patient's metabolic and nutritional status is essential. Further research is needed to best elucidate the optimal use of bariatric surgery in the era of effective GLP-1 agonists.

CANCER PREVENTION

Primary Prevention

Cancer mortality rates continue to decrease in the United States. Part of this decrease results from reductions in tobacco use, since cigarette smoking is the most important preventable cause of cancer; cancer incidence is also lower in persons with higher levels of physical activity and lower levels of obesity and alcohol use. Persons who engage in regular physical exercise, limit alcohol use, and avoid obesity have lower rates of breast and colon cancer.

Chemoprevention has been widely studied for primary cancer prevention without clear evidence of benefits (see earlier Chemoprevention section and Chapter 44). Use of tamoxifen, raloxifene, and aromatase inhibitors for breast cancer prevention is discussed in Chapters 19 and 44. Hepatitis B vaccination can prevent HCC. Screening and treatment of hepatitis C is another strategy to prevent HCC (see Chapter 18); new recommendations have extended the population eligible for screening.

HPV virus-like particle (VLP) vaccine is recommended to prevent cervical cancer (Table 1–2). HPV vaccines may also have a role in the prevention of HPV-related head and neck and possibly anal cancers. The USPSTF recommends genetic counseling and, if indicated after counseling, genetic testing for women whose family or personal history is associated with an increased risk of harmful mutations in the *BRCA1/2* gene.

Screening & Early Detection

Screening prevents death from cancers of the breast, colon, lung, and cervix. Current cancer screening recommendations from the USPSTF are available online at https://www.uspreventiveservicestaskforce.org/BrowseRec/Index/browse-recommendations.

Most guidelines are based on trial evidence from middle-aged adults, mostly of European ancestry. Cancer screening in adults over the age of 75 requires an individualized approach that considers differences in disease risk, differences in risk of adverse effects of diagnostic procedures and treatments and competing health issues.

Despite an increase in rates of screening for breast, cervical, lung, and colon cancer over the last decade, overall screening for these cancers is suboptimal. Interventions effective in promoting recommended cancer screening include group education, one-on-one education, patient reminders, reduction of structural barriers, reduction of out-of-pocket costs, and provider assessment and feedback. Multicomponent interventions are generally more effective than single-component ones.

Though breast cancer mortality is reduced with mammography screening, this screening has both benefits and downsides, including overdiagnosis (detecting cancers that would have never progressed to become clinically meaningful). Clinicians should discuss the risks and benefits with each patient and consider individual patient preferences when deciding when to begin screening (see Chapter 19).

Prostate cancer screening remains controversial: completed trials have not fully answered the question of whether early detection and treatment after screen detection produce sufficient benefits (in terms of cancer-specific mortality reduction) to outweigh harms of treatment and overdiagnosis. For men between the ages of 55 and 69, the decision to screen should be individualized and include a discussion of its risks and benefits with a clinician. The USPSTF recommends *against* PSA-based prostate cancer screening for men older than age 70 years (grade D recommendation).

The USPSTF recommends colorectal cancer screening for adults aged 45–75 years and selectively screening adults aged 76–85 years (considering the patient's preferences, overall health, and prior screening history). Choice of screening test is based on patient preferences. Screening colonoscopy every 10 years is one recommended screening option. Annual or biennial fecal occult blood testing reduces mortality from colorectal cancer and is also recommended, with fecal immunochemical tests (FIT) used most commonly. A combination of FIT and stool DNA testing has also shown good accuracy for colorectal cancer and advanced polyps. CT colonography (virtual colonoscopy) is another noninvasive option. It has been shown to have a high safety profile and accuracy similar to colonoscopy for large polyps and cancers.

The American Cancer Society recommends screening for persons aged 25–65 years with primary HPV testing every 5 years based on trial evidence showing it to be superior to other options. The USPSTF recommends screening for cervical cancer in women aged 21–65 years with a Papanicolaou smear (cytology) every 3 years or, for women aged 30–65 years who desire longer intervals, screening with cytology and HPV testing every 5 years, but its recommendation is being revised. The USPSTF recommends against screening in women younger than 21 years of age and average-risk women over 65 with adequate negative prior screenings. Receipt of HPV vaccination does not yet affect recommended screening intervals, although it may in the future, as a greater proportion of persons are vaccinated.

The USPSTF recommends offering annual lung cancer screening with low-dose CT to current smokers aged 50 to 80 years and at least a 20-pack-year smoking history and to smokers who quit within the past 15 years. Updated American Cancer Society recommendations remove the restriction on the number of years since quitting. A person should stop screening when health problem that limits life expectancy to < 5 years has developed or if the person cannot safely undergo treatment if lung cancer is detected. Screening should not be viewed as an alternative to smoking cessation but rather as a complementary approach.

PREVENTION OF INJURIES & VIOLENCE

Injuries are an important cause of morbidity and mortality, particularly before age 65. Homicide and motor vehicle collisions are a major cause of injury-related deaths among young and middle-aged adults, and accidental falls are the most common cause of injury-related death in older adults.

Men, particularly those aged 16–35, are at especially high risk for serious injury and death from firearm-related violence, with Black men at greatest risk and Latino and American Indian men also at increased risk. Firearm suicide rates are highest for White men but have been increasing for other racial/ethnic groups. *Deaths from firearms have reached epidemic levels in the United States.* Having a gun in the home increases the likelihood of homicide nearly threefold and of suicide fivefold. Educating clinicians to recognize and treat depression, assess suicide risk, and restrict access to lethal methods in persons at risk has been found to reduce suicide rates.

Clinicians have a critical role in the detection, prevention, and management of intimate partner violence (IPV). The USPSTF recommends screening women of reproductive age for IPV and providing or referring women to intervention services when needed. Inclusion of a single question in the medical history—"At any time, has a partner ever hit you, kicked you, or otherwise physically hurt you?"—can increase identification of this common problem. Assessment for abuse and offering referrals to community resources create the potential to interrupt and prevent recurrence of IPV and associated trauma (and even mortality). Clinicians should take an active role in following up with patients whenever possible, since IPV screening with passive referrals to services may not be adequate to prevent recurrence and escalation.

Physical and psychological abuse, exploitation, and neglect of older adults are serious, underrecognized problems; they may occur in up to 10% of older adults. Risk factors for elder abuse include a culture of violence in the family; a demented, debilitated, or depressed and socially isolated victim; and a perpetrator profile of mental illness, alcohol or drug abuse, or emotional or financial dependence (or both) on the victim. Clues to elder mistreatment include the patient's ill-kempt appearance, recurrent urgent-care visits, missed appointments, suspicious physical findings, and implausible explanations for injuries.

PREVENTION OF SUBSTANCE USE DISORDERS: ALCOHOL & ILLICIT DRUGS

A. Alcohol

Unhealthy alcohol use is a major public health problem in the United States. The spectrum of alcohol use disorders includes alcohol dependence; harmful pattern use of alcohol; and entities such as alcohol intoxication, alcohol withdrawal, and several alcohol-induced mental disorders. The *ICD-11* includes a new category: *hazardous alcohol use*. Categorized as a risk factor, hazardous alcohol use is a pattern of alcohol use that appreciably increases the risk of harmful physical or mental health consequences to the user.

Underdiagnosis and undertreatment of alcohol misuse are substantial. As with cigarette use, clinician identification and counseling about unhealthy alcohol use are essential. The USPSTF recommends screening adults aged 18 years and older for unhealthy alcohol use. The National Institute on Alcohol Abuse and Alcoholism recommends the following single-question screening test (validated in primary care settings): "How many times in the past year have you had X or more drinks in a day?" ("X" is 5 for men and 4 for women, and a response of > 1 time is considered a positive screen.)

Persons who screen positive on the single-item questionnaire should complete the Alcohol Use Disorder Identification Test (AUDIT), which consists of questions on the quantity and frequency of alcohol consumption, on alcohol dependence symptoms, and on alcohol-related problems (Table 1–6).

Clinicians should provide persons who screen positive for hazardous or risky drinking with brief behavioral counseling interventions to reduce alcohol misuse. Use of screening procedures and brief intervention methods (see Chapter 48) can produce a 10–30% reduction in long-term alcohol use and alcohol-related problems. Those whose AUDIT scores suggest alcohol use disorder (AUDIT > 12) should undergo more extensive evaluation and potential referral for treatment. Naltrexone and acamprosate are effective for treating alcohol use disorder. However, < 9% of eligible patients receive these effective medications.

Table 1–6. Screening for alcohol abuse using the Alcohol Use Disorder Identification Test (AUDIT).

(Scores for response categories are given in parentheses. Added together, Total Scores range from 0 to 40, with scores of 1 to 7 suggesting low-risk drinking; 8 to 14, hazardous or harmful drinking; and > 15, alcohol dependence.)				
1. How often do you have a drink containing alcohol?				
(0) Never	(1) Monthly or less	(2) Two to four times a month	(3) Two or three times a week	(4) Four or more times a week
2. How many drinks containing alcohol do you have on a typical day when you are drinking?				
(0) 1 or 2	(1) 3 or 4	(2) 5 or 6	(3) 7 to 9	(4) 10 or more
3. How often do you have six or more drinks on one occasion?				
(0) Never	(1) Less than monthly	(2) Monthly	(3) Weekly	(4) Daily or almost daily
4. How often during the past year have you found that you were not able to stop drinking once you had started?				
(0) Never	(1) Less than monthly	(2) Monthly	(3) Weekly	(4) Daily or almost daily
5. How often during the past year have you failed to do what was normally expected of you because of drinking?				
(0) Never	(1) Less than monthly	(2) Monthly	(3) Weekly	(4) Daily or almost daily
6. How often during the past year have you needed a first drink in the morning to get yourself going after a heavy drinking session?				
(0) Never	(1) Less than monthly	(2) Monthly	(3) Weekly	(4) Daily or almost daily
7. How often during the past year have you had a feeling of guilt or remorse after drinking?				
(0) Never	(1) Less than monthly	(2) Monthly	(3) Weekly	(4) Daily or almost daily
8. How often during the past year have you been unable to remember what happened the night before because you had been drinking?				
(0) Never	(1) Less than monthly	(2) Monthly	(3) Weekly	(4) Daily or almost daily
9. Have you or has someone else been injured as a result of your drinking?				
(0) No		(2) Yes, but not in the past year		(4) Yes, during the past year
10. Has a relative or friend or a doctor or other health worker been concerned about your drinking or suggested you cut down?				
(0) No		(2) Yes, but not in the past year		(4) Yes, during the past year

B. Opioids

Deaths due to opioid overdose have dramatically increased. Opioid risk mitigation strategies include use of risk assessment tools, treatment agreements (contracts), and urine drug testing to limit diversion of prescription opiates. Additional strategies include establishing and strengthening prescription drug monitoring programs, regulating pain management facilities, and establishing dosage thresholds requiring consultation with pain specialists.

More recently, non-prescription opioid use has become predominant as a cause of opioid-related mortality. Harm reduction interventions are important, including strategies to prevent or treat overdose and strategies to reduce infectious complications of injection drug use. The US FDA supports greater access to naloxone and is exploring options to make naloxone more available to treat opioid overdose (see Chapters 5 and 48).

Medication-assisted treatment, the use of medications with counseling and behavioral therapy, is effective in the prevention of opioid overdose and substance abuse disorders. Methadone, buprenorphine, and naltrexone are FDA approved for use in medication-assisted treatment. Buprenorphine has potential as a medication to ameliorate the symptoms and signs of withdrawal from opioids and is effective in reducing concomitant cocaine and opioid abuse.

Use of non-opioid drugs—including cocaine, methamphetamine, and so-called designer drugs—either sporadically or episodically remains an important problem with or without concomitant use of opioids.

Clinical aspects of substance abuse are discussed in Chapter 48.

Common Symptoms

2

Paul L. Nadler, MD
Ralph Gonzales, MD, MSPH

COUGH

ESSENTIAL INQUIRIES

- Age, duration of cough, occupational history, environmental exposures, and risk of infection with SARS-CoV-2.
- Use of tobacco, cannabis, e-cigarettes (vaping).
- Dyspnea (at rest or with exertion).
- Vital signs (heart rate, respiratory rate, body temperature); pulse oximetry.
- Chest examination.
- CXR, especially when unexplained cough lasts > 3–6 weeks.

General Considerations

Cough is the most common symptom for which patients seek medical attention. Cough results from stimulation of mechanical or chemical afferent nerve receptors in the bronchial tree. Effective cough depends on an intact afferent–efferent reflex arc, adequate expiratory and chest wall muscle strength, and normal mucociliary production and clearance.

Clinical Findings

A. Symptoms

Distinguishing **acute** (< 3 weeks), **persistent** (3–8 weeks), and **chronic** (> 8 weeks) cough illness syndromes is a useful first step in evaluation. Postinfectious cough lasting 3–8 weeks is referred to as **subacute** cough to distinguish this common, distinct clinical entity from acute and chronic cough.

1. Acute cough—In healthy adults, most acute cough syndromes are due to viral respiratory tract infections. Additional features of infection such as fever, nasal congestion, and sore throat help confirm this diagnosis. Dyspnea (at rest or with exertion) may reflect a more serious condition, and further evaluation should include assessment of oxygenation (pulse oximetry or ABG measurement), airflow (peak flow or spirometry), and pulmonary parenchymal disease (CXR). The timing and character of the cough are not useful in establishing the cause of acute cough syndromes, although cough-variant asthma should be considered when there is prominent nocturnal cough. Loss of smell or dysgeusia accompanying a new cough illness is specific but not sensitive for COVID-19 infection. The presence of posttussive emesis or inspiratory whoop in adults modestly increases the likelihood of pertussis, and the absence of paroxysmal cough and the presence of fever decrease its likelihood. Uncommon causes of acute cough should be suspected in those with HF or hay fever (allergic rhinitis) and those with occupational risk factors (such as farmworkers).

2. Persistent and chronic cough—Cough due to acute respiratory tract infection resolves within 3 weeks in > 90% of patients. Pertussis should be considered in adolescents and adults with persistent or severe cough lasting > 3 weeks, who have not been adequately boosted with Tdap, and who have been exposed to a person with confirmed pertussis. It should also be considered in geographic areas where the prevalence of pertussis approaches 20% (although the prevalence is difficult to ascertain due to the limited sensitivity of diagnostic tests).

When ACE inhibitor use, acute respiratory tract infection, and CXR abnormalities are absent, most cases of persistent and chronic cough are related to postnasal drip (upper airway cough syndrome), cough-variant asthma, or GERD, or some combination of these three entities. Approximately 10% of cases are caused by nonasthmatic eosinophilic bronchitis. A history of nasal or sinus congestion, wheezing, or heartburn should direct subsequent evaluation and treatment, though these conditions frequently cause persistent cough in the absence of typical symptoms. Dyspnea at rest or with exertion is not commonly reported with persistent cough; dyspnea requires assessment for chronic lung disease, HF, anemia, PE, or pulmonary hypertension.

Bronchogenic carcinoma is suspected when cough is accompanied by unexplained weight loss, hemoptysis, and fevers with night sweats, particularly in persons with significant tobacco or occupational exposures (asbestos, radon, diesel exhaust, and metals). Secondhand smoke is a risk factor for small airway dysfunction in patients with chronic cough who do not smoke cigarettes. Persistent and chronic cough with excessive phlegm increases the likelihood of COPD, particularly if there is a history of cigarette smoking, or of bronchiectasis if accompanied by recurrent or complicated pneumonia; CXRs are helpful in diagnosis. Chronic cough with dry eyes may represent Sjögren syndrome. A chronic dry cough may be the first symptom of idiopathic pulmonary fibrosis.

B. Physical Examination

Pneumonia is suspected when acute cough is accompanied by vital sign abnormalities (tachycardia, tachypnea, fever). Findings suggestive of airspace consolidation (crackles, decreased breath sounds, fremitus, egophony) are specific predictors of community-acquired pneumonia but are present in a minority of cases. Purulent sputum is associated with bacterial infections in patients with structural lung disease (eg, COPD, cystic fibrosis), but it is a poor predictor of pneumonia in the otherwise healthy adult. Wheezing and rhonchi are frequent findings with acute bronchitis and do not indicate consolidation or adult-onset asthma in most cases.

Examination of patients with persistent cough should include a search for chronic sinusitis, which may contribute to postnasal drip syndrome or to asthma. Physical examination may help distinguish COPD from HF. In patients with cough and dyspnea, a normal match test (ability to blow out a match from 25 cm away) and maximum laryngeal height > 4 cm (measured from the sternal notch to the cricoid cartilage at end-expiration) substantially decrease the likelihood of COPD. Similarly, normal jugular venous pressure and no hepatojugular reflux decrease the likelihood of biventricular HF.

C. Diagnostic Studies

1. Acute cough—CXR should be considered for any adult with acute cough whose vital signs are abnormal or whose chest examination suggests pneumonia. The relationship between specific clinical findings and the probability of pneumonia is shown in Table 2–1. A large, multicenter randomized study found that elevated serum CRP (> 20 mg/dL) improves diagnostic accuracy of clinical prediction rules for pneumonia in adults with acute cough; serum procalcitonin had only marginal utility in outpatient management (in contrast with severe pneumonia requiring hospital care). A meta-analysis found that lung ultrasonography had better accuracy than CXR for diagnosing adult community-acquired pneumonia. In patients with dyspnea, pulse oximetry and peak flow help exclude hypoxemia or obstructive airway disease. However, a normal pulse oximetry value (eg, > 93%) does not rule out a significant alveolar–arterial (A–a) gradient when patients have effective respiratory compensation.

Table 2–1. Positive and negative likelihood ratios of history, physical examination, and laboratory findings in the diagnosis of pneumonia (range).

Finding	Positive LR	Negative LR
Medical history		
Fever	1.7–2.1	0.6–0.7
Chills	1.3–1.7	0.7–0.9
Physical examination		
Tachypnea (respiratory rate > 25 breaths/min)	1.5–3.4	0.8
Tachycardia (> 100 beats/min in two studies or > 120 beats/min in one study)	1.6–2.3	0.5–0.7
Hyperthermia (> 37.8°C)	1.4–4.4	0.6–0.8
Chest examination		
Dullness to percussion	2.2–4.3	0.8–0.9
Decreased breath sounds	2.3–2.5	0.6–0.8
Crackles	1.6–2.7	0.6–0.9
Rhonchi	1.4–1.5	0.8–0.9
Egophony	2.0–8.6	0.8–1.0
Laboratory findings		
Leukocytosis (> 11,000/mcL [11 × 10^9/L] in one study or ≥ 10,400/mcL [10.4 × 10^9/L] in another study)	1.9–3.7	0.3–0.6
CRP > 20 mg/mL	3.8 (2.3–5.9)	0.5 (0.4–0.6)
Procalcitonin > 0.25 ng/mL	7.6 (3.3–15.1)	0.9 (0.8–0.9)

2. Persistent and chronic cough—CXR is indicated when ACE inhibitor therapy–related and postinfectious cough are excluded. If pertussis is suspected, PCR testing should be performed on a nasopharyngeal swab or nasal wash specimen—although the ability to detect pertussis decreases as the duration of cough increases. When the chest film is normal, postnasal drip, asthma, or GERD are the most likely causes. The presence of typical symptoms of these conditions directs further evaluation or empiric therapy, though typical symptoms are often absent. Definitive tests for determining the presence of each are available (Table 2–2). However, empiric treatment with a

Table 2–2. Empiric therapy or definitive testing for persistent cough.

Suspected Condition	Step 1 (Empiric Therapy)	Step 2 (Definitive Testing)
Postnasal drip	Therapy for allergy or chronic sinusitis	Sinus CT scan; otolaryngologic referral
Asthma	β_2-agonist	Spirometry; consider methacholine challenge if normal
GERD	Lifestyle and diet modifications with or without PPIs	Esophageal pH monitoring

maximum-strength regimen for postnasal drip, asthma, or GERD for 2–4 weeks is one recommended approach since the presence of postnasal drip, asthma, or GERD does not mean they are the cause of the cough. Alternative approaches to identifying corticosteroid-responsive cough due to asthma include examining induced sputum for increased eosinophil counts (> 3%) or providing an empiric trial of prednisone, 30 mg daily orally for 2 weeks.

Nonasthmatic eosinophilic bronchitis can be diagnosed by finding eosinophils with induced sputum analysis after excluding other causes for chronic cough by clinical, radiologic, and lung function assessment. The cough usually responds well to inhaled corticosteroids.

Spirometry may help measure large airway obstruction (eg, foreign body or cancer) in patients who have persistent cough and wheezing and are not responding to asthma treatment. When empiric treatment trials are unsuccessful, additional evaluation with pH manometry, endoscopy, barium swallow, sinus CT, or HRCT of the chest may identify the cause.

Differential Diagnosis

A. Acute Cough

Acute cough may be a symptom of acute respiratory tract infection, COVID-19, asthma, allergic rhinitis, HF, and ACE inhibitor therapy, as well as less common causes.

When community influenza-like illness activity levels are high, clinical diagnosis of influenza (cough, fever, chills with or without sweats, myalgias, and acute onset) has a positive predictive value of approximately 70%; this usually obviates the need for rapid diagnostic tests to guide isolation and empiric treatment decisions. The CDC's FluView displays weekly updates of influenza surveillance data (https://www.cdc.gov/fluview/index.html).

B. Persistent and Chronic Cough

Causes of persistent cough include environmental exposures (cigarette smoke and e-cigarette use, air pollution), occupational exposures, pertussis, postnasal drip, asthma (including cough-variant asthma), GERD, COPD, chronic aspiration, bronchiectasis, nonasthmatic eosinophilic bronchitis, tuberculosis or other chronic infection, interstitial lung disease, bronchogenic carcinoma, and ACE inhibitor use. The prevalence of cough 1 year after hospitalization for COVID-19 is 2.5%. COPD is a common cause of persistent cough among patients older than 50 years who have smoked cigarettes. Persistent cough may also be due to somatic cough syndrome or tic cough, or vocal fold dysfunction. When empiric treatment trials fail, consider other causes of chronic cough such as obstructive sleep apnea, tonsillar or uvular enlargement, and environmental fungi (see Chapter 41).

C. Cough in the Immunocompromised Patient

The evaluation of cough in immunocompromised patients is the same as in immunocompetent patients but with an increased concern for tuberculosis (regardless of radiographic findings), fungi, cytomegalovirus, varicella, herpesvirus, and *Pneumocystis jirovecii*.

Treatment

A. Acute Cough

Treatment of acute cough should target the underlying etiology of the illness, the cough reflex, and any additional factors that exacerbate the cough. Cough duration is typically 1–3 weeks, yet patients frequently expect cough to last fewer than 10 days. An open randomized trial of adults with uncomplicated acute bronchitis (symptoms < 3 weeks) found no benefit compared with usual care with dextromethorphan 15 mg three times a day, ipratropium bromide inhaler 20 mcg 2 puffs three times a day, or 30 mg of honey three times a day for up to 14 days.

When influenza is diagnosed, oral oseltamivir or zanamivir or intravenous peramivir are equally effective (1 less day of illness) when initiated within 30–48 hours of illness onset; treatment is recommended regardless of illness duration when patients have severe, complicated, or progressive influenza and in patients requiring hospitalization. In *Chlamydophila*- or *Mycoplasma*-documented infection or outbreaks, first-line antibiotics include erythromycin or doxycycline; antibiotics do not otherwise improve cough severity or duration in patients with uncomplicated acute bronchitis. In patients with bronchitis and wheezing, inhaled β_2-agonists reduce severity and duration of cough. In patients with acute cough, treating the accompanying postnasal drip (with antihistamines, decongestants, saline nasal irrigation, or nasal corticosteroids) can be helpful. Two studies found codeine to be no more effective than placebo in reducing acute cough symptoms.

B. Persistent and Chronic Cough

Evaluation and management of persistent cough often require multiple visits and therapeutic trials, which frequently lead to frustration, anger, and anxiety.

When pertussis infection is suspected early in its course, treatment with a macrolide antibiotic (see Chapter 38) is appropriate to reduce organism shedding and transmission. When pertussis has lasted > 7–10 days, antibiotic treatment does not affect the duration of cough, which can last up to 6 months. Early identification, revaccination with Tdap, and treatment are encouraged for adult patients who work or live with persons at high risk for complications from pertussis (eg, pregnant women, infants younger than 1 year, and immunosuppressed individuals).

Table 2–2 outlines empiric treatments for persistent cough. There is no evidence to guide how long to continue treatment for persistent cough due to postnasal drip, asthma, or GERD. Studies have not found a consistent benefit of inhaled corticosteroid therapy in adults with persistent cough.

There is insufficient evidence to recommend routine pharmacologic treatments (antibiotics, bronchodilators, mucolytics) to relieve chronic cough due to stable chronic bronchitis.

The small percentage of patients with idiopathic chronic cough should be managed in consultation with an otolaryngologist or a pulmonologist; consider an HRCT scan of the lungs. Treatment options include lidocaine throat spray, nebulized lidocaine therapy, and morphine sulfate, 5–10 mg orally twice daily. Sensory dysfunction of the laryngeal branches of the vagus nerve may contribute to persistent cough syndromes and may explain the effectiveness of gabapentin and baclofen in patients with chronic cough.

Speech pathology therapy combined with pregabalin has some benefit in chronic refractory cough. In patients with cough hypersensitivity syndrome, therapy aimed at shifting the patient's attentional focus from internal stimuli to external focal points can be helpful. PPIs are not effective when used in isolation for treating chronic cough due to gastroesophageal reflux; most benefit appears to come from lifestyle modifications and weight reduction.

When to Refer

- Failure to control persistent or chronic cough following empiric treatment trials.
- Patients with recurrent symptoms should be referred to an otolaryngologist, pulmonologist, or gastroenterologist.

When to Admit

- Patients at high risk for tuberculosis for whom adherence to respiratory precautions is uncertain.
- Need for urgent bronchoscopy, such as suspected foreign body.
- Smoke or toxic fume inhalational injury.
- Gas exchange is impaired by cough.
- Patients at high risk for barotrauma (eg, recent pneumothorax).

DYSPNEA

ESSENTIAL INQUIRIES

- Fever, cough, risk of COVID-19 infection, and chest pain.
- Vital sign measurements; pulse oximetry.
- Cardiac and chest examination.
- CXR and ABG measurement in selected patients.

General Considerations

Dyspnea is a subjective experience or perception of uncomfortable breathing. The relationship between the level of dyspnea and the severity of underlying disease varies widely. Dyspnea can result from conditions that increase the mechanical effort of breathing (eg, asthma, COPD, respiratory muscle weakness, pneumothorax, and pleural effusion [which impact gas exchange, as well]), alveolar lung disease (pulmonary edema, pneumonia, alveolar proteinosis), conditions that produce compensatory tachypnea (eg, hypoxemia, acidosis), primary pulmonary vasculopathy (pulmonary hypertension), or psychogenic conditions.

Clinical Findings

A. Symptoms

The duration, severity, and periodicity of dyspnea influence the tempo of the clinical evaluation. Rapid onset or severe dyspnea without other clinical features should raise concern for PE, increased LVEDP, or pneumothorax.

PE should always be suspected when a patient with new dyspnea reports a recent history (previous 4 weeks) of prolonged immobilization or surgery, estrogen therapy, or other risk factors for DVT (eg, previous history of thromboembolism, cancer, obesity, lower extremity trauma), but also when the cause of dyspnea is not apparent. Silent MI, which occurs more frequently in women and persons with diabetes, can result in increased LVEDP, acute HF, and dyspnea. Spontaneous pneumothorax is usually accompanied by chest pain and occurs most often in thin, young men and those with underlying lung disease.

Accompanying symptoms provide clues to causes of dyspnea. When cough and fever are present, pulmonary disease (particularly infection) is the primary concern; myocarditis, pericarditis, and septic emboli can also present in this manner. Chest pain should be further characterized as acute or chronic, pleuritic or exertional. Although acute pleuritic chest pain is the rule in acute pericarditis and pneumothorax, most patients with pleuritic chest pain in the outpatient clinic have pleurisy due to acute viral respiratory tract infection. Periodic chest pain that precedes the onset of dyspnea suggests myocardial ischemia or PE. Most cases of dyspnea associated with wheezing are due to acute bronchitis; however, other causes include new-onset asthma, foreign body, and vocal fold dysfunction. Interstitial lung disease and pulmonary hypertension should be considered in patients with symptoms (or history) of connective tissue disease, or in those who have ECG findings typical of pulmonary hypertension (RVH with strain, P pulmonale) and elevated (NT-pro-)BNP. Pulmonary lymphangitic carcinomatosis should be considered if a patient has a malignancy, especially breast, lung, or gastric cancer.

When a patient reports prominent dyspnea with mild or no accompanying features, consider chronic PE and noncardiopulmonary causes of impaired oxygen delivery (anemia, methemoglobinemia, cyanide ingestion, carbon monoxide poisoning), metabolic acidosis, panic disorder, and neuromuscular disorders.

The diagnosis of HFpEF as the cause of dyspnea is challenging in the absence of overt congestion; the diagnosis may be made by echocardiography.

Patients who recover from their initial COVID-19 infection may have persistent dyspnea as part of the "long COVID" syndrome. Platypnea-orthodeoxia syndrome is characterized by dyspnea and hypoxemia on sitting or standing that improves in the recumbent position. Hyperthyroidism can cause dyspnea from increased ventilatory drive, respiratory muscle weakness, or pulmonary hypertension.

B. Physical Examination

A focused physical examination should include evaluation of the head and neck, chest, heart, and lower extremities. Visual inspection of the patient can suggest obstructive airway disease (pursed-lip breathing, use of accessory respiratory muscles, barrel-shaped chest), pneumothorax (asymmetric excursion), or metabolic acidosis (Kussmaul respirations). Patients with impending upper airway obstruction (eg, epiglottitis, foreign body) or severe asthma sometimes assume a tripod position. Focal wheezing suggests a foreign body or other bronchial obstruction.

Maximum laryngeal height (the distance between the top of the thyroid cartilage and the suprasternal notch at end-expiration) is a measure of hyperinflation. Obstructive airway disease is virtually nonexistent when a nonsmoking patient younger than age 45 years has a maximum laryngeal height > 4 cm; factors increasing the likelihood of obstructive airway disease (in patients without known obstructive airway disease) include patient history of > 40 pack-years smoking (adjusted LR+ 11.6; LR– 0.9), patient age 45 years or older (LR+ 1.4; LR– 0.5), and maximum laryngeal height ≤ 4 cm (LR+ 3.6; LR– 0.7). With all three of these factors present, the LR+ rises to 58.5, and the LR– falls to 0.3.

Absent breath sounds suggest a pneumothorax. An accentuated pulmonic component of the second heart sound (loud P_2) is a sign of pulmonary hypertension and PE.

Clinical predictors of increased LVEDP in dyspneic patients with no prior history of HF include tachycardia, systolic hypotension, jugular venous distention, hepatojugular reflux, bibasilar crackles, third heart sound, lower extremity edema, and chest film findings of pulmonary vascular redistribution or cardiomegaly. When none is present, there is a low probability (< 10%) of increased LVEDP, but when two or more are present, there is a high probability (> 90%) of increased LVEDP.

C. Diagnostic Studies

Causes of dyspnea that can be managed without CXR are few: anemia, carbon monoxide poisoning, and ingestions causing lactic acidosis and methemoglobinemia.

1. Chest radiography—The diagnosis of pneumonia should be confirmed by CXR in most patients, and elevated blood levels of procalcitonin or CRP can support the diagnosis of pneumonia in equivocal cases or in the presence of interstitial lung disease. Conversely, a low procalcitonin can help exclude pneumonia in dyspneic patients with HF. (See Table 2–1 for other diagnostic findings in pneumonia.)

CXR has a moderate sensitivity (53–75%) and a high specificity (86–96%) for new-onset HF (represented by redistribution of pulmonary venous circulation) and can help guide treatment of patients with other cardiac diseases. NT-proBNP can assist in diagnosing HF (see below). End-expiratory CXR enhances detection of small pneumothoraces. A normal CXR has substantial diagnostic value. When there is no physical examination evidence of COPD or HF and the CXR and ECG are normal, the major remaining causes of dyspnea include PE, *P jirovecii* infection (the initial radiograph may be normal in up to 25%), upper airway obstruction, foreign body, anemia, and metabolic acidosis. If a patient has tachycardia or hypoxemia but a normal CXR and ECG, then tests to exclude pulmonary emboli, anemia, or metabolic acidosis are warranted.

2. Point-of-care ultrasonography (POCUS)—When added to a standard diagnostic pathway, studies have confirmed that using POCUS leads to statistically significantly more correct diagnoses in patients with acute dyspnea than the standard diagnostic pathway alone. POCUS consistently improves the sensitivities and specificities of standard diagnostic pathways to detect HF, pneumonia, PE, pleural effusion, or pneumothorax.

3. High-resolution chest CT—This test is particularly useful in the evaluation of interstitial and alveolar lung disease. Helical ("spiral") CT is useful to diagnose PE since the images are high resolution and require only one breath hold by the patient. To minimize unnecessary testing and radiation exposure, however, the clinician should first employ a clinical decision rule for ruling out acute PE, such as the PERC (Pulmonary Embolism Rule-Out Criteria), the Wells score, the revised Geneva scores with fixed or adapted D-dimer thresholds, or the YEARS algorithm. It is appropriate to forego CT scanning in patients with low probability of pulmonary embolus when other causes of dyspnea are more likely (see Chapter 9).

4. Pulmonary function testing with diffusing capacity of the lungs for carbon monoxide—A low DLCO is associated with interstitial lung disease, emphysema, pulmonary vascular disease, chronic HF, and drug toxicity. A DLCO above the upper limit of normal (uncommon) may occur in individuals with asthma, obesity, or increased blood volume or hemoglobin (polycythemia, left-to-right cardiac shunt, pregnancy, pulmonary hemorrhage).

5. Cardiopulmonary exercise testing—A maximal exercise test with a gas exchange analysis that provides minute ventilation, heart rate, oxygen uptake, and carbon dioxide output may help determine the cause of exertional dyspnea, exercise intolerance, or exercise-induced hypoxemia.

6. Serum BNP and cardiac troponin—Laboratory findings suggesting increased LVEDP include elevated serum BNP or NT-proBNP levels. Acute decompensated HF is unlikely if NT-proBNP is < 300 pg/mL or BNP is < 100 pg/mL, and ECG is normal. High-sensitivity cardiac troponin T (hs-CTnT) may be a marker of HFpEF causing dyspnea.

7. Arterial blood gas—ABG measurement may be considered if clinical examination and routine diagnostic testing are equivocal. With two notable exceptions (carbon monoxide poisoning and cyanide toxicity), ABG measurement distinguishes increased mechanical effort causes of dyspnea (respiratory acidosis with or without hypoxemia) from compensatory tachypnea (respiratory alkalosis with or without hypoxemia or metabolic acidosis) and from psychogenic dyspnea (respiratory alkalosis). Carbon monoxide and cyanide impair oxygen delivery with minimal alterations in PO_2; percent carboxyhemoglobin identifies carbon monoxide toxicity. Cyanide poisoning should be considered when profound lactic acidosis follows exposure to burning vinyl (eg, theater fire or industrial accident). Suspected carbon monoxide poisoning or methemoglobinemia can also be confirmed with venous carboxyhemoglobin or methemoglobin levels. Venous blood gas testing is also an option for assessing acid-base and respiratory status by measuring venous pH and PCO_2 but is unable to provide information on oxygenation. To correlate with ABG values, venous pH is typically 0.03–0.05 units lower, and venous PCO_2 is typically 4–5 mm Hg higher than arterial samples.

8. Pulse oximetry—Because ABG testing is impractical in most outpatient settings, pulse oximetry is useful in the office evaluation of dyspnea. Oxygen saturation values above 96% almost always correspond with a PO_2 above 70 mm Hg, whereas values < 94% may represent clinically significant hypoxemia. Important exceptions to this rule include carbon monoxide toxicity, which leads to normal oxygen and methemoglobinemia, which results in an oxygen saturation of about 85% that fails to increase with supplemental oxygen. Pulse oximetry to detect occult hypoxia is less accurate in Black patients (OR, 2.57) compared with White patients. A delirious or obtunded patient with obstructive lung disease warrants immediate measurement of ABGs to exclude hypercapnia and the need for intubation, regardless of the oxygen saturation. If a patient reports dyspnea with exertion, but resting oximetry is normal, assessment of desaturation with ambulation (eg, a brisk walk around the clinic) can be useful for confirming impaired gas exchange. Persons with COVID-19 may have low oxygen saturation with minimal dyspnea and profound desaturation with minimal exertion.

For patients without known cardiac or pulmonary disease reporting dyspnea on exertion, spirometry, NT-proBNP, and CT imaging are the most informative tests.

Episodic dyspnea can be challenging if an evaluation cannot be performed during symptoms. Life-threatening causes include recurrent PE, myocardial ischemia, and reactive airway disease. When dyspnea follows an emotionally or physically stressful event, Takotsubo cardiomyopathy (stress cardiomyopathy or broken heart syndrome) should be considered. When associated with audible wheezing, vocal fold dysfunction should be considered, particularly in a young woman who does not respond to asthma therapy. Spirometry is helpful in further classifying patients with obstructive airway disease but is rarely needed in the initial or emergent evaluation of patients with acute dyspnea.

Differential Diagnosis

Urgent and emergent conditions causing acute dyspnea include pneumonia, COPD, asthma, pneumothorax, PE, cardiac disease (eg, HF, acute MI, valvular dysfunction, arrhythmia, intracardiac shunt), pleural effusion, COVID-19, diffuse alveolar hemorrhage, metabolic acidosis, cyanide toxicity, methemoglobinemia, and carbon monoxide poisoning. Chronic dyspnea may be caused by interstitial lung disease, pulmonary hypertension, or pulmonary alveolar proteinosis.

Treatment

Patients with hypoxemia should immediately be provided supplemental oxygen unless significant hypercapnia is strongly suspected pending ABG measurement. In managing acute respiratory failure, high-flow nasal oxygen may reduce all-cause mortality, rates of intubation, and hospital-acquired pneumonia compared with noninvasive ventilation. Dyspnea frequently occurs in patients nearing the end of life. Opioid therapy, anxiolytics, and corticosteroids can provide substantial relief independent of the severity of hypoxemia. Inhaled opioids are not effective.

Oxygen therapy is most beneficial to patients with significant hypoxemia ($PaO_2 < 55$ mm Hg) (see Chapter 5). In patients with severe COPD and hypoxemia, oxygen therapy improves exercise performance and mortality. Pulmonary rehabilitation programs are another therapeutic option for patients with moderate to severe COPD or interstitial pulmonary fibrosis. Noninvasive ventilation may be considered for patients with dyspnea caused by an acute COPD exacerbation.

When to Refer

- Following acute stabilization, patients with advanced COPD should be referred to a pulmonologist, and patients with HF or valvular heart disease should be referred to a cardiologist.
- Cyanide toxicity or carbon monoxide poisoning should be managed in conjunction with a toxicologist.
- Lung transplantation can be considered for patients with advanced interstitial lung disease.

When to Admit

- Impaired gas exchange from any cause or high risk of PE pending definitive diagnosis.
- Suspected cyanide toxicity or carbon monoxide poisoning.

HEMOPTYSIS

ESSENTIAL INQUIRIES

- Fever, cough, and other symptoms of lower respiratory tract infection.
- Smoking history.
- Nasopharyngeal or GI bleeding.
- CXR and CBC (and, in some cases, INR).

General Considerations

Hemoptysis is the expectoration of blood that originates below the vocal folds. It is commonly classified as trivial, mild, or massive—the latter defined as > 200–600 mL (about 1–2 cups) in 24 hours. Massive hemoptysis can be usefully defined as any amount that is hemodynamically significant or threatens ventilation. Its in-hospital mortality was 6.5% in one study. The initial goal of management of massive hemoptysis is therapeutic, not diagnostic.

The causes of hemoptysis can be classified anatomically.

Upper airway bleeding may be from trauma, neoplasm, or foreign body.

Lower airway hemoptysis may arise from COPD, bronchiectasis, bronchial Dieulafoy disease, or bronchogenic carcinoma.

Pulmonary vasculature can be the source of hemoptysis in LV failure, mitral stenosis, PE, pulmonary arterial hypertension, telangiectasias, arteriovenous malformations, and multiple pulmonary artery aneurysms. Diffuse alveolar hemorrhage—manifested by alveolar infiltrates on CXR—is due to small vessel bleeding usually caused by autoimmune or hemostatic disorders, or rarely precipitated by hypertensive emergency, the antiplatelet medication tirofiban, anticoagulant therapy and infection.

Systemic circulation can be the source of hemoptysis when there is intralobar pulmonary sequestration or aortobronchial fistula.

Pulmonary parenchyma diseases due to pneumonia, fungal infections, inhalation of crack cocaine, granulomatosis with polyangiitis, or Takayasu arteritis with pulmonary arteritis can cause hemoptysis. Hemoptysis can also be caused by the parasitic diseases paragonimiasis (most common cause worldwide) and human echinococcosis (also called hydatid disease).

Most cases of hemoptysis in the outpatient setting are due to infection (eg, acute or chronic bronchitis, pneumonia, tuberculosis, infection with *Mycobacterium avium* complex, aspergillosis). Hemoptysis due to lung cancer increases with age, causing up to 20% of cases among older adults. Pulmonary venous hypertension (eg, mitral stenosis, PE) causes hemoptysis in < 10% of cases. Most cases of hemoptysis that have no visible cause on CT scan or bronchoscopy will resolve within 6 months without treatment, with the notable exception of patients at high risk for lung cancer (patients who smoke cigarettes and are older than 40 years). Iatrogenic hemorrhage may follow transbronchial lung biopsies, anticoagulation, or pulmonary artery rupture due to distal placement of a balloon-tipped catheter. Obstructive sleep apnea with elevated pulmonary arterial pressure may be a risk factor for hemoptysis. Amyloidosis of the lung can cause hemoptysis, as can endometriosis. No cause is identified in up to 15–30% of cases.

Clinical Findings

A. Symptoms

Blood-tinged sputum in the setting of an upper respiratory tract infection in an otherwise healthy, young (age under 40 years) nonsmoker does not warrant an extensive diagnostic evaluation if the hemoptysis subsides with resolution of the infection. However, hemoptysis is frequently a sign of serious disease, especially in patients with a high prior probability of underlying pulmonary pathology. Hemoptysis is the only symptom found to be a specific predictor of lung cancer. There is no value in distinguishing blood-streaked sputum and cough productive of blood during evaluation; the goal of the history is to identify patients at risk for one of the disorders listed earlier. Pertinent features include duration of symptoms, presence of respiratory infection, and past or current tobacco use. Nonpulmonary sources of hemorrhage—from the sinuses or the GI tract—must be excluded.

B. Physical Examination

Elevated pulse, hypotension, and decreased oxygen saturation suggest large-volume hemorrhage that warrants emergent evaluation and stabilization. The nares and oropharynx should be carefully inspected to identify a potential upper airway source of bleeding. Chest and cardiac examination may reveal evidence of HF or mitral stenosis.

C. Diagnostic Studies

Diagnostic evaluation should include a CXR and CBC. Kidney function tests, UA, and coagulation studies are appropriate in specific circumstances. Hematuria that accompanies hemoptysis may be a clue to anti-glomerular basement membrane antibody disease or vasculitis. Flexible bronchoscopy reveals endobronchial cancer in 3–6% of patients with hemoptysis who have a normal (non-lateralizing) CXR. Nearly all these patients are cigarette smokers over the age of 40, and most will have had symptoms for > 1 week. HRCT of the chest complements bronchoscopy; it can visualize unsuspected bronchiectasis and arteriovenous malformations and will show central endobronchial cancers in many cases. It is the test of choice for suspected small peripheral malignancies. Helical pulmonary CT angiography is the initial test of choice for evaluating patients with suspected PE, although caution should be taken to avoid large contrast loads with even mild CKD (serum creatinine > 2.0 g/dL or rapidly rising creatinine in normal range). Helical CT scanning can be avoided in patients who are at “unlikely” risk for PE using the Wells score or PERC (Pulmonary Embolism Rule-Out Criteria) rule for PE and the sensitive D-dimer test (see Chapter 9). Echocardiography may reveal evidence of HF or mitral stenosis. Multidetector CT angiography is the study of choice to determine the location, etiology, and mechanism of the bleeding.

Treatment

Mild hemoptysis management consists of identifying and treating the specific cause. One double-blind RCT compared treatment with inhalations of tranexamic acid (an antifibrinolytic drug) versus placebo (normal saline) in patients hospitalized with mild hemoptysis (< 200 mL of expectorated blood per 24 hours). The study findings included faster resolution of bleeding, shorter length of hospital stay, and fewer invasive procedures with tranexamic acid treatment. Decreased in-hospital mortality was observed in a separate randomized trial (11.5% mortality rate in control group versus 9.0% in patients who received tranexamic acid).

Massive hemoptysis is life-threatening. The airway should be protected with endotracheal intubation, ventilation ensured, and effective circulation maintained. If the location of the bleeding site is known, the patient should be placed in the decubitus position with the involved lung dependent. Uncontrollable hemorrhage warrants rigid bronchoscopy and surgical consultation. In stable patients, flexible bronchoscopy may localize the bleeding site, and angiography can embolize the involved bronchial arteries. Embolization is effective initially in 85% of cases, although rebleeding may occur in up to 20% of patients during the following year. The anterior spinal artery arises from the bronchial artery in up to 5% of people, and paraplegia may result if it is inadvertently cannulated and embolized.

When to Refer

- Refer to a pulmonologist when bronchoscopy of the lower respiratory tract is needed.
- Refer to an otolaryngologist when an upper respiratory tract bleeding source is identified.
- Refer to a hematologist when severe coagulopathy complicates management.

When to Admit

- To stabilize bleeding in patients at risk for or experiencing massive hemoptysis.
- To correct disordered coagulation (using clotting factors or platelets, or both) or to reverse anticoagulation.
- To stabilize gas exchange.

CHEST PAIN

ESSENTIAL INQUIRIES

- Pain onset, character, location/size, duration, periodicity, and exacerbators; shortness of breath.
- Vital signs; chest and cardiac examinations.
- ECG and biomarkers of myocardial necrosis in selected patients.

General Considerations

Chest pain (or chest discomfort) can occur as a result of cardiovascular, pulmonary, pleural, or musculoskeletal disease; esophageal or other GI disorders; herpes zoster; cocaine use; or anxiety states. The frequency and distribution of life-threatening causes of chest pain, such as ACS, pericarditis, aortic dissection, vasospastic angina, PE, pneumonia, and esophageal perforation, vary substantially between clinical settings.

SLE, rheumatoid arthritis, reduced eGFR, and HIV infection are conditions that confer a strong risk of CAD. Precocious ACS (occurring in patients aged 35 years or younger) may represent acute thrombosis independent of underlying atherosclerotic disease. Risk factors for precocious ACS are obesity, familial hypercholesterolemia, and cigarette use.

Although ACS presents with a broader range of symptoms in women than men, typical chest pain characteristics of acute MI do not differ in frequency or strength between men and women.

Because PE can present with a variety of symptoms, consideration of the diagnosis and rigorous risk factor assessment for VTE is critical. VTE risk factors include cancer, trauma, recent surgery, prolonged immobilization, pregnancy, oral contraceptives, family history, HF, COPD, and prior history of VTE. Sickle cell anemia can cause acute chest syndrome, often with chest pain, fever, and cough.

Clinical Findings

A. Symptoms

Myocardial ischemia is usually described as a dull, aching sensation of “pressure,” “tightness,” “squeezing,” or “gas,” rather than as sharp or spasmodic. Chest discomfort at rest is the most common presenting symptom of ACS, reported by 79% of men and 74% of women. Pain reaching maximum intensity in seconds is uncommon. Ischemic symptoms usually subside within 5–20 minutes but may last longer. Progressive symptoms or symptoms at rest may represent unstable angina. Up to one-third of patients with acute MI do not report chest pain. In patients who have a STEMI, chest pain is present in > 90% of persons under age 65 but in only 57% of those over age 85.

Continuous chest pain lasting 24 hours or longer is unlikely to be due to an acute MI (LR, 0.15). However, chest pain lasting 1 minute or less does not exclude MI (LR, 0.95). When present, pain due to myocardial ischemia is commonly accompanied by a sense of anxiety or uneasiness. The location is usually retrosternal or left precordial, although a significant number of patients will report pain in the right shoulder, right arm and back. Because the heart lacks somatic innervation, precise localization of pain due to cardiac ischemia is difficult; the pain is commonly referred to the throat, lower jaw, shoulders, inner arms, upper abdomen, or back. Ischemic pain may be precipitated or exacerbated by exertion, cold temperature, meals, stress, or combinations of these factors and is usually relieved by rest. However, many episodes do not conform to these patterns, and a broader range of symptoms of ACS are more common in women, older adults, and persons with diabetes mellitus. Other symptoms that are associated with ACS include shortness of breath; dizziness; a feeling of impending doom; and vagal symptoms, such as nausea and diaphoresis. In older persons, unusual or unexplained fatigue is a common presenting symptom of ACS.

The presenting symptoms of acute MI in patients aged 18–55 (average age, 47) differ in men and women. The VIRGO study of this younger cohort hospitalized for MI found that women are more likely than men to present with three or more associated symptoms (eg, epigastric symptoms; palpitations; and pain or discomfort in the jaw, neck, arms, or between the shoulder blades; 61.9% for women versus 54.8% for men). In adjusted analyses, women with an acute STEMI were more likely than men to present without chest pain (OR, 1.51). In comparison with men, women were more likely to perceive symptoms as stress/anxiety (20.9% versus 11.8%) but less likely to attribute symptoms to muscle pain (15.4% versus 21.2%).

One analysis found the following clinical features to be associated with acute MI: chest pain that radiates to the left, right, or both arms (LR, 2.3); diaphoresis (LR, 2.0); nausea and vomiting (LR, 1.9); third heart sound (LR, 3.2); systolic blood pressure 80 mm Hg or less (LR, 3.1); pulmonary crackles (LR, 2.1); any ST-segment elevation ≥ 1 mm (LR, 11.2); any ST depression (LR, 3.2); any Q wave (LR, 3.9); any conduction defect (LR, 2.7); and new conduction defect (LR, 6.3).

A meta-analysis reported the clinical features and risk factors with highest positive LRs for ACS were prior abnormal stress test (specificity, 96%; LR, 3.1), peripheral arterial disease (specificity, 97%; LR, 2.7), and pain radiation to both arms (specificity, 96%; LR, 2.6), as well as the following ECG findings: ST-segment depression (specificity, 95%; LR, 5.3) and any evidence of ischemia (specificity, 91%; LR, 3.6). Risk scores derived from both the HEART trial (https://www.mdcalc.com/heart-score-major-cardiac-events) and TIMI trial (https://www.mdcalc.com/timi-risk-score-ua-nstemi#use-cases) performed well in detecting ACS (LR, 13 for HEART score of 7–10, and LR, 6.8 for TIMI score of 5–7).

Hypertrophy of either ventricle or aortic stenosis may give rise to chest pain with less typical features. Pericarditis produces pain that may be greater when supine than upright and increases with breathing, coughing, or swallowing. Pleuritic chest pain is usually not ischemic, and pain on palpation may indicate a musculoskeletal cause. Aortic dissection classically produces an abrupt onset of intense tearing pain that often radiates to the back; however, this classic presentation occurs in a small proportion of cases. Anterior aortic dissection can also lead to myocardial or cerebrovascular ischemia.

In PE, chest pain is present in about 75% of cases. The chief objective in evaluating patients with suspected PE is to assess the clinical risk for VTE based on medical history and associated symptoms and signs (see above and Chapter 9). Rupture of the thoracic esophagus iatrogenically or from vomiting is another cause of chest pain.

B. Physical Examination

Findings on physical examination can occasionally yield important clues to the underlying cause of chest pain; however, a normal physical examination should never be used as the sole basis for ruling out most causes of chest pain, particularly ACS and aortic dissection. Vital signs (including pulse oximetry) and cardiopulmonary examination are the first steps for assessing the urgency and tempo of the subsequent examination and diagnostic workup. Although chest pain that is reproducible or worsened with palpation strongly suggests a musculoskeletal cause, up to 15% of patients with ACS will have reproducible chest wall tenderness. In one study, reproducible chest pain had a negative predictive value of 98%. A prominent xyphoid process painful to palpation may indicate xiphodynia. Slipping rib syndrome should be suspected if the chest pain is reproduced by the examiner pulling superiorly and anteriorly under the costal margin with their fingers. Pointing to the location of the pain with one finger has been shown to be highly correlated with nonischemic chest pain.

Aortic dissection can result in differential blood pressures between arms (> 20 mm Hg), pulse amplitude deficits, and new diastolic murmurs. Although hypertension is considered the rule in patients with aortic dissection, systolic blood pressure < 100 mm Hg is present in up to 25% of patients.

A cardiac friction rub represents pericarditis until proven otherwise. It can best be heard with the patient sitting forward at end-expiration. Tamponade should be excluded in all patients with a clinical diagnosis of pericarditis by assessing pulsus paradoxus (at least a 10 mm Hg decrease in systolic blood pressure during inspiration) and inspection of jugular venous pulsations. Subcutaneous emphysema is common following cervical esophageal perforation but present in only about one-third of thoracic perforations (ie, those most commonly presenting with chest pain).

The absence of abnormal physical examination findings in patients with suspected PE usually serves to *increase* its likelihood, although a normal physical examination is also compatible with the more common conditions of panic/anxiety disorder and musculoskeletal disease.

C. Diagnostic Studies

1. ECG—Unless a competing diagnosis can be confirmed, an ECG is warranted in the initial evaluation of most patients with acute chest pain to help exclude ACS. When compared with White patients, Black patients who came to the emergency department with chest pain were less likely to have an ECG ordered (adjusted OR, 0.82). In a study of 11 emergency departments in Italy, 67% of patients with confirmed ACS had new-onset alterations of the ECG (compared with only 6.2% among patients without ACS). ST-segment elevation is the ECG finding that is the strongest predictor of acute MI; however, up to 20% of patients with ACS can have a normal ECG.

In the emergency department, patients with suspected ACS can be safely removed from cardiac monitoring if pain-free at initial clinician assessment and have a normal or nonspecific ECG. This decision rule had 100% sensitivity for serious arrhythmia. Clinically stable patients with CVD risk factors, normal ECG, normal cardiac biomarkers, and no alternative diagnoses (such as typical GERD or costochondritis) should be followed up with an exercise stress test, ideally within 24–48 hours, that includes perfusion imaging. However, > 25% of patients with stable chest pain referred for noninvasive testing will have normal coronary arteries and no long-term clinical events. The ECG can also provide evidence for alternative diagnoses, such as pericarditis and PE.

2. Troponins—Diagnostic protocols using a single high-sensitivity troponin assay combined with a standardized clinical assessment are an efficient strategy to rapidly determine whether patients with chest pain are at low risk and may be discharged from the emergency department. A study of the modified HEART score using a single blood draw had a sensitivity of 100% for 30-day major adverse cardiac events if the results exceeded the threshold of either high-sensitivity troponin (3.9 ng/L), high-sensitivity troponin I (0.9 ng/L), or conventional troponin I (0.0 ng/L) at presentation.

Point-of-care conventional troponin testing (cut point of 0.080 ng/mL) for acute MI during ambulance transport to the emergency department has good specificity and positive predictive value (99.2% and 85.7%) but poor sensitivity (26.5%).

3. Risk scores—Six established risk scores for predicting acute MI are (1) the revised Goldman Risk Score, (2) TIMI Risk Score, (3) Global Registry of Acute Cardiac Events Risk Score, (4) HEART Risk Score, (5) Vancouver Chest Pain Rule, and (6) the European Society of Cardiology (ESC) 0/1, 0/2, 0/3-h algorithm. A study comparing these risk scores (not including the ESC algorithm) for predicting acute MI within 30 days reported a sensitivity of 98% (which correlates with a negative predictive value of ≥ 99.5%) if patients had a TIMI score of 1 or less with normal high-sensitivity troponin T, modified Goldman score of 1 or less with normal high-sensitivity troponin T, TIMI score of 0 with normal high-sensitivity troponin T, or HEART score of 3 or less with normal high-sensitivity troponin I. In Black patients with average cardiovascular risk, HEART score is a better predictive tool for 6-week major adverse cardiac events when compared to TIMI score. Six-week major adverse cardiac events among patients with a low-risk HEART score (0–3) is 0.9–1.7%. However, the HEART score performs less accurately in stratifying risk from cocaine-associated chest pain and does not eliminate the potential for gender bias. A study found that female patients with high HEART scores were admitted to the hospital from the emergency room at lower rates than male patients with similar HEART scores, although the clinical decision pathway did not result in sex-based differences in risk stratification or noninvasive testing.

4. Chest radiography—CXR is often useful in evaluating chest pain and is always indicated when cough or shortness of breath accompanies chest pain. Findings of pneumomediastinum or new pleural effusion are consistent with esophageal perforation.

5. Stress echocardiography—Stress echocardiography is useful in risk stratifying patients with chest pain, even among those with significant obesity. Patients who arrive at the emergency department with chest pain of intermediate probability for ACS without electrocardiographic or biomarker evidence of an MI can be safely discharged from an observation unit after stress echocardiography.

6. Coronary CT angiography—Sixty-four–slice coronary CT angiography is an alternative to stress testing in the emergency department for detecting ACS among patients with normal or nonspecific ECG and normal biomarkers. A meta-analysis of nine studies found CT angiography had an estimated sensitivity of 95% for ACS and specificity of 87%, yielding a negative LR of 0.06 and a positive LR of 7.4.

7. Functional testing—Exercise ECG, nuclear stress testing, or stress echocardiography appear to be the best initial noninvasive tests in symptomatic patients with suspected CAD.

A minimal-risk model for discharging patients with suspected ACS for whom noninvasive testing may be deferred was developed by the PROMISE investigators, and includes 10 clinical variables that correlate with normal coronary CT angiography results and no clinical events: (1) younger age (mean 57.5); (2) female sex; (3) racial or ethnic minority; (4–6) no history of hypertension, diabetes, or dyslipidemia; (7) no family history of premature CAD; (8) never smoked cigarettes; (9) symptoms unrelated to physical or mental stress; and (10) higher HDL cholesterol level.

In the PROMISE trial, women had higher rates of normal noninvasive testing compared with men, but women with abnormalities on such testing were less likely to be referred for catheterization or to receive statin therapy.

In the evaluation of PE as the cause of chest pain, diagnostic test decisions and results must be interpreted in the context of the clinical likelihood of VTE. A negative D-dimer test helps exclude PE in patients with low clinical probability of VTE (3-month incidence, 0.5%); however, the 3-month risk of VTE among patients with intermediate and high risk of VTE is sufficiently high in the setting of a negative D-dimer test (3.5% and 21.4%, respectively) to warrant further imaging given the life-threatening nature of an untreated PE. CT angiography has replaced ventilation-perfusion scanning as the preferred initial diagnostic test, having approximately 90–95% sensitivity and 95% specificity for detecting PE (compared with pulmonary angiography). However, for patients with high clinical probability of VTE, lower extremity ultrasound or pulmonary angiogram may be indicated even with a normal helical CT.

Panic disorder is a common cause of chest pain, accounting for up to 25% of cases that present to emergency departments and a higher proportion of cases presenting in primary care office practices. Features that correlate with an increased likelihood of panic disorder include absence of CAD, atypical quality of chest pain, female sex, younger age, and a high level of self-reported anxiety. Depression is associated with recurrent chest pain with or without CAD (OR, 2.11).

Treatment

Treatment of chest pain should be guided by the underlying etiology. The term "noncardiac chest pain" is used when a diagnosis remains elusive after an extensive workup. Almost half of patients with noncardiac chest pain reported symptom improvement with high-dose PPI therapy. Relief of constipation may be therapeutic in PPI refractory noncardiac chest pain. A meta-analysis of 15 trials suggested modest to moderate benefit for psychological (especially cognitive-behavioral) interventions. It is unclear whether tricyclic or SSRI antidepressants have benefit in noncardiac chest pain. Hypnotherapy may offer some benefit.

When to Refer

- Refer patients with angina that is poorly controlled using maximal medical therapy to a cardiologist.
- Refer patients with poorly controlled, noncardiac chest pain to a pain specialist.
- Refer patients with sickle cell anemia to a hematologist.

When to Admit

- Failure to adequately exclude life-threatening causes of chest pain, particularly MI, dissecting aortic aneurysm, PE, and esophageal rupture.
- Patients with high risk of complications from PE, or when PE is likely despite negative spiral CT.
- TIMI score of 1 or more, HEART score > 3, abnormal ECG, and abnormal 0- and 2-hour troponin tests.
- Pain control for rib fracture that impairs gas exchange.

PALPITATIONS

ESSENTIAL INQUIRIES

- Forceful, rapid, or irregular beating of the heart.
- Rate, duration, and degree of heartbeat regularity; age at first episode.
- Factors that precipitate or terminate episodes.
- Lightheadedness or syncope; neck pounding.
- Chest pain; history of MI or structural heart disease.

General Considerations

Palpitations are defined as an unpleasant awareness of the forceful, rapid, or irregular beating of the heart. Palpitations are the reason that approximately 16% of patients with a cardiac symptom visit an outpatient clinic. Palpitations are experienced in 3.3% to 11.5% of pregnancies. Palpitations represent 5.8 of every 1000 emergency department visits, with an admission rate of 24.6%. While palpitations are usually benign, they are occasionally the symptom of a life-threatening arrhythmia. To avoid missing a dangerous cause of the patient's symptoms, clinicians sometimes pursue costly and invasive testing when a conservative diagnostic evaluation is sufficient. The converse is also true.

Table 2–3 lists history, physical examination, and ECG findings suggesting a cardiovascular cause for the palpitations.

When assessing palpitations in an acute care setting, the clinician must ascertain whether the symptoms represent (1) significant CVD, (2) a cardiac manifestation of a systemic disease such as thyrotoxicosis, (3) an arrhythmia that

Table 2–3. Palpitations: Patients at high risk for a cardiovascular cause.

Historical risk factors
Family history of significant arrhythmias
Personal or family history of syncope or resuscitated from sudden death
History of MI
Palpitations that occur during sleep
Anatomic abnormalities
Structural heart disease such as dilated or hypertrophic cardiomyopathies
Valvular disease (stenotic or regurgitant)
ECG findings
Long QT syndrome
Bradycardia
Second- or third-degree heart block
Sustained ventricular arrhythmias

is minor and transient, or (4) a benign somatic symptom that is amplified by the patient's underlying psychological state.

Etiology

Patients with palpitations who come to an emergency department instead of a medical clinic are more likely to have a cardiac cause (47% versus 21%), whereas psychogenic causes are more common among those who seek care in office practices (45% versus 27%). In a study of patients who went to a university medical clinic with the chief complaint of palpitations, the causes were cardiac in 43%, psychogenic in 31%, and miscellaneous in 10%.

Cardiac arrhythmias that can manifest as palpitations include sinus bradycardia; atrial fibrillation or flutter; sinus, supraventricular, and ventricular tachycardia; premature ventricular and atrial contractions; sick sinus syndrome; and advanced atrioventricular block.

Structural cardiac conditions that lead to palpitations due to cardiac arrhythmias include valvular heart diseases, such as aortic regurgitation or stenosis, atrial or ventricular septal defect, cardiomyopathy, congenital heart disease, pericarditis, arrhythmogenic RV cardiomyopathy, atrial myxoma, and rarely, left atrial appendage aneurysm, and primary cardiac angiosarcoma. Mitral valve prolapse is not associated with arrhythmic events, but ventricular arrhythmias are frequent in mitral annulus disjunction.

Pericardial or myocardial infection with SARS-CoV-2 and other viruses, tuberculosis, and *Trypanosoma cruzi* (Chagas disease) can cause palpitations.

The most common psychogenic causes of palpitations are anxiety and panic disorder. The release of catecholamines during a significant stress or panic attack can trigger an arrhythmia. Asking a single question, "Have you experienced brief periods, for seconds or minutes, of an overwhelming panic or terror that was accompanied by racing heartbeats, shortness of breath, or dizziness?" can help identify patients with panic disorder.

Other causes of palpitations include fever, dehydration, hypoglycemia, hyperkalemia, anemia, thyrotoxicosis, mastocytosis, postural orthostatic tachycardia syndrome, and pheochromocytoma. Drugs (eg, cocaine, alcohol, caffeine, pseudoephedrine, cannabis, and illicit ephedra), prescription medications and drugs that prolong the QT interval (eg, digoxin, amitriptyline, erythromycin, methylphenidate), class 1 antiarrhythmics, dihydropyridine calcium channel blockers, acetylcholinesterase inhibitors, phenothiazines, theophylline, chemotherapeutic agents, and β-agonists can precipitate palpitations.

Clinical Findings

A. Symptoms

Guiding patients through a careful description of their palpitations may indicate a mechanism and narrow the differential diagnosis. Pertinent questions include the age at first episode; precipitants; and rate, duration, and degree of regularity of the heartbeat during the subjective palpitations. Palpitations lasting < 5 minutes and a family history of panic disorder reduce the likelihood of an arrhythmic cause (LR+ = 0.38 and LR+ = 0.26, respectively). To better understand the symptom, ask patients to "tap out" the rhythm with their fingers. The circumstances associated with onset and termination can also help determine the cause. Palpitations that start and stop abruptly suggest supraventricular or ventricular tachycardias. Termination of palpitations using vagal maneuvers (eg, Valsalva maneuver or forced coughing) suggests supraventricular tachycardia.

Three common descriptions of palpitations are (1) "flip-flopping" (or "stop and start"), often caused by premature contraction of the atrium or ventricle, with the perceived "stop" from the pause following the contraction, and the "start" from the subsequent forceful contraction; (2) rapid "fluttering in the chest," with regular "fluttering" suggesting supraventricular or ventricular arrhythmias (including sinus tachycardia) and irregular "fluttering" suggesting atrial fibrillation, atrial flutter, or tachycardia with variable block; and (3) "pounding in the neck" or neck pulsations, often due to "cannon" A waves in the jugular venous pulsations that occur when the right atrium contracts against a closed tricuspid valve (common with premature ventricular contractions and atrial ventricular dissociation).

Palpitations associated with chest pain suggest ischemic heart disease, or if the chest pain is relieved by leaning forward, pericardial disease. Palpitations with lightheadedness, presyncope, or syncope suggest hypotension and may signify a life-threatening cardiac arrhythmia. Palpitations that occur regularly with exertion suggest silent ischemia, a rate-dependent bypass tract, hypertrophic cardiomyopathy, or arrhythmogenic RV cardiomyopathy. If a benign etiology cannot be ascertained at the initial visit, ambulatory monitoring or prolonged inpatient cardiac monitoring might be warranted.

Noncardiac symptoms should be elicited since palpitations may be caused by a normal heart responding to a metabolic or inflammatory condition. Weight loss suggests hyperthyroidism. Palpitations can be precipitated by vomiting or diarrhea causing electrolyte disorders and hypovolemia. Hyperventilation, hand tingling, and nervousness are common when anxiety or panic disorder is the cause of the palpitations. Palpitations associated with flushing, episodic hypertension, headaches, anxiety, and diaphoresis may be caused by a pheochromocytoma or paraganglioma.

A family history of palpitations or sudden death suggests an inherited etiology such as long QT syndrome or Brugada syndrome. Chagas disease may cause palpitations and acute myocarditis. Younger patients should be asked about consumption of "energy drinks." Dual use of cigarettes and e-cigarettes may cause palpitations.

B. Physical Examination

Cardiovascular examination can find abnormalities that increase the likelihood of specific cardiac arrhythmias. The midsystolic click of mitral valve prolapse suggests the diagnosis of a supraventricular arrhythmia. The harsh holosystolic murmur of hypertrophic cardiomyopathy, which occurs along the left sternal border and increases with the Valsalva maneuver, suggests atrial fibrillation or ventricular tachycardia. A crescendo mid-diastolic murmur may be caused by an atrial myxoma. The presence of dilated cardiomyopathy, suggested by a displaced and enlarged cardiac point-of-maximal impulse, increases the likelihood of ventricular tachycardia and atrial fibrillation. In patients with chronic atrial fibrillation, in-office exercise (eg, a brisk walk in the hallway) may reveal an intermittent accelerated ventricular response. The clinician should look for signs of hyperthyroidism (eg, tremulousness, brisk deep tendon reflexes, or fine hand tremor) or signs of stimulant drug use (eg, dilated pupils or skin or nasal septal perforations). Visible neck pulsations (LR+, 2.68) in association with palpitations increase the likelihood of atrioventricular nodal reentry tachycardia.

C. Diagnostic Studies

1. ECG—A 12-lead ECG should be performed on all patients reporting palpitations; however, a specific arrhythmia will not be detected in most instances. Evidence of prior MI on ECG (eg, Q waves) increases the patient's risk of nonsustained or sustained ventricular tachycardia. Ventricular preexcitation (Wolff-Parkinson-White syndrome) is suggested by a short PR interval (< 0.20 ms) and δ-waves (upsloping PR segments). Left atrial enlargement (a terminal P-wave force in V1 more negative than 0.04 ms and notching in lead II) reflects an increased risk of atrial fibrillation. A prolonged QT interval and abnormal T-wave morphology suggest the long QT syndrome and an increased risk of ventricular tachycardia.

2. Monitoring devices—For high-risk patients (Table 2–3), further diagnostic studies are warranted. A stepwise approach has been suggested—starting with ambulatory monitoring devices (ambulatory ECG monitoring if the palpitations are expected to occur within the subsequent 72-hour period, event monitoring [see Zio Patch, below] if less frequent). An implantable loop recorder can be used for extended monitoring if clinical suspicion is high and symptom to rhythm correlation cannot be otherwise established. Although the use of an implantable loop recorder has traditionally been reserved for patients experiencing syncope, the diagnostic yield of this device may be cost-effective for a broader range of patients. In patients with recurrent unexplained palpitations, a single-lead, lightweight, continuously recording ambulatory adhesive patch monitor (Zio Patch) worn for 14–21 days increases diagnostic yield while reducing the cost of diagnosis. Inpatient continuous monitoring is indicated if serious arrhythmias are strongly suspected despite normal findings on the ambulatory monitoring; invasive electrophysiologic testing should be done if the ambulatory or inpatient monitor records a worrisome arrhythmia.

An ambulatory cardiac monitoring or a signal-averaged ECG is an appropriate next step to help exclude ventricular tachycardia in patients with a prior MI. ECG exercise testing is appropriate in patients with suspected CAD and those with palpitations with physical exertion. Echocardiography is useful when physical examination or ECG suggests structural abnormalities or decreased ventricular function.

▶ Treatment

After ambulatory monitoring, most patients with palpitations are found to have benign atrial or ventricular ectopy or nonsustained ventricular tachycardia. In patients with structurally normal hearts, these arrhythmias are not associated with adverse outcomes. Abstention from caffeine and tobacco may help. Often, reassurance suffices. If not, or in symptomatic patients, a trial of a β-blocker may be prescribed. A three-session course of cognitive-behavioral therapy that includes some physical activity has proven effective for patients with benign palpitations with or without chest pain. For treatment of specific atrial or ventricular arrhythmias, see Chapter 12.

▶ When to Refer

- For electrophysiologic studies.
- For advice regarding treatment of atrial or ventricular arrhythmias.

▶ When to Admit

- Palpitations associated with syncope or near-syncope, particularly when the patient is 75 years or older and has an abnormal ECG, hematocrit < 30%, shortness of breath, respiratory rate higher than 24/min, or a history of HF.
- Patients with risk factors for a serious arrhythmia.

LOWER EXTREMITY EDEMA

ESSENTIAL INQUIRIES

- History of VTE.
- Symmetry of swelling.
- Pain.
- Change with dependence.
- Hyperpigmentation, stasis dermatitis, lipodermatosclerosis, ulceration.

General Considerations

Acute and chronic lower extremity edema present important diagnostic and treatment challenges.

Chronic venous insufficiency is by far the most common cause of lower extremity edema, affecting up to 2% of the population, and the incidence of venous insufficiency has not changed over the past 25 years. Venous insufficiency is a common complication of DVT; however, only a small number of patients with chronic venous insufficiency report a history of this disorder. Venous ulceration commonly affects patients with chronic venous insufficiency, and its management is labor-intensive and expensive. Normal lower extremity venous pressure (in the erect position: 80 mm Hg in deep veins, 20–30 mm Hg in superficial veins) and cephalad venous blood flow require competent bicuspid venous valves, effective muscle contractions, normal ankle range of motion, and normal respirations. When one or more of these components fail, venous hypertension may result. The risk of cellulitis increases as the stage of chronic edema increases. Adults with unilateral or bilateral chronic edema have a 37–47% lifetime prevalence of cellulitis.

Clinical Findings

A. Symptoms and Signs

1. Unilateral lower extremity edema—Among common causes of unilateral lower extremity swelling, DVT is the most life-threatening. Clues suggesting DVT include a history of cancer, recent limb immobilization, or confinement to bed for at least 3 days following major surgery within the past month (Table 2–4). Adults with varicose veins have a significantly increased risk of DVT. Lower extremity swelling and inflammation in a limb recently affected by DVT could represent anticoagulation failure and thrombus recurrence but more often are caused by **postphlebitic syndrome** with valvular incompetence. Other causes of a painful, swollen calf include cellulitis, musculoskeletal disorders (Baker cyst rupture [“pseudothrombophlebitis”]), gastrocnemius tear or rupture, calf strain or trauma, and left common iliac vein compression (May-Thurner syndrome), complex regional pain syndrome, diabetic myonecrosis, as well as other sites of nonthrombotic venous outflow obstruction, such as the inguinal ligament, iliac bifurcation, and popliteal fossa.

Table 2–4. Risk stratification of adults referred for ultrasound to rule out DVT.

Step 1:		
Score 1 point for each		
Active cancer (treatment within the previous 6 months or current palliative care)		
Paralysis, paresis, or recent plaster immobilization of the lower extremities		
Recently bedridden for ≥ 3 days, or major surgery within the previous 12 weeks		
Localized tenderness along distribution of deep venous system		
Entire leg swelling		
Swelling of one calf ≥ 3 cm more than the other (measured 10 cm below the tibial tuberosity)		
Ipsilateral pitting edema		
Collateral superficial (nonvaricose) veins		
Previously documented DVT		
Step 2:		
Subtract 2 points if alternative diagnosis has equal or greater likelihood than DVT		
Step 3:		
Obtain sensitive D-dimer for score ≥ 0		
Score	**D-Dimer Positive[1]**	**D-Dimer Negative**
0–1	Obtain ultrasound	Ultrasound not required
≥ 2	Obtain ultrasound	

[1] “Positive” is above local laboratory threshold based on specific test and patient age.

Based on Wells PS et al. Evaluation of D-dimer in the diagnosis of suspected deep-vein thrombosis. N Engl J Med. 2003;349:1227. [PMID: 14507948]

2. Bilateral lower extremity edema—Bilateral involvement and significant improvement upon awakening favor systemic causes (eg, venous insufficiency) and can be presenting symptoms of volume overload (HF, cirrhosis, kidney disease [eg, nephrotic syndrome]). The most frequent symptom of chronic venous insufficiency is the sensation of “heavy legs,” followed by itching. Chronic exposure to elevated venous pressure accounts for the brawny, fibrotic skin changes observed in patients with chronic venous insufficiency and the predisposition toward skin ulceration, particularly in the medial malleolar area. Pain, particularly if severe, is uncommon in uncomplicated venous insufficiency.

Lower extremity swelling is a familiar complication of therapy with calcium channel blockers (particularly felodipine and amlodipine), pioglitazone, gabapentin, and minoxidil. Airline flights longer than 10 hours are associated with edema even in the absence of DVT.

B. Physical Examination

Physical examination should include assessment of the heart, lungs, and abdomen for evidence of pulmonary hypertension (primary or secondary to chronic lung disease), HF, or cirrhosis. The skin findings related to chronic venous insufficiency depend on the severity and chronicity of the disease, ranging from hyperpigmentation and stasis dermatitis to abnormalities highly specific for chronic venous insufficiency: lipodermatosclerosis (thick, brawny skin; in advanced cases, the lower leg resembles an inverted champagne bottle) and atrophie blanche (small, depigmented macules within areas of heavy pigmentation). The size of both calves should be measured 10 cm below the tibial tuberosity and pitting and tenderness elicited. Swelling of the entire leg or of one leg 3 cm more than the other suggests deep venous obstruction. The left calf is normally slightly larger than the right due to the left common iliac vein coursing under the aorta.

A shallow, large, modestly painful ulcer located over the *medial* malleolus is a hallmark of chronic venous insufficiency, whereas small, deep, and more painful ulcers over the *lateral* malleolus are more apt to be due to arterial insufficiency, vasculitis, or infection. Diabetic vascular ulcers, however, may be painless. When an ulcer is on the foot or above the mid-calf, causes other than venous insufficiency should be considered.

The physical examination is usually inadequate to distinguish lymphedema from venous insufficiency. Only the Kaposi-Stemmer sign (inability to pinch a fold of skin at the base of the second toe because of its thickness) is a significant predictor of lymphedema (OR, 7.9).

C. Diagnostic Studies

Patients without an obvious cause of acute unilateral lower extremity swelling (eg, calf strain) should have an ultrasound performed since DVT is difficult to exclude on clinical grounds. A prediction rule allows a clinician to exclude a lower extremity DVT in patients without an ultrasound if the patient has low pretest probability for DVT and a negative sensitive D-dimer test (the "Wells prediction rule") (https://www.mdcalc.com/wells-criteria-pulmonary-embolism) (Chapter 9). Previously unidentified lower extremity thrombi may be discovered in 21% of patients incompletely studied during the initial evaluation.

The diagnostic study of choice to detect chronic venous insufficiency due to venous incompetence is duplex ultrasonography. Assessment of the ankle-brachial pressure index is important in the management of chronic venous insufficiency since peripheral arterial disease may be exacerbated by compression therapy (see Chronic Venous Insufficiency, Chapter 14). Caution is required in interpreting the results of ankle-brachial pressure index in older patients and patients with diabetes due to the decreased compressibility of their arteries. A urine dipstick test that is strongly positive for protein can suggest nephrotic syndrome, and serum creatinine can estimate kidney function. Measuring serum albumin can further assess for nephrotic syndrome or chronic liver disease. Lymphoscintigraphy can be used to confirm a clinical suspicion of lymphedema.

▶ Treatment

See relevant chapters for treatment of edema in patients with HF (Chapter 11), nephrosis (Chapter 25), cirrhosis (Chapter 18), and lymphedema and venous stasis ulcers (Chapter 14). Edema resulting from calcium channel blocker therapy may respond to concomitant therapy with ACE inhibitors or ARBs.

In patients with chronic venous insufficiency without comorbid volume overload (eg, HF), it is best to avoid diuretic therapy since intravascular volume is relatively decreased. Instead, the most effective treatment involves (1) leg elevation, above the level of the heart, for 30 minutes three to four times daily and during sleep; (2) compression therapy; and (3) ambulatory exercise to increase venous return through calf muscle contractions.

A wide variety of stockings and devices are effective in decreasing swelling, preventing and healing venous leg ulcers, treating stasis dermatitis, and reducing the risk of cellulitis. They should be put on with awakening before hydrostatic forces result in edema. To control mild edema, 20–30 mm Hg compression is usually sufficient, whereas 30–40 mm Hg compression is usually required to control moderate to severe edema associated with ulcer formation. To maintain improvement, consider switching from an elastic stocking to one made of inelastic grosgrain material. Patients with decreased ankle-brachial pressure index should be managed in concert with a vascular surgeon. Compression stockings (12–18 mm Hg at the ankle) are effective in preventing edema and asymptomatic thrombosis associated with long airline flights in low- to medium-risk persons, and compression therapy decreases recurrence of cellulitis among patients with chronic venous insufficiency. Support stockings made of lighter material than compression stockings are recommended for pregnant women during air travel. For lymphedema, bandaging systems applied twice weekly can be effective. Multicomponent compression bandaging may offer additional benefit. Short-term manual lymphatic drainage treatment may improve chronic venous insufficiency severity, symptoms, and quality of life. For patients with reduced mobility and leg edema, intermittent pneumatic compression treatment can reduce edema and improve ankle range of motion.

Liposuction, suction-assisted lipectomy, and subcutaneous drainage may have treatment benefit if conservative measures fail in treatment of lymphedema.

▶ When to Refer

- Refer patients with chronic lower extremity ulcerations to wound care specialist.
- Refer patients with coexisting severe arterial insufficiency (claudication) that would complicate treatment with compression stockings to a vascular surgeon.

▶ When to Admit

- Pending definitive diagnosis in patients at high risk for DVT despite normal lower extremity ultrasound.
- Severe, acute swelling, raising concern for an impending compartment syndrome.
- Severe edema impairs ability to ambulate or perform activities of daily living.

Kılınç F et al. Cutaneous findings in patients with chronic venous insufficiency. J Cosmet Dermatol. 2022;21:2106. [PMID: 34240795]

FEVER & HYPERTHERMIA

ESSENTIAL INQUIRIES

- Age; injection substance use.
- Localizing symptoms of infection, weight loss; joint pain.
- Immunosuppression or neutropenia; history of cancer.
- Medications.
- Travel.

General Considerations

The average normal oral body temperature taken in midmorning is 36.7°C (range, 36–37.4°C). This range includes a mean and two standard deviations, thus encompassing 95% of a normal population (normal diurnal temperature variation is 0.5–1°C).

The normal rectal or vaginal temperature is 0.5°C higher than the oral temperature, and the axillary temperature is 0.5°C lower. However, a normal body temperature based on a peripheral thermometer (tympanic membrane, temporal artery, axillary, oral) does not always exclude the presence of a fever. To exclude a fever, a rectal temperature is more reliable than an oral temperature (particularly in patients who breathe through their mouth, are tachypneic, or are in an ICU setting where a rectal temperature probe can be placed to detect fever).

Fever is a regulated rise to a new “set point” of body temperature in the hypothalamus induced by pyrogenic cytokines. These cytokines include IL-1, TNF, interferon-γ, and IL-6. The elevation in temperature results from either increased heat production (eg, shivering) or decreased heat loss (eg, peripheral vasoconstriction). **Hyperthermia**—not mediated by cytokines—occurs when body metabolic heat production (as in thyroid storm) or environmental heat load exceeds normal heat loss capacity or when there is impaired heat loss (eg, heat stroke).

Body temperature in cytokine-induced fever seldom exceeds 41.1°C unless there is structural damage to hypothalamic regulatory centers; body temperature in hyperthermia may rise to levels (> 41.1°C) capable of producing irreversible protein denaturation and resultant brain damage; no diurnal variation is observed.

Clinical Findings

A. Fever

Fever as a symptom provides important information about the presence of illness—particularly infections—and about changes in the clinical status of the patient. Fever may be more predictive of bacteremia in older patients. The fever pattern, however, is of marginal value for most specific diagnoses except for the relapsing fever of malaria, borreliosis, and occasional cases of lymphoma, especially Hodgkin disease. The degree of temperature elevation does not necessarily correspond to the severity of the illness. Fever with rash and eosinophilia defines the drug reaction with eosinophilia and systemic symptoms (DRESS) syndrome.

In general, the febrile response tends to be greater in children than adults. Older persons, neonates, and persons receiving certain medications (eg, NSAIDs, corticosteroids), rather than a fever, a normal temperature or even hypothermia may be observed. Markedly elevated body temperature may result in profound metabolic disturbances. Febrile patients admitted to a hospital with a body temperature above 39.5°C had higher mortality and AKI events compared to patients with less fever (38.0–38.1°C). High temperature during the first trimester of pregnancy may cause congenital disabilities, such as anencephaly. Fever increases insulin requirements and alters the metabolism and disposition of drugs used to treat the diverse diseases associated with fever.

The source of fever varies by population and setting. In a study of 92 patients who underwent shoulder arthroplasty and developed fever, an infectious cause was found in only six patients. In the neurologic ICU, fever can occur directly from brain injury (“central fever”). One model predicted “central fever” with 90% probability if a patient met all of the following criteria: (1) < 72 hours of neurologic ICU admission; (2) presence of subarachnoid hemorrhage, intraventricular hemorrhage, or brain tumor; (3) absence of infiltrate on CXR; and (4) negative cultures. For patients in the ICU, elevated procalcitonin and CRP levels favor infection, rather than central fever, as the cause of fever.

Spinal cord injury may cause fever by the loss of supraspinal control of the sympathetic nervous system and defective thermoregulation due to loss of sensation. Fever may also be more common in patients with other forms of trauma. In a study of 268 patients, including patients with multiple injuries (n = 59), isolated head injuries (n = 97), isolated body injuries (n = 100), and minor trauma (n = 12), the incidence of fever was similar in all groups irrespective of injury (11–24%). In all groups, there was a significant association between the presence of early fever and death in the hospital (6–18% versus 0–3%), as well as longer median ICU stays (3–7 days versus 2–3 days).

The prevalence of intrapartum fever of ≥ 38°C in pregnancies of 36 weeks’ gestation or more is 6.8% (1 in 15 women in labor), but the neonatal sepsis rate among affected mothers is 0.24% (< 1 in 400 babies). This finding calls into question the need for universal laboratory work, cultures, and antibiotic treatment pending culture results for this newborn population.

Contrary to classical teaching, postoperative atelectasis probably does not cause fever. Febrile nonhemolytic transfusion reaction is common, occurring in about 1% of transfusion episodes, and is mediated by proinflammatory cytokines elaborated by donor leukocytes during storage.

B. Hyperthermia

Malignant catatonia consists of catatonic symptoms, hyperthermia, autonomic instability, and altered mental status.

Neuroleptic malignant syndrome is a variant of malignant catatonia that is a rare and potentially lethal idiosyncratic reaction to neuroleptic medications, particularly haloperidol and fluphenazine. It has also been reported with atypical neuroleptics (such as olanzapine or risperidone) (see Chapter 28).

Serotonin syndrome resembles neuroleptic malignant syndrome but occurs within hours of ingestion of agents that increase levels of serotonin in the CNS, including SSRIs, MAOIs, tricyclic antidepressants, meperidine, dextromethorphan, bromocriptine, tramadol, lithium, and psychostimulants (such as cocaine, methamphetamine, and MDMA) (see Chapter 43).

Clonus and hyperreflexia are more common in serotonin syndrome, whereas "lead pipe" rigidity is more common in neuroleptic malignant syndrome.

Malignant hyperthermia of anesthesia (see Chapter 43) shares common clinical and pathophysiologic features with neuroleptic malignant and serotonin syndromes.

C. Fever of Undetermined Origin

See Fever of Unknown Origin, Chapter 35.

Treatment

Most fever is well tolerated. When the temperature is < 40°C, symptomatic treatment only is required. Although fever may be associated with poor clinical outcomes in patients with traumatic brain injury, cerebrovascular accident, and cardiac arrest, the treatment of fever with antipyretics does not appear to affect mortality of critically ill patients or the number of ICU-free days. A temperature > 41°C is likely to be hyperthermia rather than cytokine-mediated fever, and *emergent management is indicated*. (See Heat Stroke, Chapter 42.)

A. General Measures for Removal of Heat

Regardless of the cause of the fever, alcohol sponges, cold sponges, ice bags, ice-water enemas, and ice baths will lower body temperature (see Chapter 42). They are more useful in hyperthermia since patients with cytokine-related fever will attempt to override these therapies.

B. Pharmacologic Treatment of Fever

1. Antipyretic drugs—Antipyretic therapy is only needed for patients with marginal hemodynamic status. It can, however, be used for symptomatic relief. Aspirin or acetaminophen, 325–650 mg orally every 4 hours, is effective in reducing fever. Early administration of acetaminophen to treat fever due to probable infection does not affect the number of ICU-free days. These drugs are best administered around the clock, rather than as needed, since "as needed" dosing results in periodic chills and sweats due to fluctuations in temperature caused by varying levels of drug.

2. Prophylactic antimicrobial therapy—Antibacterial and antifungal prophylactic regimens are recommended only for patients expected to have < 100 neutrophils/mcL for > 7 days, unless other factors increase risks for complications or mortality.

3. Empiric antimicrobial therapy—Empiric antibiotic therapy is sometimes warranted. Even before infection can be documented, prompt broad-spectrum antimicrobials are indicated for febrile patients who have hemodynamic instability, severe neutropenia (neutrophils < 500/mcL [0.5×10^9/L]), asplenia (surgical or from sickle cell disease), or immunosuppression (from HIV infection [see Chapter 36] or from medications such as systemic corticosteroids, azathioprine, cyclosporine) (Tables 35–1 and 35–5). Patients who are febrile and neutropenic should receive initial doses of empiric antibacterial therapy within an hour of triage and should either be monitored for at least 4 hours to determine suitability for outpatient management or be admitted to the hospital (see Infections in the Immunocompromised Patient, Chapter 35). It is standard to admit patients to the hospital with febrile neutropenic episodes, although carefully selected patients may be managed as outpatients after systematic assessment beginning with a validated risk index (eg, Multinational Association for Supportive Care in Cancer [MASCC] score or Talcott rules). In the MASCC index calculation, low-risk factors include the following: age under 60 years (2 points), burden of illness (5 points for no or mild symptoms and 3 points for moderate symptoms), outpatient status (3 points), solid tumor or hematologic malignancy with no previous fungal infection (4 points), no COPD (4 points), no dehydration requiring parenteral fluids (3 points), and systolic blood pressure above 90 mm Hg (5 points). Patients with MASCC scores of 21 or higher or in Talcott group 4 (presentation as an outpatient without significant comorbidity or uncontrolled cancer), and without other risk factors, can be managed safely as outpatients.

The carefully selected outpatients determined to be at low risk by MASCC score (particularly in combination with a normal serum CRP level) or by Talcott rules can be managed with an oral fluoroquinolone plus amoxicillin/clavulanate (or clindamycin, if penicillin allergic), unless fluoroquinolone prophylaxis was used before fever developed. For treatment of fever during neutropenia following chemotherapy, outpatient parenteral antimicrobial therapy can be provided effectively and safely in low-risk patients with a single agent, such as cefepime, piperacillin/tazobactam, imipenem, meropenem, or doripenem. High-risk patients should be referred for inpatient management with combination parenteral antimicrobial therapy based on specific risk factors such as pneumonia-causing pathogens or central line–associated bloodstream infections (see Infections in the Immunocompromised Patient and Table 35–1 in Chapter 35 and see Infections in Chapter 44).

If a fungal infection is suspected in patients with prolonged fever and neutropenia, fluconazole is equally effective as amphotericin B but less toxic.

C. Treatment of Hyperthermia

Discontinuation of the offending agent is mandatory. Treatment of neuroleptic malignant syndrome includes dantrolene in combination with bromocriptine or levodopa (see Chapter 28). Treatment of serotonin syndrome includes a central serotonin receptor antagonist—cyproheptadine or chlorpromazine—alone or in combination with a benzodiazepine (see Chapter 43). In patients for whom it is difficult to distinguish which syndrome is present, treatment with a benzodiazepine may be the safest therapeutic option.

When to Admit

- For vital sign abnormalities or evidence of end-organ dysfunction when early sepsis is suspected.
- Patients with febrile neutropenia at high risk for clinical decompensation.
- For measures to control a temperature higher than 41°C or when fever is associated with seizure or other mental status changes.
- Heat stroke (see Chapter 42).
- Malignant catatonia; neuroleptic malignant syndrome; serotonin syndrome; malignant hyperthermia of anesthesia.

INVOLUNTARY WEIGHT LOSS

ESSENTIAL INQUIRIES

- Age; caloric intake; secondary confirmation (eg, changes in clothing size).
- Fever; change in bowel habits.
- Substance use.
- Age-appropriate cancer screening history.

General Considerations

Body weight is determined by a person's caloric intake, absorptive capacity, metabolic rate, and energy losses. Body weight normally peaks by the fifth or sixth decade and then gradually declines at a rate of 1–2 kg per decade. In NHANES II, a national survey of community-dwelling older adults (aged 50–80 years), recent involuntary weight loss (IWL) (more than 5% usual body weight) was reported by 7% of respondents, and this was associated with a 24% higher mortality. In postmenopausal women, unintentional weight loss was associated with increased rates of hip and vertebral fractures.

Etiology

IWL is clinically significant when it exceeds 5% or more of usual body weight over a 6- to 12-month period. While it often indicates serious physical or psychological illness, nonmalignant diseases more commonly cause unintentional weight loss than malignant causes. Physical causes are usually evident during the initial evaluation, but an easily identifiable cause is not found in 6–28% of cases. The most common causes are cancer (about 30%), GI disorders (about 15%), and dementia or depression (about 15%). At a university hospital in Thailand, the three most common causes of IWL were reduced appetite (20.1%), dementia (13.7%), and medications (11.0%). Nearly half of patients with Parkinson disease have weight loss associated with disease progression. When an adequately nourished–appearing patient reports weight loss, inquiry should be made about exact weight changes (with approximate dates) and changes in clothing size. Family members can confirm weight loss, as can old documents such as photographs from driver's licenses. A mild, gradual weight loss occurs in some older individuals because of decreased energy requirements. However, rapid IWL is predictive of morbidity and mortality.

In addition to various disease states, causes in older individuals include loss of teeth and consequent difficulty with chewing, medications interfering with taste or causing nausea, alcohol use disorder, and social isolation. Among Black persons at an adult day health center, 65% had a significant nutritional disorder: 48.5% reported IWL or gain, 21% ate fewer than two meals daily, and 41.2% had tooth loss or mouth pain.

Clinical Findings

Once the weight loss is established, the history, medication profile, physical examination, and conventional laboratory and radiologic investigations (eg, CBC, liver biochemical tests, kidney panel, serologic tests including HIV, TSH level, UA, fecal occult blood test, and CXR) usually reveal the cause. Age-appropriate cancer screening should be completed as recommended by guidelines (eg, Papanicolaou smear, mammography, fecal occult blood test/screening colonoscopy/flexible sigmoidoscopy, possibly PSA) (Chapter 1). Whole-body CT imaging is increasingly used for diagnosis; one study found its diagnostic yield to be 33.5%. Another study found a low yield from CT scanning with contrast of the abdomen and pelvis for malignancy (2.3%) in patients whose only symptom was weight loss. When these tests are normal, a more definitive GI investigation (eg, tests for malabsorption, endoscopy) should be considered. However, one prospective case study in patients with IWL showed that colonoscopy did not find colorectal cancer if weight loss was the sole indication for the test. A low spot urinary creatinine may be a marker of muscle wasting in patients with new-onset or worsening HF as a cause of IWL.

If the initial evaluation is unrevealing, follow-up is preferable to further diagnostic testing. Death at 2-year follow-up was not nearly as common in patients with unexplained IWL (8%) as in those with weight loss due to malignant (79%) and established nonmalignant diseases (19%). Psychiatric consultation should be considered when there is evidence of depression, dementia, anorexia nervosa, or other emotional problems. Ultimately, in approximately 15–25% of cases, no cause for the weight loss can be found.

Differential Diagnosis

Malignancy, GI disorders (poorly fitting dentures, cavities, swallowing or malabsorption disorders, pancreatic insufficiency), HF, HIV, tuberculosis, psychological problems (dementia, depression, paranoia), endocrine disorders (hyper-, hypothyroidism, hyperparathyroidism, hypoadrenalism), Whipple disease, eating problems (dietary restrictions, lack of money for food, teeth problems), social issues (alcohol use disorder, social isolation), and medication side effects are all established causes.

Treatment

Weight stabilization occurs in most surviving patients with both established and unknown causes of weight loss through treatment of the underlying disorder and caloric supplementation. Nutrient intake goals are established in relation to the severity of weight loss, in general ranging from 30–40 kcal/kg/day. In order of preference, routes of administration include oral, temporary nasojejunal tube, or percutaneous gastric or jejunal tube. Parenteral nutrition is reserved for patients with serious associated problems. Various pharmacologic agents have been proposed for the treatment of weight loss. These can be categorized into appetite stimulants (corticosteroids, progestational agents, cannabinoids, and serotonin antagonists); anabolic agents (growth hormone, ghrelin, and testosterone derivatives); and anticatabolic agents (omega-3 fatty acids, pentoxifylline, hydrazine sulfate, and thalidomide). There is no evidence that appetite stimulants decrease mortality, and they may have severe adverse side effects. The anabolic agent nandrolone decanoate reversed weight and lean tissue loss in women with HIV, and human growth hormone temporarily increased weight and walking speed in undernourished older patients. However, studies have not consistently shown mortality benefit.

Exercise training may prevent or even reverse the process of muscle wasting in HF ("cardiac cachexia"). Protein or creatine supplementation combined with resistance exercise training and aerobic activity may prevent aging-related attenuation of muscle mass and functional performance. Some patients with cancer-associated weight loss may benefit from nutritional assessment and intervention as decreased food intake may be playing a role.

When to Refer

- Weight loss caused by malabsorption.
- Persistent nutritional deficiencies despite adequate supplementation.
- Weight loss as a result of anorexia or bulimia.

When to Admit

- Severe protein-energy malnutrition, including the syndromes of kwashiorkor and marasmus.
- Vitamin deficiency syndromes.
- Cachexia with anticipated progressive weight loss secondary to unmanageable psychiatric disease.
- Careful electrolyte and fluid replacement in protein-energy malnutrition and avoidance of "re-feeding syndrome."

FATIGUE

ESSENTIAL INQUIRIES

- Weight loss; fever.
- Sleep-disordered breathing.
- Medications; substance use.

General Considerations

Fatigue, as an isolated symptom, accounts for 1–3% of visits to generalists. Fatigue or lassitude and the closely related complaints of weakness, tiredness, and lethargy are often attributed to overexertion, poor physical conditioning, sleep disturbance, obesity, undernutrition, and emotional problems. A history of the patient's daily living and working habits may obviate the need for extensive and unproductive diagnostic studies.

Fatigue in older adults increases the risk of developing negative health outcomes (mortality OR, 2.14), the development of disabilities in basic activities of daily living (OR, 3.22), or the occurrence of physical decline (OR, 1.42).

Chronic fatigue conditions have been classified using numerous approaches since 1986. The prevailing clinical criteria in use today is the Institute of Medicine's (National Academy of Medicine) **systemic exertion intolerance disease (SEID).** The CDC has adopted the SEID criteria but continue to use the term **myalgic encephalitis/chronic fatigue syndrome (ME/CFS)** to reference this disorder. Common to all definitions is the lack of a single pathogenic mechanism, and no single physical finding or laboratory test can be used to confirm the diagnosis.

Clinical Findings

A. Fatigue

Clinically relevant fatigue is composed of three major components: generalized weakness (difficulty in initiating activities); easy fatigability (difficulty in completing activities); and mental fatigue (difficulty with concentration and memory). Important diseases that can cause fatigue include hyper- and hypothyroidism, hyperparathyroidism, HF, infections (endocarditis, hepatitis), COPD, asthma, interstitial lung disease, ESKD, sleep apnea, anemia, autoimmune disorders, multiple sclerosis, IBD, irritable bowel syndrome, Parkinson disease, cerebral vascular accident, and cancer.

Alcohol use disorder, vitamin C deficiency (scurvy), side effects from medications (eg, sedatives and β-blockers), and psychological conditions (eg, insomnia, depression, anxiety, panic attacks, dysthymia, and somatic symptom disorder) may be the cause. Common outpatient infectious causes include mononucleosis and sinusitis. These conditions are usually associated with other characteristic signs, but patients may emphasize fatigue and not discuss their other symptoms unless directly asked. The lifetime prevalence of significant fatigue (present for at least 2 weeks) is about 25%. Fatigue of unknown cause or related to psychiatric illness exceeds that due to physical illness, injury, alcohol, or medications.

Although frequently associated with Lyme disease, severe fatigue as a long-term sequela is rare. Posttraumatic brain injury fatigue and sleep disturbance may respond to a light box and in-home dynamic light therapy.

B. Chronic Fatigue

Diagnosis of SEID or ME/CFS requires the presence of all three of the following symptoms:

1. Substantial reduction or impairment in the ability to engage in pre-illness levels of occupational, educational, social, or personal activities that persists for > 6 months and is accompanied by fatigue, which is often profound, is of new or definite onset (not lifelong), is not the result of ongoing excessive exertion, and is not substantially alleviated by rest.
2. Post-exertional malaise.
3. Unrefreshing sleep.

In addition, the patient must have at least one of the following two manifestations: (1) cognitive impairment or (2) orthostatic intolerance (lightheadedness, dizziness, and headache that worsen with upright posture and improve with recumbency).

The evaluation of SEID includes a history and physical examination as well as CBC; ESR; kidney function; serum electrolytes, glucose, creatinine, calcium; liver biochemical tests and thyroid function tests; UA; tuberculin skin test; and screening questionnaires for psychiatric disorders. Other tests to be performed as clinically indicated are serum cortisol, ANA, rheumatoid factor, immunoglobulin levels, Lyme serology in endemic areas (although rarely a long-term complication of this infection), and HIV antibody. More extensive testing is usually unhelpful, including antibody to Epstein-Barr virus. There may be an abnormally high rate of postural hypotension.

Treatment

A. Fatigue

Resistance training and aerobic exercise lessens fatigue and improves performance for several chronic conditions associated with a high prevalence of fatigue, including HF, COPD, arthritis, and cancer. Continuous positive airway pressure is an effective treatment for obstructive sleep apnea. Pitolisant, a selective histamine H_3-receptor antagonist with wake-promoting effect, may reduce daytime sleepiness in patients with moderate to severe obstructive sleep apnea who decline continuous positive airway pressure treatment.

Psychostimulants such as methylphenidate have shown inconsistent results in randomized trials of treatment of cancer-related fatigue. Methylphenidate and cognitive-behavioral therapy may improve mental fatigue and cognitive function in patients with traumatic brain injury. Modafinil and armodafinil appear to be effective, well-tolerated agents in patients who have HIV with fatigue and as adjunctive agents in patients who have depression or bipolar disorder with fatigue. Testosterone replacement in hypoandrogenic men over age 65 had no significant benefits for walking distance or vitality, as assessed by the Functional Assessment of Chronic Illness Therapy-Fatigue scale. However, men receiving testosterone reported slightly better mood and lower severity of depressive symptoms than those receiving placebo. Vitamin D treatment significantly improved fatigue after kidney transplantation and in otherwise healthy persons with vitamin D deficiency. Solution-focused therapy has a significant initial beneficial effect on the severity of fatigue and quality of life in patients with quiescent IBD. Internet-based cognitive-behavioral therapy is effective in reducing severe fatigue in those who have experienced breast cancer. Therapeutic Care (a complementary medicine modality that uses acupressure) reduced fatigue in some patients with breast cancer receiving chemotherapy, while moderate-intensity exercise did not. Six weeks of Swedish massage therapy reduced fatigue in women with breast cancer who had surgery plus radiation, chemotherapy/chemoprevention, or both. There is limited and preliminary evidence that rasagiline, modafinil, and doxepin are associated with improvement of fatigue in Parkinson disease. Amantadine, modafinil, and methylphenidate were not found to be superior to placebo in improving fatigue associated with multiple sclerosis and caused more frequent adverse events.

The treatment of subclinical hypothyroidism is unlikely to benefit symptoms of fatigue. Oral melatonin does not improve fatigue in patients with advanced cancer. Exceeding the recommended dietary allowance for protein intake does not increase muscle or physical function, augment anabolic response to testosterone in older men, or reduce muscle soreness or fatigue after prolonged moderate-intensity walking exercise.

B. Systemic Exertion Intolerance Disease or Myalgic Encephalitis/Chronic Fatigue Syndrome

A variety of agents and modalities have been tried for the treatment of SEID without improvement in symptoms.

Some patients with postural hypotension report response to increases in dietary sodium and fludrocortisone, 0.1 mg orally daily. The immunomodulator rintatolimod improved some measures of exercise performance compared with placebo in two trials (with low strength of evidence). Low-dose naltrexone is being used off-label with anecdotal reports of benefit. There is limited evidence that dietary modification is beneficial.

Patients with SEID have benefited from a comprehensive multidisciplinary intervention, including optimal medical management, treating any ongoing affective or anxiety disorder pharmacologically, and implementing a comprehensive cognitive-behavioral treatment program. Cognitive-behavioral therapy and graded exercise are the treatments of choice for patients with SEID.

Graded exercise may result in mild-to-moderate improvements in functional work capacity and physical function in some patients but may prove risky in others. A 2011 randomized trial (PACE trial) confirmed the independent benefits of cognitive-behavioral therapy and graded exercise, but recent meta-analyses and re-analysis of PACE call into question the magnitude of the benefit and safety of graded exercise. Physiologic studies find an altered immune response to exercise in patients with chronic fatigue syndrome. A self-help booklet describing a six-step graded exercise program over 12 weeks and up to four guidance sessions with a physiotherapist over 8 weeks may be as helpful as specialist medical care alone.

When to Refer

- Infections not responsive to standard treatment.
- Difficult-to-control hyper- or hypothyroidism.
- Severe psychological illness.
- Malignancy.

When to Admit

- Failure to thrive.
- Fatigue severe enough to impair activities of daily living.

ACUTE HEADACHE

ESSENTIAL INQUIRIES

- Age > 40 years.
- Rapid onset and severe intensity (ie, "thunderclap" headache), trauma, onset during exertion.
- Fever, vision changes, neck stiffness.
- HIV infection.
- Current or past history of hypertension.
- Neurologic findings (mental status changes, motor or sensory deficits, loss of consciousness).

General Considerations

Approximately 90% of people in the United States experience a headache in their lifetime. A broad range of disorders can cause headache (see Chapter 27). This section deals only with acute nontraumatic headache in adults and adolescents; migraine headache is covered in Chapter 27. The challenge in the initial evaluation of acute headache is to identify which patients exhibit an uncommon but life-threatening condition; approximately 1% of patients seeking care in emergency department settings and considerably less in office practice settings fall into this category.

Diminution of headache in response to typical migraine therapies (such as serotonin receptor antagonists or ketorolac) does not rule out critical conditions such as subarachnoid hemorrhage or meningitis as the underlying cause. A "sentinel headache" before a subarachnoid hemorrhage is a sudden, intense, persistent headache different from previous headaches; it precedes subarachnoid hemorrhage by days or weeks and occurs in 15–60% of patients with spontaneous subarachnoid hemorrhage.

Clinical Findings

A. Symptoms

A careful history and physical examination should aim to identify causes of acute headache that require immediate treatment. These causes can be broadly classified as (1) imminent or completed vascular events (intracranial hemorrhage, thrombosis, cavernous sinus thrombosis, vasculitis, malignant hypertension, arterial dissection, cerebral venous thrombosis, reversible cerebral vasoconstriction syndrome, transient ischemic attack, or aneurysm); (2) infections (abscess, encephalitis, or meningitis), intracranial masses causing intracranial hypertension, preeclampsia; and (3) carbon monoxide poisoning and methemoglobinemia. Having the patient carefully describe the onset of headache can help diagnose a serious cause.

Report of a sudden-onset headache that reaches maximal and severe intensity within seconds or a few minutes is the classic description of a "thunderclap" headache; it should precipitate workup for subarachnoid hemorrhage, since the estimated prevalence of subarachnoid hemorrhage in patients with thunderclap headache is 43%.

Thunderclap headache during the postpartum period precipitated by the Valsalva maneuver or recumbent positioning may indicate reversible cerebral vasoconstriction syndrome or irreversible cerebral venous sinus thrombosis. Venous-specific imaging sequences may be needed for diagnosis. Other historical features that raise the need for diagnostic testing include headache brought on by cough, exertion, or sexual activity.

The medical history can guide the need for additional workup. Under most circumstances (including a normal neurologic examination), new headache in a patient older than 50 years or with HIV infection warrants immediate neuroimaging (Table 2–5). When the patient has a history of hypertension—particularly uncontrolled hypertension—a complete search for other features of "malignant hypertension" is appropriate to determine the urgency of control of hypertension (see Chapter 13). Headache and hypertension associated with pregnancy may be due to preeclampsia. Episodic headache associated with the triad of hypertension, palpitations, and sweats is suggestive of pheochromocytoma. In the absence of thunderclap headache, advanced age, and HIV infection, a careful physical examination and detailed neurologic examination will usually determine acuity of the workup and need for further diagnostic testing. A history consistent with hypercoagulability is associated with an increased risk of cerebral venous thrombosis.

Findings in migraine headache are discussed in Chapter 27. A systematic list called the SNNOOP10 has been developed as a screening method for secondary causes of headache (Table 2–6).

B. Physical Examination

Critical components of the physical examination of a patient with acute headache include vital signs, neurologic examination, and vision testing with funduscopic examination. The finding of fever with acute headache warrants additional maneuvers to elicit evidence of meningeal inflammation, such as a Kernig sign (a supine patient with hips flexed to 90 degrees who displays resistance or reports pain with passive extension of the knees) and Brudzinski sign (supine patient who reflexively flexes the hip and knees after the examiner passively flexes the neck). The absence of jolt accentuation of headache cannot accurately rule out meningitis. Patients older than 60 should be examined for scalp or temporal artery tenderness.

Table 2–5. Clinical features associated with acute headache that warrant urgent or emergent neuroimaging.

Indications for neuroimaging prior to lumbar puncture
Abnormal neurologic examination (particularly focal neurologic deficits)
Abnormal mental status
Abnormal funduscopic examination (papilledema; loss of venous pulsations)
Meningeal signs
Indications for emergent neuroimaging completed prior to leaving office or emergency department
Abnormal neurologic examination
Abnormal mental status
"Thunderclap" headache
Patients with HIV with new type of headache[1]
Indications for urgent neuroimaging scheduled prior to leaving office or emergency department
Age > 50 years (normal neurologic examination) with new type of headache

[1] Use CT with or without contrast or MRI if positive for HIV.

Data from American College of Emergency Physicians. Clinical policy: critical issues in the evaluation and management of patients presenting to the emergency department with acute headache. Ann Emerg Med. 2008;52:407.

Careful assessment of visual acuity, ocular gaze, visual fields, pupillary defects, optic disks, and retinal vein pulsations is crucial. Diminished visual acuity suggests glaucoma, temporal arteritis, or optic neuritis. Ophthalmoplegia or visual field defects may be signs of venous sinus thrombosis, tumor, or aneurysm. Afferent pupillary defects can be due to intracranial masses or optic neuritis. In the setting of headache and hypertension, retinal cotton wool spots, flame hemorrhages, and disk swelling indicate acute severe hypertensive retinopathy. Ipsilateral ptosis and miosis suggest Horner syndrome and in conjunction with acute headache may signify carotid artery dissection. Finally, papilledema or absent retinal venous pulsations are signs of elevated intracranial pressure—findings that should be followed by neuroimaging before performing lumbar puncture (Table 2–5). On nonmydriatic fundoscopy, up to 8.5% of patients who arrive at the emergency department reporting headache had abnormalities; although few had other significant physical examination findings, 59% of them had abnormal neuroimaging studies.

Complete neurologic evaluations should include assessment of mental status, motor and sensory systems, reflexes, gait, cerebellar function, and pronator drift. Any abnormality on neurologic evaluation (especially mental status) warrants emergent neuroimaging (Table 2–5).

C. Diagnostic Studies

1. Neuroimaging indications—Indications for neuroimaging are listed in Table 2–5. Under most circumstances, a noncontrast head CT is sufficient to exclude intracranial hypertension with impending herniation, intracranial hemorrhage, and many types of intracranial masses (notable exceptions include lymphoma and toxoplasmosis in patients with HIV, herpes simplex encephalitis, and brain abscess). When needed, a contrast study can be ordered to follow a normal noncontrast study. A normal neuroimaging study does not exclude subarachnoid hemorrhage and should be followed by lumbar puncture. One study supported a change of practice wherein a lumbar puncture can be withheld when a head CT scan was performed < 6 hours after headache onset and showed no evidence of subarachnoid hemorrhage (negative predictive value 99.9%.

In a prospective study of 1536 emergency department patients, the yield for acute findings on head CT differed based on the indications for imaging and were 27% for seizures, 20% for confusion, 19% for syncope, 16% for focal neurologic deficit, 15% for head injury, 12% for headache, and 8% for dizziness.

Table 2–6. SNNOOP10 list of "red" flags for secondary causes of headache.

Sign or Symptom	Related Secondary Headaches
Systemic symptoms[1]	Headache attributed to infection, nonvascular intracranial disorders, carcinoid, or pheochromocytoma
Neoplasm in history	Neoplasms of the brain; metastasis
Neurologic deficit/dysfunction	Headaches attributed to vascular, nonvascular intracranial disorders; brain abscess and other infections
Onset of headache is sudden or abrupt	Subarachnoid hemorrhage and other headache attributed to cranial or cervical vascular disorders
Older age (> 50 years)	Giant cell arteritis and other headache attributed to cranial or cervical vascular disorders; neoplasms and other nonvascular intracranial disorders
Pattern change or recent onset of headache	Neoplasms, headaches attributed to vascular, nonvascular intracranial disorders
Positional headache	Intracranial hypertension or hypotension
Precipitated by sneezing, coughing, or exercise	Posterior fossa malformations; Chiari malformation
Papilledema	Neoplasms and other nonvascular intracranial disorders; intracranial hypertension
Progressive headache and atypical presentations	Neoplasms and other nonvascular intracranial disorders
Pregnancy or puerperium	Headaches attributed to cranial or cervical vascular disorders; postdural puncture headache; hypertension-related disorders (eg, preeclampsia); cerebral sinus thrombosis; hypothyroidism; anemia; diabetes mellitus
Painful eye with autonomic features	Pathology in posterior fossa, pituitary region, or cavernous sinus; Tolosa-Hunt syndrome (severe, unilateral headaches with orbital pain and ophthalmoplegia due to extraocular palsies); other ophthalmic causes
Posttraumatic onset of headache	Acute and chronic posttraumatic headache; subdural hematoma and other headache attributed to vascular disorders
Immunosuppression, eg, HIV, immunosuppressive medications	Opportunistic infections
Painkiller overuse or new drug at onset of headache	Medication overuse headache; drug incompatibility

[1] "Orange" flag (orange flag is only alarming when it occurs with other orange or red flags) for isolated fever alone.

Reproduced with permission from Do TP et al. Red and orange flags for secondary headaches in clinical practice: SNNOOP10 list. Neurology. 2019;92(3):134. https://n.neurology.org/content/92/3/134.long

In patients for whom there is a high level of suspicion for subarachnoid hemorrhage or aneurysm, a normal CT and lumbar puncture should be followed by angiography within the next few days (provided the patient is medically stable).

MRI is the modality of choice for evaluation of headache in pregnant patients and supported as safe by the American College of Radiology. Gadolinium contrast should be avoided whenever possible.

2. Lumbar puncture—This test is indicated to exclude infectious causes of acute headache, particularly in patients with fever or meningeal signs. CSF tests should routinely include Gram stain, WBC count with differential, RBC count, glucose, total protein, and bacterial culture. In appropriate patients, also consider testing CSF for Venereal Disease Research Laboratory (syphilis), cryptococcal antigen (patients with HIV), acid-fast bacillus stain and culture, and complement fixation and culture for coccidioidomycosis. Storage of an extra tube with 5 mL of CSF is prudent for conducting unanticipated tests in the immediate future. PCR tests for specific infectious pathogens (eg, herpes simplex 2) should be considered in patients with evidence of CNS infection but no identifiable pathogen.

The Ottawa subarachnoid hemorrhage clinical decision rule had 100% sensitivity (and 13–15% specificity in different studies) in predicting subarachnoid hemorrhage. According to it, patients who seek medical attention in an emergency department describing an acute nontraumatic headache should be evaluated for subarachnoid hemorrhage if they have one or more of the following factors: age 40 years or older, neck pain or stiffness, witnessed loss of consciousness, onset during exertion, thunderclap headache (instantly peaking pain), or limited neck flexion on examination.

In addition to neuroimaging and lumbar puncture, additional diagnostic tests for exclusion of life-threatening causes of acute headache include ESR (temporal arteritis; endocarditis), UA (malignant hypertension; preeclampsia), and sinus CT (bacterial sinusitis, independently or as a cause of venous sinus thrombosis).

Treatment

The treatment of migraine headaches is discussed in Chapter 27. Table 5–4 lists common medications used to treat benign headaches. Severe benign headache treated in the emergency department responds to haloperidol (2.5 mg intravenously).

Galcanezumab is an approved treatment for episodic cluster headache. High-flow oxygen therapy may effectively treat all headache types in the emergency department setting (eg, benefiting older patients with cluster headaches).

A study found that metoclopramide plus diphenhydramine was more effective than placebo for acute posttraumatic headache (with 43% of the patients who received metoclopramide reporting adverse events).

When to Admit

- Need for repeated doses of parenteral pain medication.
- To facilitate an expedited workup requiring a sequence of neuroimaging and procedures.
- To monitor for progression of symptoms and to obtain neurologic consultation when the initial emergency department workup is inconclusive.
- Pain severe enough to impair activities of daily living or impede follow-up appointments or consultations.
- Patients with subarachnoid hemorrhage, intracranial mass, or meningitis.

DYSURIA

ESSENTIAL INQUIRIES

- ▶ Fever; new back or flank pain; nausea or vomiting.
- ▶ Vaginal discharge.
- ▶ Pregnancy risk.
- ▶ Structural abnormalities.
- ▶ Instrumentation of urethra or bladder.

General Considerations

Dysuria (painful urination) is a common reason for adults and adolescents to seek urgent medical attention.

An inflammatory process (eg, bacterial UTI, herpes simplex, autoimmune disorder) underlies most causes of dysuria. In women, cystitis is diagnosed in up to 50–60% of cases. Cystitis has an incidence of 0.5–0.7% per year in sexually active young women. The key objective in evaluating women with dysuria is to exclude serious upper urinary tract disease, such as acute pyelonephritis, and STIs. In older men, dysuria may be a symptom of prostatitis; in younger men, urethritis accounts for most cases of dysuria. Male cyclists have no worse sexual or urinary functions than swimmers or runners, but cyclists are more prone to urethral stricture.

Clinical Findings

A. Symptoms

Well-designed cohort studies have shown that some cases of uncomplicated cystitis can be reliably diagnosed without a physical examination or UA, and RCTs show that telephone management of uncomplicated cystitis is safe and effective. An increased likelihood of UTI is present when women report multiple irritative voiding symptoms (dysuria, urgency, frequency), fever, or back pain (positive LRs, 1.6–2.0). A cohort study found that dysuria most reliably predicted a culture-positive UTI, although older patients with cognitive impairment may not have local urinary tract symptoms. History of recurrent UTI is associated with a positive urine culture (recurrent UTI adjusted OR 2.45). Inquiring about symptoms of vulvovaginitis is imperative. When reproductive age women report dysuria and urinary frequency and deny vaginal discharge and irritation, the LR for culture-confirmed cystitis is 24.5. In contrast, when vaginal discharge or irritation is present, as well as dysuria or urinary frequency, the LR is 0.7. Gross hematuria in women with voiding symptoms usually represents hemorrhagic cystitis but can be a sign of bladder cancer (particularly in older patients) or upper tract disease. Failure of hematuria to resolve with antibiotic treatment should prompt further evaluation of the bladder and kidneys. Chlamydial infection should be strongly considered among women aged 25 years or younger who are sexually active and seeking medical attention for a suspected UTI for the first time or who have a new sexual partner.

Fever, back pain, nausea, and vomiting are clinical criteria for acute pyelonephritis. Women with these symptoms should usually be examined before initiation of treatment to exclude coexistent urosepsis, hydronephrosis, or nephrolithiasis that would affect management decisions. Risk factors for acute pyelonephritis among women aged 18–49 years relate to sexual behaviors (frequent sexual intercourse [three times per week or more], new sexual partner in the previous year, recent spermicide use), as well as diabetes mellitus and recent UTI or incontinence.

Presence of UTI during pregnancy is strongly associated with preeclampsia (particularly UTI during the third trimester).

B. Physical Examination

Fever, tachycardia, or hypotension suggests urosepsis and potential need for hospitalization. In uncomplicated circumstances, a focused examination in women can be limited to ascertainment of costovertebral angle tenderness as a finding for pyelonephritis and to a lower abdominal and pelvic examination if the history suggests vulvovaginitis or cervicitis. Findings of vulvar atrophy, pale mucosa, and narrowing of the introitus is consistent with genitourinary syndrome of menopause.

C. Diagnostic Studies

1. Urinalysis—UA is probably overutilized in the evaluation of dysuria. The probability of culture-confirmed UTI among women with a history and physical examination compatible with uncomplicated cystitis is about 70–90%. UA is most helpful in atypical presentations of cystitis. Dipstick detection (> trace) of leukocytes, nitrites, or blood supports a diagnosis of cystitis. When both leukocyte and nitrite tests are positive, the LR is 4.2, and when both are negative, the LR is 0.3.

The negative predictive value of UA is not sufficient to exclude culture-confirmed UTI in women with multiple typical symptoms, and randomized trial evidence shows that antibiotic treatment is beneficial to women with typical symptoms and negative UA dipstick tests. Microscopy of unspun urine may also be helpful in diagnosis and reduces unnecessary use of antibiotics. The combination of urgency, dysuria, and pyuria assessed with the high-power (40×) objective for leukocytes (more than 1 leukocyte/7 high-power fields) had a positive predictive value of 71 and LR of 2.97. Urine samples produced at home rarely meet diagnostic standards.

2. Urine culture—Urine culture should be considered for all women with upper urinary tract symptoms (before initiating antibiotic therapy), concern for complicated (structural or functional abnormality, immunosuppression) urinary tract infection, as well as those with dysuria and a negative urine dipstick test. In symptomatic women, a clean-catch urine culture is considered positive when 10^2–10^3 colony-forming U/mL of a uropathogenic organism are detected. While awaiting culture results in these women, it is reasonable to use NSAIDs for symptom relief and recommend cranberry (pure extract) while continuing close follow-up. Urine culture sensitivity decreases rapidly after empiric antibiotic administration (75% of cultures are negative 9 hours after antibiotic treatment). Multiplex PCR analysis is as beneficial as a urine culture.

3. Renal imaging—When severe flank or back pain is present, the possibility of complicated kidney infection (perinephric abscess, nephrolithiasis) or hydronephrosis should be considered. Renal ultrasound or CT scanning should be done to rule out abscess and hydronephrosis. To exclude nephrolithiasis, noncontrast helical CT scanning is more accurate than renal ultrasound and is the diagnostic test of choice. In a meta-analysis, the positive and negative LRs of helical CT scanning for diagnosis of nephrolithiasis were 23.2 and 0.05, respectively.

Differential Diagnosis

The differential diagnosis of dysuria in women includes acute cystitis, acute pyelonephritis, vaginitis (*Candida*, bacterial vaginosis, *Trichomonas*, herpes simplex), urethritis/cervicitis (*Chlamydia*, gonorrhea, *Mycoplasma genitalium*, and interstitial cystitis/painful bladder syndrome). Recurrent or chronic culture-negative dysuria may represent genitourinary syndrome of menopause. Pelvic congestion syndrome (dilated and refluxing pelvic veins) may also cause dysuria and pelvic pain.

Nucleic acid amplification tests from first-void urine or vaginal swab specimens are highly sensitive for detecting chlamydial infection in men and women. Other infectious pathogens associated with dysuria and urethritis in men include *Mycoplasma genitalium* and Enterobacteriaceae.

Treatment

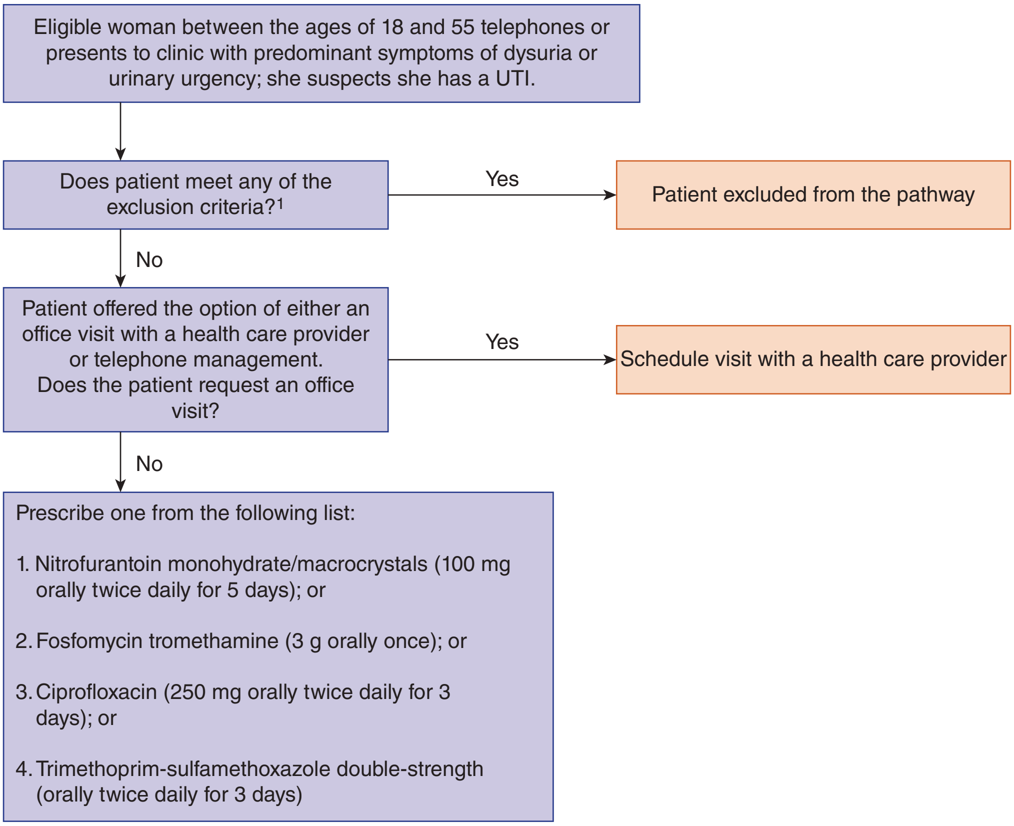
An evidence-informed algorithm for managing suspected UTI in women is shown in Figure 2–1. This algorithm supports antibiotic treatment of most women with multiple and typical symptoms of UTI without performing UA or urine culture. Pregnancy, underlying structural factors (polycystic kidney disease, nephrolithiasis, neurogenic bladder), immunosuppression, diabetes mellitus, and a history of recent bladder or urethral instrumentation usually alter the treatment regimen (antibiotic choice or duration of treatment, or both) for cystitis.

Telemedicine may be an appropriate technology to assess and manage uncomplicated UTIs for average-risk patients who can self-diagnose. Antibiotic selection should be guided by local resistance patterns and expert-panel clinical practice guidelines; major options for uncomplicated cystitis include nitrofurantoin, fosfomycin, ciprofloxacin, and trimethoprim-sulfamethoxazole. Five days of nitrofurantoin results in a significantly greater likelihood of clinical and microbiologic resolution than single-dose fosfomycin.

According to the American Academy of Pediatrics Committee on Drugs, antibiotics that are usually acceptable when treating women who are breastfeeding include trimethoprim-sulfamethoxazole (unless G6PD deficiency is present), amoxicillin, nitrofurantoin, ciprofloxacin, and ofloxacin.

In men, prolonged treatment of UTIs (> 7 days) out of concern for delayed clearance of infection within the prostate does not appear to reduce early or late recurrences. A 5-day course of fluoroquinolones for outpatient men with UTI is as effective as a 10-day course. Among afebrile men with symptoms of UTI, treatment with ciprofloxacin or trimethoprim/sulfamethoxazole for 7 days was noninferior to 14 days regarding resolution of UTI symptoms.

Symptomatic relief can be provided with phenazopyridine, a urinary analgesic available over the counter; it is used in combination with antibiotic therapy (when a UTI has been confirmed) but for no more than 2 days. Patients should be informed that phenazopyridine will cause orange/red discoloration of their urine and other body fluids (eg, some contact lens wearers have reported discoloration of their lenses). Rare cases of methemoglobinemia and hemolytic anemia have been reported, usually with overdoses or underlying kidney dysfunction. NSAIDs have also been shown to be of symptomatic benefit, but less effective than antibiotic therapy. Although some women recover from uncomplicated UTI when treated with NSAIDs alone (53% in a Norwegian study),



Eligible woman between the ages of 18 and 55 telephones or presents to clinic with predominant symptoms of dysuria or urinary urgency; she suspects she has a UTI.
Does patient meet any of the exclusion criteria?1
Yes
Patient excluded from the pathway
No
Patient offered the option of either an office visit with a health care provider or telephone management. Does the patient request an office visit?
Yes
Schedule visit with a health care provider
No
Prescribe one from the following list:
1. Nitrofurantoin monohydrate/macrocrystals (100 mg orally twice daily for 5 days); or
2. Fosfomycin tromethamine (3 g orally once); or
3. Ciprofloxacin (250 mg orally twice daily for 3 days); or
4. Trimethoprim-sulfamethoxazole double-strength (orally twice daily for 3 days)

[1] Primary exclusion criteria include documented fever 38°C or greater; symptoms of dysuria or urgency ≥ 7 days; symptoms of vaginitis are present; abdominal pain, nausea, or vomiting; gross hematuria in patients older than 50 years; immunosuppression (eg, current use of chemotherapeutic agents); diabetes mellitus; known pregnancy; chronic renal or urologic abnormalities, other than stress urinary incontinence (eg, polycystic kidney disease, neurogenic bladder, renal failure); recent or persistent urinary stones; urinary catheterization or other urologic procedure ≤ 2 wk ago; discharge from hospital or nursing home ≤ 2 wk ago; treatment for UTI ≤ 2 wk ago; recurrent symptomatic UTI.

▲ **Figure 2–1.** Proposed algorithm for evaluating women with symptoms of acute UTI. (Data from Gupta K et al; Infectious Diseases Society of America; European Society for Microbiology and Infectious Diseases. International clinical practice guidelines for the treatment of acute uncomplicated cystitis and pyelonephritis in women: a 2010 update by the Infectious Diseases Society of America and the European Society for Microbiology and Infectious Diseases. Clin Infect Dis. 2011;52:e103.)

the rate of progression to pyelonephritis was substantial. Delayed antibiotic therapy in older patients with UTI leads to a substantially higher rate of urosepsis and all-cause mortality. If a broad-spectrum antibiotic was initially prescribed empirically for UTI and urine culture results return establishing efficacy of a narrow-spectrum antibiotic, treatment should be "de-escalated" to the narrow-spectrum antimicrobial. Among premenopausal women with recurrent UTIs, the group with increased daily water consumption (1500 mL per day) had a lower mean number of cystitis episodes over a 12-month period of 1.7 compared with 3.2 in the control group and reduced number of antibiotic prescriptions (1.9 and 3.6, respectively). A double-blind, randomized, placebo-controlled trial across 99 primary care centers examined the use of D-mannose for protection against recurrent UTIs and found no benefit. A systematic review of six randomized controlled trials found methenamine hippurate to be as effective as antibiotic prophylaxis in reducing recurrent UTIs. In patients with asymptomatic renal calculi and recurrent UTIs, stone extraction eliminated infections in 50% of women. Vaginal estrogen effectively relieves urinary urgency and frequency as well as recurrent UTIs associated with genitourinary syndrome of menopause.

In cases of interstitial cystitis/painful bladder syndrome (see Chapter 26), patients will often respond to a multimodal approach that may include urethral/vesicular dilation, biofeedback, cognitive-behavioral therapy, antidepressants, dietary changes, vaginal emollients, and other supportive measures.

Asymptomatic bacteriuria—The incidence of asymptomatic bacteriuria increases with age and may be > 15%

in women older than age 80 (50% for those who reside in long-term care facilities). A meta-analysis found that antibiotic treatment for most people with asymptomatic bacteriuria is not beneficial and may be harmful. Antibiotic treatment benefits pregnant women with asymptomatic bacteriuria as well as persons about to undergo urologic surgery. The USPSTF recommends screening pregnant patients for asymptomatic bacteriuria by obtaining a urine culture (B recommendation). The USPSTF recommends against screening for asymptomatic bacteriuria in nonpregnant adults (D recommendation). Urine WBC count > 25 cells/high-power field was associated with a 53.8% rate of bacteriuria in a study of 46,127 adult inpatients and is suggested to be the optimal "cutoff" value.

There were no differences in the prevalence of postoperative UTI in women who had mixed flora on preoperative urine cultures compared to those with no growth on preoperative urine cultures.

When to Refer

- Anatomic abnormalities leading to repeated urinary infections.
- Infections associated with nephrolithiasis.
- Persistent interstitial cystitis/painful bladder syndrome.

When to Admit

- Severe pain requiring parenteral medication or impairing ambulation or urination (such as severe primary herpes simplex genitalis).
- Dysuria associated with urinary retention or obstruction.
- Pyelonephritis with ureteral obstruction.
- Symptoms and signs suggesting urosepsis.

Preoperative Evaluation & Perioperative Management

Hugo Q. Cheng, MD

EVALUATION OF THE ASYMPTOMATIC PATIENT

Patients without significant medical problems—especially those under age 50—are at very low risk for perioperative complications. Their preoperative evaluation should include a history and physical examination; emphasis should be on a pharmacologic history and assessment of functional status, exercise tolerance, and cardiopulmonary status to look for unrecognized disease that may require further evaluation before surgery. In addition, a directed bleeding history (Table 3–1) should be taken to uncover coagulopathy that could contribute to excessive surgical blood loss. Routine preoperative laboratory tests in asymptomatic healthy patients under age 50 have *not* been found to help predict or prevent complications. Even older patients undergoing minor or minimally invasive procedures (eg, cataract surgery) are unlikely to benefit from preoperative screening tests.

Harris AHS et al. Frequency and costs of low-value preoperative tests for patients undergoing low-risk procedures in the Veterans Health Administration. Perioper Med (Lond). 2022;13:33. [PMID: 36096937]

CARDIAC RISK ASSESSMENT & REDUCTION IN NONCARDIAC SURGERY

The most important perioperative cardiac complications are MI and cardiac death. Other complications include HF, arrhythmias, and need for urgent revascularization. The principal patient-specific risk factor for cardiac complications is the presence of end-organ CVD. This includes not only CAD and HF but also CKD and cerebrovascular disease. Diabetes mellitus, especially if treated with insulin, is considered a CVD equivalent that increases the risk of cardiac complications. Major abdominal, thoracic, and vascular surgical procedures carry a higher risk of postoperative cardiac complications. These six risk factors comprise the Revised Cardiac Risk Index (RCRI), a validated, multifactorial risk prediction tool (Table 3–2). Another widely used risk prediction tool comes from the American College of Surgeons' National Surgical Quality Improvement Program (NSQIP). This tool uses patient age, the type of operation, serum creatinine > 1.5 mg/dL (132.6 mcmol/L), dependency in activities of daily living, and the patient's American Society of Anesthesiologists physical status classification as predictors for postoperative MI or cardiac arrest. A risk calculator using the NSQIP tool can be found at https://qxmd.com/calculate/calculator_245/gupta-perioperative-cardiac-risk. The American College of Cardiology and American Heart Association endorse both prediction tools and define "elevated risk" as the presence of two or more RCRI predictors or a risk of perioperative MI or cardiac arrest > 1% as calculated by the NSQIP prediction tool.

Table 3–1. Directed bleeding history: Findings suggestive of a bleeding disorder.

Unprovoked bruising on the trunk of > 5 cm in diameter
Frequent unprovoked epistaxis or gingival bleeding
Menorrhagia with iron deficiency
Hemarthrosis with mild trauma
Prior excessive surgical blood loss or reoperation for bleeding
Family history of abnormal bleeding
Presence of severe kidney or liver disease
Use of medications that impair coagulation, including nutritional supplements and herbal remedies

Exercise capacity also predicts cardiac risk. Patients unable to exercise to four metabolic equivalents (METs), which is equivalent to walking two blocks on a flat surface at a normal pace or climbing one to two flights of stairs, have an elevated risk of cardiac complications.

Figure 3–1 shows an approach to perioperative cardiac risk assessment and management based on the 2024 American College of Cardiology and American Heart Association guideline and incorporating prediction tools, functional capacity, biomarkers, and noninvasive ischemia testing.

Role of Preoperative Noninvasive Ischemia Testing

History and physical examination are sufficient to risk stratify most patients. A resting ECG should be obtained in patients with known or suspected heart or vascular disease before major surgery but generally omitted in

Table 3–2. Revised Cardiac Risk Index (RCRI).

Independent Predictors of Postoperative Cardiac Complications	
Intrathoracic, intraperitoneal, or suprainguinal vascular surgery	
History of ischemic heart disease	
History of HF	
Insulin treatment for diabetes mellitus	
Serum creatinine level > 2 mg/dL (> 176.8 mcmol/L)	
History of cerebrovascular disease	
Scoring (Number of Predictors Present)	**Risk of Major Cardiac Complications**[1]
0	0.4%
1	1%
2	2.4%
> 2	5.4%

[1] Cardiac death, MI, or nonfatal cardiac arrest.

Data from Devereaux PJ et al. Perioperative cardiac events in patients undergoing noncardiac surgery: a review of the magnitude of the problem, the pathophysiology of the events and methods to estimate and communicate risk. CMAJ. 2005;173:627.

asymptomatic patients undergoing minor operations. Additional noninvasive ischemia testing rarely improves risk stratification or management and should be avoided in patients without elevated risk based on a prediction tool, undergoing minor operations, or who have at least fair functional capacity. The 2024 American College of Cardiology and American Heart Association guideline emphasizes that ischemia evaluation by stress testing or coronary CT angiography is primarily indicated to exclude high-risk coronary anatomy, such as left main coronary artery disease, rather than to identify undiagnosed CAD or assess risk.

Role of Cardiac Biomarkers

Preoperative BNP or N-terminal fragment of proBNP (NT-proBNP) levels directly correlate with the risk for cardiac complications, and their measurement may improve risk assessment. The 2024 American College of Cardiology and American Heart Association guideline recommends measuring BNP or NT-proBNP in selected patients who have both elevated risk based on a prediction tool and limited functional capacity. Patients with normal biomarker measurements, defined as BNP < 92 ng/L or NT-proBNP < 300 ng/L, generally have acceptable cardiac risk and do not require additional risk stratification testing. A 2014 meta-analysis found that biomarker levels above these thresholds was associated with a fourfold increase in 30-day mortality and MI.

Perioperative Management of Patients with Coronary Artery Disease

Patients with ACS require immediate management of their cardiac disease before any preoperative evaluation (see Chapter 10).

A. Medications

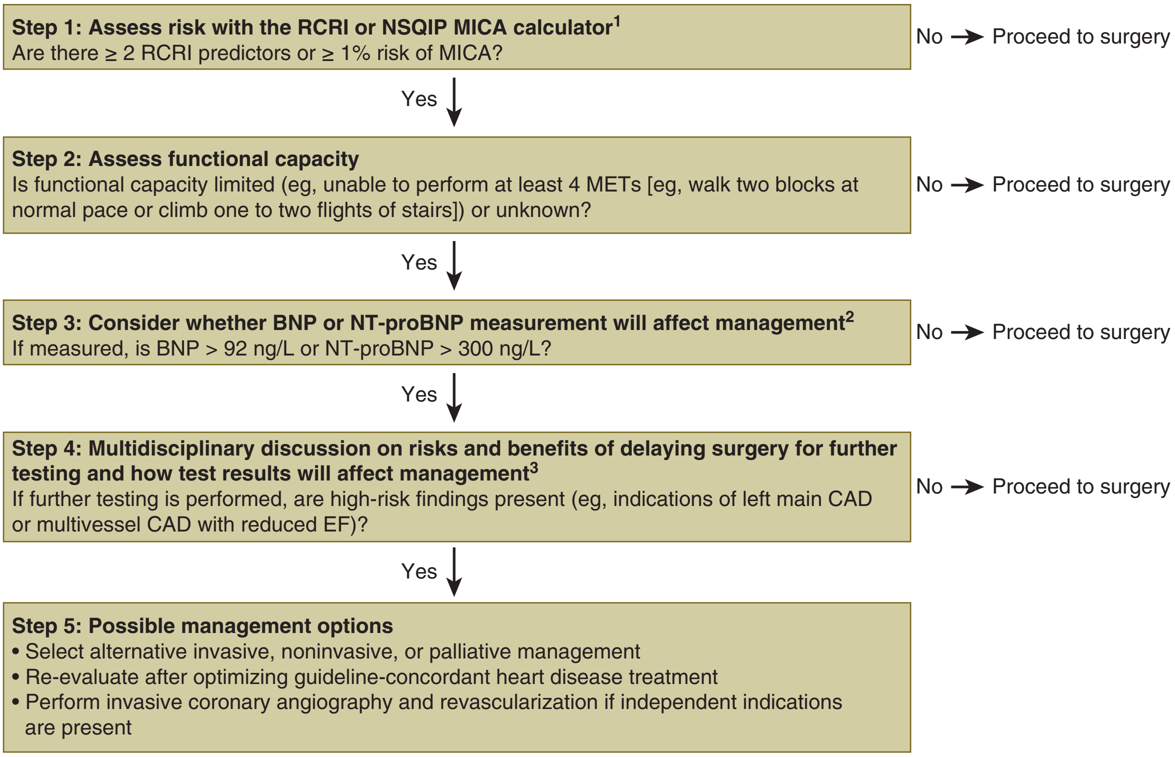
1. Antianginal medications—Preoperative antianginal medications, including β-blockers, calcium channel blockers, and nitrates, should be continued throughout the perioperative period. Several trials have shown that initiation of β-blockers before major noncardiac surgery reduces the risk of nonfatal MI. However, in a 2008 trial, a high fixed-dose of metoprolol succinate *increased* total mortality and the risk of stroke. Because of the uncertain benefit-to-risk ratio, initiation of perioperative β-blockade should be considered only in patients with an indication that is independent of surgery. Initiation should be done far enough in advance of surgery (ideally more than 1 week) to allow time assess tolerability and titrate dosage; β-blockers should not be started on the day of surgery.

2. Statins—Several randomized trials have found that HMG-CoA reductase inhibitors (statins) prevent MI in patients undergoing noncardiac surgery. Safety concerns, such as liver injury or rhabdomyolysis, have not materialized in these studies. Based on treatment protocols used in clinical trials, at least a moderate statin dose (eg, atorvastatin 20 mg or fluvastatin 80 mg orally daily) should be started in statin-naïve adults who meet criteria for long-term statin use and are scheduled for noncardiac surgery. Patients already taking statins should continue these agents during the perioperative period.

3. Aspirin—In patients without coronary stents, initiation of aspirin therapy before noncardiac surgery is not recommended because it did not reduce cardiac risk and caused increased bleeding in a large, randomized trial. Holding long-term prophylactic aspirin therapy in such patients does not increase cardiac risk.

B. Coronary Revascularization

A 2004 trial that randomized over 500 patients with angiographically proven CAD to either coronary revascularization (with either coronary artery bypass grafting [CABG] or percutaneous coronary interventions [PCI]) or medical management alone before vascular surgery found no difference in postoperative MI, 30-day mortality, and long-term mortality. Thus, **preoperative CABG or PCI should be performed only when patients have guideline-concordant indications independent of the planned noncardiac operation.** In addition, surgical patients who have undergone recent coronary stenting are at high risk for stent thrombosis, especially if antiplatelet therapy is stopped prematurely. **Elective surgery should be deferred for at least 30 days after placement of a bare-metal stent, for 6 months after placement of a drug-eluting stent for stable CAD, and for 12 months after drug-eluting stent placement for ACS.** If this delay poses significant risks, such as in patients undergoing an operation for cancer, surgery could be considered 3 months after drug-eluting stent implantation. Antiplatelet agents should be continued perioperatively if possible or resumed as soon as possible after surgery. The patient, surgeon, anesthesiologist, and cardiologist should discuss risks and benefits of delaying surgery and management options for dual antiplatelet therapy.



Step 1: Assess risk with the RCRI or NSQIP MICA calculator[1]
Are there ≥ 2 RCRI predictors or ≥ 1% risk of MICA?

Step 2: Assess functional capacity
Is functional capacity limited (eg, unable to perform at least 4 METs [eg, walk two blocks at normal pace or climb one to two flights of stairs]) or unknown?

Step 3: Consider whether BNP or NT-proBNP measurement will affect management[2]
If measured, is BNP > 92 ng/L or NT-proBNP > 300 ng/L?

Step 4: Multidisciplinary discussion on risks and benefits of delaying surgery for further testing and how test results will affect management[3]
If further testing is performed, are high-risk findings present (eg, indications of left main CAD or multivessel CAD with reduced EF)?

Step 5: Possible management options

- Select alternative invasive, noninvasive, or palliative management
- Re-evaluate after optimizing guideline-concordant heart disease treatment
- Perform invasive coronary angiography and revascularization if independent indications are present

[1] Regardless of prediction tool results, patients who have severe valve disease, severe pulmonary hypertension, cardiac implanted electronic devices, prior coronary revascularization, congenital heart disease, recent stroke, or severe frailty warrant condition-specific evaluation and management before surgery.

[2] If biomarker is not measured, consider deferral of planned operation, alternative invasive or noninvasive treatment, or palliation; or proceed to surgery with knowledge of elevated risk.

[3] Potential evaluation strategies include noninvasive stress testing, coronary CT angiography, and echocardiography. If further testing is not performed, consider deferral of planned operation, alternative invasive or noninvasive treatment, or palliation; or proceed to surgery with knowledge of elevated risk.

▲ **Figure 3–1.** Approach to cardiac evaluation in stable patients undergoing major elective surgery. METs, metabolic equivalents; NSQIP MICA, National Surgical Quality Improvement Program Myocardial Infarction and Cardiac Arrest; RCRI, Revised Cardiac Risk Index.

Postoperative MI

Postoperative MI (defined by a combination of ECG abnormality and cardiac enzyme elevation) typically occurs within 3 days of surgery and is not associated with chest pain in most cases. Clinical findings that should prompt its consideration include unexplained hypotension, hypoxemia, and delirium. Postoperative MI or isolated postoperative elevation of troponin level without ECG abnormalities or other findings of MI are associated with higher mortality, whether or not chest symptoms are present. Canadian and European cardiology society guidelines advocate routine postoperative screening of high-risk patients with troponin levels, whereas American guidelines remain equivocal. Postoperative type 1 MI (caused by a primary coronary event, such as plaque rupture) should generally be managed in the same manner as in nonsurgical patients; however, recent surgery may impose limitations on diagnostic and treatment options, such as anticoagulation. It is unclear how to best manage postoperative type 2 MI or isolated troponin elevation after surgery, but optimizing cardiac risk reduction strategies is reasonable.

Heart Failure & LV Dysfunction

Elective surgery should be postponed until decompensated HF (manifested by an elevated jugular venous pressure, an audible third heart sound, or evidence of pulmonary edema) has been brought under control. In patients with compensated HF, the risk of perioperative cardiac complications is similar in patients with ischemic or nonischemic cardiomyopathy. HF with reduced EF likely confers more risk than HF with preserved EF. Guidelines recommend preoperative echocardiography to evaluate LV function in patients without known HF who have unexplained dyspnea and in patients with known HF with clinical deterioration. Routine evaluation of LV function should not be performed in asymptomatic and clinically stable patients.

Patients receiving diuretics should have serum electrolytes measured before surgery because abnormalities in these levels may increase the risk of perioperative arrhythmias. Clinicians must be cautious not to give too much diuretic since the volume-depleted patient will be much more susceptible to intraoperative hypotension. The surgeon and anesthesiologist should be made aware of the presence and severity of LV dysfunction so that appropriate decisions can be made regarding perioperative fluid management and intraoperative monitoring. Although most HF medications should be continued perioperatively in stable patients, SGLT-2 should be stopped for 3–4 days before elective surgery to reduce the risk of euglycemic ketoacidosis.

Valvular Heart Disease

If the nature or severity of valvular lesions is unknown, or if there has been a recent change in clinical status, echocardiography should be performed before noncardiac surgery. In addition, patients with known or suspected moderate to severe stenotic or regurgitant valvular disease should undergo echocardiography within 1 year before surgery. Candidates for valvular intervention independent of elective noncardiac surgery should have the valve correction procedure performed first. Patients with uncorrected critical or symptomatic aortic stenosis are at particular risk for cardiac complications. They should undergo surgery only after consultation with a cardiologist and anesthesiologist. Patients with asymptomatic moderate or severe aortic stenosis and normal LV systolic function appear to be at lower risk than patients with symptomatic aortic stenosis and may be reasonable surgical candidates with appropriate intraoperative and postoperative monitoring at centers with experience operating on such patients. Patients with mitral stenosis require heart rate control to prolong diastolic filling time. Regurgitant valvular lesions are generally less problematic during surgery because the vasodilatory effect of anesthetics promotes forward flow. Patients with aortic or mitral regurgitation likely benefit from afterload reduction and careful attention to volume status; negative chronotropes may worsen the regurgitant volume and should be avoided.

Arrhythmias

The finding of a rhythm disturbance on preoperative evaluation should prompt consideration of further cardiac evaluation, particularly when the finding of structural heart disease would alter perioperative management. **Patients with adequately controlled rhythm disturbance without evidence of underlying heart disease are at low risk for perioperative cardiac complications.** While long-term antiarrhythmic medications should be continued perioperatively, there is no evidence that the use of medications to suppress an asymptomatic arrhythmia alters perioperative risk.

Patients with symptomatic arrhythmias should not undergo elective surgery until their cardiac condition has been addressed. Adequate rate control of atrial fibrillation or other supraventricular arrhythmias should be established before surgery. Symptomatic ventricular tachycardia must be thoroughly evaluated and controlled before surgery. Patients who have an independent indication for a permanent pacemaker or implanted defibrillator should have it placed before noncardiac surgery. **The anesthesiologist must be notified that a patient has a cardiac implantable electronic device to prevent device malfunction from intraoperative electrocautery.**

After major surgery, previously undiagnosed atrial fibrillation develops in approximately 1% of patients. Although most episodes resolve spontaneously within hours to days, postoperative atrial fibrillation is associated with increased long-term risk of recurrent atrial fibrillation and stroke that may be similar to that of nonoperative cases. Whether the same criteria for anticoagulation therapy should be used for patients undergoing surgery as for patients not undergoing surgery is unclear.

Hypertension

No evidence supports delaying surgery to control mild to moderate hypertension (systolic blood pressure below 180 mm Hg and diastolic blood pressure below 110 mm Hg). Severe hypertension (systolic pressure > 180 mm Hg or a diastolic pressure > 110 mm Hg) appears to be an independent predictor of perioperative cardiac complications, including MI and HF. It is reasonable to consider delaying elective surgery in patients with such severe hypertension until blood pressure can be controlled, although it is not known whether the risk of cardiac complications is reduced with this approach.

Most medications for chronic hypertension should be continued up to and including the day of surgery. Cardiology societies' guidelines differ in their recommendation on whether to continue or hold ACE inhibitors and ARBs on the day of surgery. Continuation increases the risk of intraoperative and postoperative hypotension; however, a 2024 trial found no difference in complications, such as AKI or MI. Diuretic agents are sometimes held on the day of surgery to prevent hypovolemia and electrolyte disorders, although the benefit of this practice is uncertain.

Patients without chronic hypertension may manifest hypertension after surgery, and patients being treated for hypertension often experience decreased control of their blood pressure. Potential causes include elevated sympathetic tone due to injury or pain, volume overload from intravenous fluids, hypercarbia, urine retention, and withholding long-term antihypertensive medications. Before initiating postoperative medical management of hypertension, reversible contributors should be addressed. A 2023 trial found similar outcomes when blood pressure was tightly or loosely controlled during and after surgery.

PULMONARY EVALUATION IN NON–LUNG RESECTION SURGERY

Pneumonia and respiratory failure requiring prolonged mechanical ventilation are the most important postoperative pulmonary complications. The occurrence of these complications has been associated with a significant increase in mortality and hospital length of stay. Pulmonary thromboembolism is another serious complication; prophylaxis against venous thromboembolic disease is detailed in Table 16–14.

Risk Factors for the Development of Postoperative Pulmonary Complications

Procedure-related risk factors for postoperative pulmonary complications include location of surgery (highest rates occur in cardiac, thoracic, and upper abdominal cases), prolonged anesthesia, and emergency cases. Operations not requiring general anesthesia tend to have lower rates of postoperative pulmonary complications; laparoscopic procedures tend to have lower risk than comparable open procedures.

A summary of patient-specific risk factors for pulmonary complications is presented in Table 3–3. The presence and severity of systemic disease of any type is associated with pulmonary complications. In particular, patients with COPD or HF have at least twice the risk of postoperative pulmonary complications compared with patients without these conditions. Advanced age, physical debility, malnutrition, and poor functional capacity also predict higher risk of postoperative pulmonary complications. A NSQIP risk calculator for predicting postoperative respiratory failure is available (https://qxmd.com/calculate/calculator_261/postoperative-respiratory-failure-risk-calculator).

Pulmonary Function Testing & Laboratory Studies

The main role for preoperative pulmonary function testing (PFT) is to identify pulmonary disease in patients with unexplained symptoms before major abdominal or cardiothoracic surgery. In patients with diagnosed lung disease, PFT usually adds little information above clinical assessment. CXRs in unselected patients also rarely add clinically useful information. The benefit of polysomnography to diagnose obstructive sleep apnea before bariatric surgery is unproven. ABG measurement is not routinely recommended except in patients with known lung disease and suspected hypoxemia or hypercapnia.

Table 3–3. Clinical risk factors for postoperative pulmonary complications.

Upper abdominal or cardiothoracic surgery
Prolonged anesthesia time (> 4 hours)
Emergency surgery
Age > 60 years
COPD
HF
Severe systemic disease
Tobacco use (> 20 pack-years)
Impaired cognition or sensorium
Functional dependency or prior stroke
Preoperative sepsis
Low serum albumin level
Obstructive sleep apnea

Preoperative Risk Reduction

Retrospective studies have shown that smoking cessation reduced the incidence of pulmonary complications, but only if it was initiated at least 1–2 months before surgery. A meta-analysis of randomized trials found that preoperative smoking cessation programs reduced both pulmonary and surgical wound complications, especially if smoking cessation was initiated at least 4 weeks before surgery. **The preoperative period may be an optimal time to initiate smoking cessation efforts.** A systematic review found that smoking cessation programs started in a preoperative evaluation clinic increased the odds of abstinence at 3–6 months by nearly 60%.

Elective surgery should not be scheduled within 2 weeks of SARS-CoV-2 infection, and risks and benefits should be assessed when infection occurred 2–7 weeks before scheduled surgery.

Postoperative Risk Reduction

Postoperative risk reduction strategies have centered on promoting lung expansion using incentive spirometry, deep breathing exercises, and in selected populations, continuous positive airway pressure (CPAP) or intermittent positive-pressure breathing (IPPB). Although trial results have been mixed, all these techniques reduce the incidence of postoperative atelectasis and, in a few studies, reduce the incidence of other postoperative pulmonary complications. In most comparative trials, these methods were equally effective. Given the higher cost of CPAP and IPPB, **incentive spirometry and deep breathing exercises are the preferred methods for most patients.** Multicomponent respiratory care programs may be particularly beneficial. One program termed "I COUGH"—an acronym for *I*ncentive spirometry, *C*oughing and deep breathing, *O*ral care, *U*nderstanding (patient education), *G*et out of bed (early ambulation), and *H*ead of bed elevation—reduced the rates of pneumonia and unplanned intubation after general and vascular surgery.

EVALUATION OF THE PATIENT WITH LIVER DISEASE

Risk Assessment in Surgical Patients with Liver Disease

Screening unselected patients with liver biochemical tests has a low yield and is not recommended. Patients with suspected or known liver disease based on history or physical examination, however, should have measurement of liver enzyme levels as well as tests of hepatic synthetic function performed before surgery.

Elective surgery in patients with acute viral or alcoholic hepatitis should be delayed until the acute episode has resolved. In three small series of patients with acute viral hepatitis who underwent abdominal surgery, the mortality rate was roughly 10%. Similarly, patients with undiagnosed alcoholic hepatitis had high mortality rates when undergoing abdominal surgery. In the absence of cirrhosis or synthetic dysfunction, chronic viral hepatitis is unlikely to increase risk significantly. Similarly, nonalcoholic fatty liver disease without cirrhosis probably does not pose a serious risk in surgical patients.

In patients with cirrhosis, postoperative complication rates correlate with the severity of liver dysfunction, and decompensated cirrhosis is associated with an extremely high perioperative mortality. Traditionally, severity of dysfunction has been assessed with the Child-Pugh score (see Chapter 18). A conservative approach would be to avoid elective surgery in patients with Child-Pugh class C cirrhosis and pursue it with great caution in class B patients. The Model for End-stage Liver Disease (MELD) score, based on serum bilirubin and creatinine levels, and the prothrombin time expressed as the INR, also predicted surgical mortality and outperformed the Child-Pugh classification in some studies. Generally, a MELD score < 10 predicts low risk, whereas a score > 16 portends high mortality after elective surgery. The VOCAL-Penn score also predicted mortality and risk of hepatic decompensation in surgical patients with cirrhosis and performed better than MELD-based prediction tools in an external validation study.

Ascites, encephalopathy, and coagulopathy should be controlled preoperatively. Ascites is a particular problem in abdominal operations, where it can lead to wound dehiscence and hernias. Great care should be taken when using analgesics and sedatives, since these can worsen hepatic encephalopathy; in general, short-acting agents and lower doses should be used. Postoperative constipation should be aggressively treated because it can precipitate encephalopathy. Kidney function and volume status need to be closely monitored to prevent AKI and volume overload, which are common complications in these patients. Patients with coagulopathy should receive vitamin K and may need fresh frozen plasma transfusion at the time of surgery; however, transfusing to a specific INR target for cirrhosis is discouraged.

Kalo E et al. Evolution of risk prediction models for post-operative mortality in patients with cirrhosis. Hepatol Int. 2023;17:542. [PMID: 36971983]

PERIOPERATIVE HEMATOLOGIC EVALUATION

Three of the more common clinical situations faced by the medical consultant are anemia, assessment of bleeding risk, and the perioperative management of long-term anticoagulation.

The main goals of the preoperative evaluation of patients with anemia are to determine the need for preoperative diagnostic evaluation and the need for transfusion. **When feasible, the diagnostic evaluation of the patient with previously unrecognized anemia should be done before surgery because certain types of anemia (particularly those due to sickle cell disease, hemolysis, and acute blood loss) have implications for perioperative management.** These types of anemia are typically associated with an elevated reticulocyte count. Given the prevalence of iron deficiency, excluding it as the cause of anemia is reasonable. However, the practice of administering intravenous iron to unselected patients with anemia before elective surgery has not been proven beneficial. Preoperative anemia is associated with higher perioperative morbidity and mortality. Whether raising preoperative hemoglobin level to specific targets will improve postoperative outcomes is unknown. The clinician determining the need for preoperative transfusion in a patient must consider factors other than the absolute hemoglobin level, including the presence of cardiopulmonary disease, the type of surgery, and the likely severity of surgical blood loss. For most hemodynamically stable hospitalized patients, the AABB (formerly American Association of Blood Banks) recommends transfusion for a hemoglobin level < 7 g/dL (70 g/L). However, a meta-analysis of trials comparing transfusion strategies suggests that a trigger of 8 g/dL (80 g/L) was associated with lower mortality than more restrictive thresholds in surgical patients. Furthermore, many transfusion trials in surgical patients used a slightly higher threshold of 7.5–8 g/dL (75–80 g/L) in their restrictive transfusion arm. Thus, the AABB states that a threshold of 7.5 g/dL (75 g/L) could be considered for hospitalized patients undergoing cardiac surgery, and 8 g/dL (80 g/L) could be considered for hospitalized patients undergoing orthopedic surgery or who have underlying CVD.

The most important component of the bleeding risk assessment is a directed bleeding history (see Table 3–1). Patients who provide a reliable history of no abnormal bleeding and have no suggestion of abnormal bleeding on physical examination are at very low risk for having an occult bleeding disorder. Laboratory tests of hemostatic parameters in these patients are generally not needed. When the directed bleeding history is unreliable or incomplete, or when abnormal bleeding is suggested, a formal evaluation of hemostasis should be done before surgery and include measurement of the prothrombin time, activated partial thromboplastin time, and platelet count (see Chapter 14).

Patients receiving long-term oral anticoagulation are at risk for thromboembolic complications when an operation requires interruption of this therapy. However, “bridging anticoagulation,” where unfractionated or low-molecular-weight heparin is administered parenterally while oral anticoagulants are held, has not been shown to be beneficial and can increase bleeding. A cohort study found that DOACs could be safely held without bridging by using a protocol based on the patient’s kidney function; the DOACs are withheld several days before surgery and restarted

Table 3–4. Recommendations for perioperative management of DOACs.

Drug and Kidney Function	Last Dose Before Procedure	Resume Medication
Dabigatran with normal creatinine clearance (> 50 mL/min [0.83 mL/s]); rivaroxaban, apixaban, edoxaban	2 days before procedure with low risk of bleeding or 3 days before procedure with high risk of bleeding	If hemostasis is adequate, resume 24 hours after procedure with low risk of bleeding or 48–72 hours after procedure with high risk of bleeding
Dabigatran with reduced creatinine clearance (30–50 mL/min [0.5–0.83 mL/s])	3 days before procedure with low risk of bleeding or 5 days before procedure with high risk of bleeding	

24–48 hours after surgery if hemostasis appears adequate (Table 3–4). A 2015 randomized trial of bridging anticoagulation in surgical patients taking warfarin for atrial fibrillation demonstrated no difference in thromboembolism between those with and without bridging. Bleeding complications, however, were twice as common in patients who received bridging anticoagulation. A 2021 trial of postoperative bridging anticoagulation that included patients with atrial fibrillation or mechanical prosthetic heart valves also found no benefit for stroke prevention. **Most experts recommend bridging therapy only in patients at high risk for thromboembolism.** An approach to perioperative anticoagulation management with warfarin is shown in Table 3–5, but the recommendations must be considered in the context of patient preference and hemorrhagic risk.

NEUROLOGIC EVALUATION

Delirium can occur after any major operation but is particularly common after hip fracture repair and cardiovascular surgery, where the incidence is 30–60%. Postoperative delirium has been associated with higher rates of major postoperative cardiac and pulmonary complications, poor functional recovery, increased length of hospital stay, increased risk of subsequent dementia and functional decline, and increased mortality. The American Geriatrics Society recommends screening preoperative patients for these delirium risk factors: age > 65 years, chronic cognitive impairment or dementia, severe illness, poor vision or hearing, and the presence of infection. Patients with any of these risk factors should be enrolled in a multicomponent, nonpharmacologic delirium prevention program after surgery, which includes interventions such as reorientation, sleep hygiene, bowel and bladder care, mobilization and physical therapy, and the elimination of unnecessary medications. Moderate-quality evidence supports the use of these nonpharmacologic interventions.

Only a minority of patients with postoperative delirium will have a single, reversible etiology for their condition (see Delirium, Chapter 4). Evaluation of delirious patients

Table 3–5. Recommendations for management of perioperative anticoagulation with warfarin.

Thromboembolic Risk without Anticoagulation	Recommendation
Low Risk (eg, atrial fibrillation with CHA$_2$DS$_2$VASc score 0–6,[1] mechanical bileaflet aortic valve prosthesis, or single VTE > 3 months ago without hypercoagulability condition[2])	Stop warfarin 5 days before surgery Measure INR the day before surgery to confirm that it is acceptable (< 1.6 for most operations) Resume warfarin when hemostasis permits No bridging with parenteral anticoagulants before or after surgery
High Risk (eg, either atrial fibrillation or mechanical heart valve with stroke < 3 months prior, atrial fibrillation with CHA$_2$DS$_2$VASc score 7–9,[1] mechanical mitral valve prosthesis, caged-ball or tilting disk valve prosthesis, or VTE < 3 months ago or associated with hypercoagulability condition[2])	Stop warfarin 5 days before surgery Begin bridging with therapeutic dose UFH infusion or LMWH 2 days after stopping oral anticoagulation Administer last dose of LMWH 24 hours before surgery; discontinue UFH 4–6 hours before surgery Measure INR the day before surgery to confirm that it is acceptable (< 1.6 for most operations) Resume warfarin when hemostasis permits If hemostasis permits, consider bridging with therapeutic dose UFH infusion or LMWH beginning 48–72 hours after surgery and continuing until the INR is therapeutic

[1] See Table 12–2.

[2] Patients should receive VTE prophylaxis after surgery (see Chapter 16).

LMWH, low-molecular-weight heparin; UFH, unfractionated heparin.

should exclude electrolyte derangements, occult UTI, and adverse effects from psychotropic medications such as opioids, sedatives, anticholinergic agents, and antispasmodics. Conservative management includes reassuring and reorienting the patient; eliminating unneeded medications, intravenous lines, and urinary catheters; and keeping the patient active during the day while allowing uninterrupted sleep at night. Use of multimodal postoperative analgesic strategies can reduce or avoid the need for opioids. Scheduled administration of non-opiate analgesics such as acetaminophen or NSAID in the absence of contraindications often forms the core of these techniques. The analgesic effect of both opioid and non-opioid analgesics can be augmented by medications, such as gabapentin, which targets neuropathic pain; local or regional anesthetic agents; and nonpharmacologic approaches such as cognitive-behavioral therapy. When agitation jeopardizes patient or provider safety, neuroleptic agents given at the lowest effective dose for the shortest duration needed are preferred over the use of benzodiazepines or physical restraints (Table 28–1).

Stroke complicates < 1% of all surgical procedures but may occur in 1–6% of patients undergoing cardiac or carotid artery surgery. Most of the strokes in cardiac surgery patients are embolic in origin, and about half occur within the first postoperative day. Patients who had previously suffered a stroke had a high risk of MI, recurrent stroke, or cardiac death if they underwent noncardiac surgery within 3 months of the stroke. One retrospective study found that this risk declined over time and reached a nadir 9 months after the stroke, while another study found little additional risk reduction after 3 months. American cardiology and neurology societies suggest delaying elective surgery for 6–9 months after a stroke.

Symptomatic carotid artery stenosis is associated with a high risk of stroke in patients undergoing cardiac surgery. In general, patients with independent indications for correction of carotid stenosis should have the procedure done before elective surgery. In contrast, most studies suggest that asymptomatic carotid bruits and asymptomatic carotid stenosis are associated with little or no increased risk of stroke in surgical patients.

MANAGEMENT OF ENDOCRINE DISEASES

Diabetes Mellitus

The goal of management for all patients with diabetes is the prevention of severe hyper- or hypoglycemia in the perioperative period. In addition, patients with type 1 diabetes are at risk for developing ketoacidosis. Increased secretion of cortisol, epinephrine, glucagon, and growth hormone during and after surgery causes insulin resistance and hyperglycemia in patients with diabetes. Conversely, reduced caloric intake after surgery and frequent, unpredictable periods of fasting increase the risk for hypoglycemia. Thus, all surgical patients with diabetes require frequent blood glucose monitoring. Ideally, such patients should undergo surgery early in the morning to avoid prolonged fasting. The specific pharmacologic management of diabetes during the perioperative period depends on the type of diabetes (insulin-dependent or not), the level of glycemic control, and the type and length of surgery.

Poor preoperative glycemic control, sometimes defined as a hemoglobin A_{1c} level > 8%, is associated with a greater risk of surgical complications, particularly infections. However, a strategy of delaying surgery until glycemic control improves has not been rigorously studied. The ideal postoperative blood glucose target is also unknown. Based on trials that showed increased mortality in hospitalized patients randomized to tight control, the American College of Physicians recommends maintaining serum glucose between 140 mg/dL and 200 mg/dL (7.8–11.1 mmol/L), whereas the British National Health Service guidelines recommend a range of 108–180 mg/dL (6–10 mmol/L).

A. Diabetes Controlled by Diet

For people with diabetes controlled with diet alone, no special precautions must be taken unless diabetic control is markedly disturbed by the procedure. If this occurs, small doses of short-acting insulin as needed will correct the hyperglycemia.

B. Diabetes Treated with Oral Hypoglycemic Agents

Most oral hypoglycemic agents should be held on the day of surgery. However, the SGLT-2 inhibitors (eg, canagliflozin) should be discontinued for 3–4 days before surgery due to their long half-life and associated risk of ketoacidosis. Oral hypoglycemic agents should not be restarted after surgery until patients are clinically stable and oral intake is adequate and unlikely to be interrupted. A possible exception are dipeptidyl peptidase-4 inhibitors which have a low risk of causing hypoglycemia and might be continued perioperatively. Patients who experience significant hyperglycemia when oral agents are held should be treated in the same way as patients with type 2 diabetes who require insulin, as described below. Postoperative kidney function should be checked with a serum creatinine level before restarting metformin.

C. Diabetes Treated with Insulin

The protocol used to control glucose depends on (1) the kind of diabetes (type 1 or type 2); (2) whether it is minor surgery (lasting < 2 hours and patient able to eat afterward) or major surgery (lasting more than 2 hours, with invasion of a body cavity, and patient not able to eat afterward); and (3) the preoperative insulin regimen (basal bolus or premixed insulin twice a day or premeal bolus only or regular insulin before meals and NPH at bedtime).

1. Preoperative insulin regimen—For patients with either type 1 or type 2 diabetes who are receiving insulin, a common practice is to reduce the last preoperative dose of long-acting, basal insulin (used to control fasting glucose levels) by 30–50% and hold rapid-onset, short-acting nutritional insulin (used to prevent hyperglycemia following meals).

2. Perioperative insulin regimen—Patients with type 1 diabetes must receive basal insulin to prevent the development of diabetic ketoacidosis. **Consultation with an endocrinologist or hospitalist should be strongly considered when a patient with type 1 diabetes mellitus undergoes major surgery.** Major surgical procedures in patients with type 1 diabetes lasting more than 2 hours usually require an insulin infusion. Some patients with type 2 diabetes who are taking insulin will also need insulin infusion to maintain adequate glycemic control. An insulin infusion is a complex procedure for a high-risk medication and involves extensive monitoring, dose titrations, and contingency plans. There are a number of algorithms available for insulin infusions (http://ucsfinpatientdiabetes.pbworks.com).

3. Postoperative insulin regimen—After surgery, when a patient with either type 1 or type 2 diabetes has resumed adequate oral intake, subcutaneous administration of insulin can be restarted. Intravenous administration of insulin and dextrose can be stopped 30 minutes after the first subcutaneous dose of long-acting insulin. Insulin needs may vary in the first several days after surgery because of continuing postoperative stresses and because of variable caloric intake. In this situation, multiple doses of short-acting insulin plus some long-acting basal insulin, guided by blood glucose determinations, can keep the patient in acceptable metabolic control. Use of correctional insulin only (without basal or nutritional insulin) after surgery is discouraged.

Glucocorticoid Replacement

Hypotension or shock resulting from primary or secondary adrenocortical insufficiency is rare, and the practice of administering supraphysiologic "stress-dose" glucocorticoid perioperatively is inadequately studied. A guideline from rheumatology and orthopedic surgery societies recommends that patients taking glucocorticoids continue their regimen when undergoing arthroplasty and not receive "stress-dose" glucocorticoids. Another approach is to administer stress-dose glucocorticoids to patients who have received the equivalent of at least 7.5 mg of prednisone daily for 3 weeks within the past year when they undergo major surgery. A commonly used stress-dose regimen is hydrocortisone 100 mg intravenously daily, divided every 8 hours, beginning before induction of anesthesia and stopped after 24 hours without tapering. Patients who have been taking < 5 mg of prednisone daily and those receiving alternate-day glucocorticoid dosing are unlikely to require supplemental coverage.

Thyroid Disease

Severe symptomatic hypothyroidism has been associated with perioperative complications, including intraoperative hypotension, HF, cardiac arrest, and death. Elective surgery should be delayed in patients with severe hypothyroidism until adequate thyroid hormone replacement can be achieved. Patients with symptomatic hyperthyroidism are at risk for perioperative thyroid storm and should not undergo elective surgery until their thyrotoxicosis is controlled; an endocrinologist should be consulted if emergency surgery is needed. Patients with mild hypothyroidism (median TSH level 8.6 mIU/L) tolerate surgery well, with only a slight increase in the incidence of intraoperative hypotension; surgery need not be delayed for the month or more required to ensure adequate thyroid hormone replacement.

Chen Cardenas SM et al. Perioperative evaluation and management of patients on glucocorticoids. J Endocr Soc. 2022;7: bvac185. [PMID: 36545644]

KIDNEY DISEASE

The development of AKI in patients undergoing general surgery is an independent predictor of mortality, even if mild or if kidney dysfunction resolves. The mortality associated with the development of perioperative AKI that requires dialysis exceeds 50%. Risk factors associated with postoperative deterioration in kidney function are shown in Table 3–6. Several medications, including "renal-dose" dopamine, mannitol, *N*-acetylcysteine, and clonidine, failed to preserve kidney function during the perioperative period in clinical trials and should not be used for this indication. **Maintenance of adequate intravascular volume is likely to be the most effective method to reduce the risk of perioperative deterioration in kidney function.** Exposure to renal-toxic agents, such as NSAIDs and intravenous contrast, should be minimized or avoided. ACE inhibitors and ARBs reduce renal perfusion and may increase the risk of perioperative AKI. Although firm evidence is lacking, it

Table 3–6. Risk factors for the development of AKI after non-cardiac surgery.[1]

Age > 50 years
CKD
HF
Hepatic failure
Diabetes mellitus
Sepsis
Volume depletion
Crush injury
Volume depletion

may be useful to temporarily discontinue these medications in patients at risk for perioperative AKI.

Although the mortality rate for elective major surgery is low (1–4%) in patients with dialysis-dependent ESRD, the risk for perioperative complications, including postoperative hyperkalemia, pneumonia, fluid overload, and bleeding, is substantially increased. Patients should undergo dialysis preoperatively within 24 hours before surgery, and their serum electrolyte levels should be measured just before surgery and monitored closely during the postoperative period.

ANTIBIOTIC PROPHYLAXIS OF SURGICAL SITE INFECTIONS

Surgical site infection (SSI) is estimated to occur in roughly 4% of general or vascular operations. Although the type of procedure is the main factor determining the risk of developing a SSI, certain patient factors are associated with increased risk, including diabetes mellitus, older age, obesity, cigarette smoking, heavy alcohol consumption, admission from a long-term care facility, and multiple medical comorbidities. **For most major procedures, prophylactic antibiotics have been shown to reduce the incidence of SSIs.** Substantial evidence suggests that a single dose of an appropriate intravenous antibiotic—or combination of antibiotics—administered 30–60 minutes before skin incision is as effective as multiple-dose regimens that extend into the postoperative period. For most procedures, a first-generation cephalosporin (eg, cefazolin 2 g intravenously) is as effective as later-generation agents.

Guidelines for antibiotic prophylaxis against infective endocarditis in patients undergoing invasive procedures are presented in Chapter 38. Given the lack of evidence for antibiotic prophylaxis before dental procedures to prevent prosthetic joint infection, guidelines from the American Academy of Orthopedic Surgeons and the American Dental Association recommend against this practice.

Geriatric Disorders

Leah J. Witt, MD
Rossana Lau-Ng, MD
Tina R. Sadarangani, PhD, RN, ANP-C, GNP-BC, FAAN
G. Michael Harper, MD

GENERAL PRINCIPLES OF GERIATRIC CARE

The following principles help guide the care of older adults:

1. Many disorders are multifactorial in origin and are best managed by multifactorial interventions.
2. Diseases often present atypically or with nonspecific symptoms (eg, confusion, functional decline).
3. Not all abnormalities require evaluation and treatment.
4. Multiple chronic conditions and geriatric syndromes often coexist and should be managed in concert with one another.

The Geriatric 5Ms is a framework for optimizing care for the older adult, addressing Mind, Mobility, Medications, Multicomplexity, and what Matters Most. This framework represents a practical and easy-to-remember summary of core geriatric principles. "Mind" relates to dementia, delirium, and depression. "Mobility" relates to immobility, falls, and gait disorders. "Medications" includes pharmacotherapy and polypharmacy. What "Matters Most" assesses patient values and goals of care. "Multicomplexity" is evaluated (for example, in a comprehensive geriatric assessment) to guide treatment decision-making, incorporating the interplay of disease burden, comorbidities, functional status, prognosis, and patient preferences.

COMPREHENSIVE ASSESSMENT OF THE OLDER ADULT

The comprehensive geriatric assessment (CGA) is a multidisciplinary evaluation of an older adult's medical conditions, functional limitations, and psychosocial risk factors. Its outcome is a goal-concordant care plan that maximizes the health and well-being of the individual being evaluated. CGAs incorporate an evaluation of the Geriatric 5M "multicomplexity," which (1) expands upon the conventional assessment of symptoms, diseases, and medications; (2) considers the biopsychosocial situation; and (3) includes an analysis of prognosis, values and preferences, and ability to function independently.

▶ Assessment of Prognosis

When an older person's life expectancy is > 10 years (ie, 50% of similar persons live > 10 years), it is reasonable to consider effective tests and treatments such as they are considered in younger persons. When life expectancy is < 10 years (and especially when it is much less), choices of tests and treatments should be made based on their ability to affect *a clinical outcome that is valued by the patient in the context of their estimated life expectancy* (Figure 4–1). The relative benefits and harms of tests and treatments often change as prognosis worsens and net benefit (benefits minus harms) diminishes.

Social determinants of health are important factors that impact health outcomes and prognosis. As part of the comprehensive assessment, asking about socioeconomic status, food security, access to healthcare, education, support system, and neighborhoods can impart significant insight into the management of chronic diseases, outcomes after acute hospitalizations, or medical decisions.

▶ Assessment of Values & Preferences

Although patients vary in their values and preferences, *many frail older adults prioritize maintaining their independence over prolonging survival*. Values and preferences, described by the Geriatric 5M what "Matters Most," are determined by speaking directly with a patient or, when the patient cannot express preferences reliably, with the patient's surrogate.

In assessing values and preferences, it is important to keep in mind the following:

1. Patients are experts about their preferences for outcomes and experiences; however, they may not have adequate information to make and express informed preferences for specific tests or treatments.
2. Patients' preferences often change over time. For example, some patients find living with a disability more acceptable than they thought before experiencing it.

▶ Assessment of Function

People often lose function in multiple domains as they age, and as a result, they may not be able to do some activities as quickly or capably and may need assistance. Assessment of function improves prognostic estimates. *Assessment of function, which is described by the Geriatric 5M "Mobility," is essential to determine an individual's needs in the context of his or her values and preferences and the possible effects of recommended treatment.*

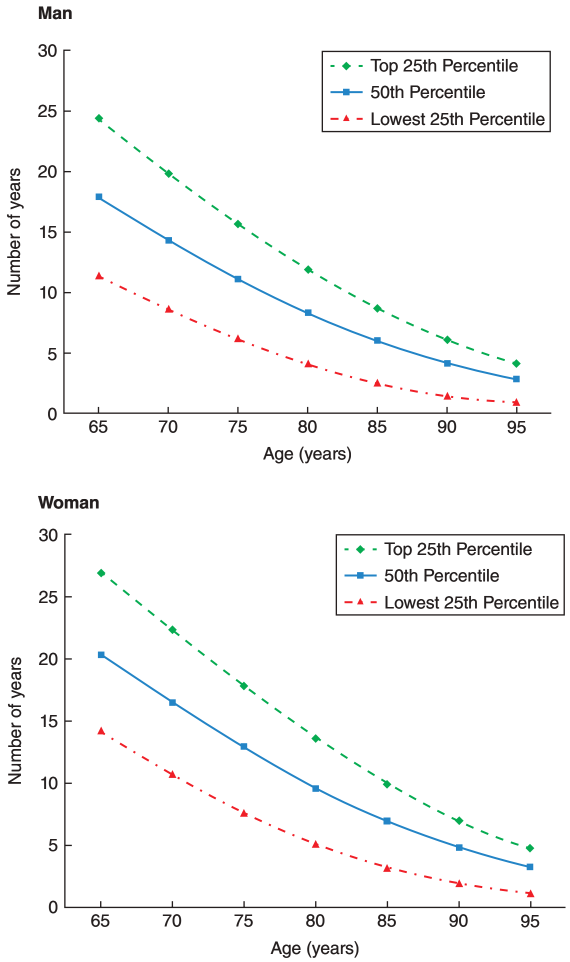

Figure 4–1. Median life expectancy of older men and women. (Data derived from Arias E. United States Life Tables, 2011. Natl Vital Stat Rep. 2015;64(11):1–63.)

About one-fourth of patients over age 65 and half of persons older than 85 need help performing their **basic activities of daily living (ADLs)**, such as bathing, dressing, eating, transferring from bed to chair, continence, and toileting; or **instrumental activities of daily living (IADLs)**, such as transportation, shopping, cooking, using the telephone, managing money, taking medications, housecleaning, or laundry.

Functional screening should include assessment of ADLs and IADLs and questions to detect weight loss, falls, incontinence, depressed mood, self-neglect, fear for personal safety, and common serious impairments (eg, hearing, vision, cognition, and mobility). One technique for these patients is to identify and ask about a *target routine activity*, such as bowling or gardening. Difficulty with or discontinuation of the activity may indicate new or worsening impairment.

Frailty

Frailty is a syndrome characterized by loss of physiologic reserve and dysregulation across multiple systems, ultimately resulting in greater risk of poor health outcomes. Estimates of its prevalence in community-dwelling older adults range from 4.0% to 59.1%. Elements of frailty include **weakness (diminished grip strength), slow gait speed, decreased physical activity, weight loss,** and **exhaustion or low energy.** While there is not one universally agreed upon definition or assessment tool for frailty, generally an individual is defined as frail when three or more of the above features are present. Persons with frailty are at increased risk for falls, hospitalization, functional decline, poorer outcomes associated with medical interventions (eg, surgery, dialysis), and death. *Exercise, particularly strength and resistance training, can increase walking speed and improve function.* There is evidence that optimal nutrition, especially higher levels of protein intake, may be associated with reduced incidence of frailty. However, once frailty is established, the treatment is largely supportive, multifactorial, and individualized based on patient goals, life expectancy, and chronic conditions. Sometimes, transitioning a patient to a comfort-focused or hospice approach is the most appropriate clinical intervention when irreversible complications from frailty develop.

MANAGEMENT OF COMMON GERIATRIC PROBLEMS

1. Dementia

ESSENTIALS OF DIAGNOSIS

- Progressive decline of mental processes.
- Acquired cognitive deficits severe enough to impair function.
- Not due to delirium or another mental disorder.

General Considerations

Dementia, also called major neurocognitive disorder, is an acquired, persistent, and progressive impairment in mental processes, with compromise of one or more cognitive domains. The *DSM-5* identifies these domains (with example deficits) as: (1) **complex attention** (easily distracted, difficulty performing calculations), (2) **executive function** (poor organizing, mental flexibility, planning, and judgment), (3) **learning and memory** (difficulty recalling items from a list, forgetting recent events), (4) **language** (word finding and object naming difficulty), (5) **perceptual-motor function** (difficulty navigating in known environments, copying a drawing), and (6) **social cognition** (change in personality, trouble reading social cues).

The diagnosis of dementia requires a significant decline in function that is *severe enough to result in the loss of independence in IADLs.*

For the past two decades, the prevalence of dementia among US adults 65 years or older has been declining. This improvement has been attributed to higher education levels and better control of cardiovascular risk factors. However, as the population continues to age, the overall burden of disease continues to grow, and some evidence shows that dementia mortality increased between 1999 and 2020 in the United States. (See Chapter 27 for further details about dementia in young people.) Alzheimer disease accounts for roughly two-thirds of dementia cases in the United States, with vascular dementia (either alone or combined with Alzheimer disease) and Lewy body dementia accounting for much of the rest.

Depression and delirium are also common in older adults, may coexist with dementia, and may also present with cognitive impairment. Delirium, characterized by acute confusion, occurs much more commonly in patients with underlying dementia. Major depressive disorder may occur in up to 20–50% of patients with dementia, and because they share common features, distinguishing the two can prove difficult. Psychiatric disease sometimes leads to complaints of impaired cognition (**pseudodementia**). Impaired attention is usually to blame, and in some patients with depression or anxiety, poor focus and concentration may even be a primary complaint. The symptoms should improve with appropriate psychiatric treatment. Mood disorders are commonly seen in patients with neurodegenerative disease and in some cases are an early symptom. There is some evidence that a persistent, untreated mood disorder may predispose to the development of an age-related dementia, and psychiatric symptoms can exacerbate cognitive impairment in patients who already have dementia; therefore, suspicion of dementia should not distract from appropriate screening for and treatment of depression or anxiety. In persons diagnosed with depressive pseudodementia, ongoing surveillance for cognitive impairment is warranted because many will develop dementia over time.

Clinical Findings

A. Screening

1. Cognitive impairment—According to the USPSTF, there is insufficient evidence to recommend for or against screening all older adults for cognitive impairment. While there is logic in the argument that early detection may improve future planning and patient outcomes, empiric evidence that demonstrates a clear benefit for either patients or caregivers is lacking. For primary care clinicians, the Medicare Annual Wellness Visit mandates that clinicians assess patients for cognitive impairment based on the clinician's observations and reports from others.

At-home genetic testing for the Alzheimer disease susceptibility gene APOE-e4 is US FDA-approved and available to consumers. Although APOE-e4 carrier status influences the risk for developing Alzheimer disease, not all carriers will develop the dementia syndrome. Therefore, routine testing for screening purposes is *not* recommended, and for individuals who are considering it, genetic counseling should occur first.

When there is suspicion of cognitive impairment, a clinical evaluation that includes a cognitive history and a brief validated cognitive assessment instrument should follow. An example is the **Mini-Cog**, a combination of a three-item word recall with a clock drawing task that can be completed in 3 minutes. When a patient fails this simple test, further cognitive evaluation is warranted. The **Montreal Cognitive Assessment (MoCA©)** is a 30-point test that takes about 10 minutes to administer and examines several areas of cognitive function. A score below 26 has a sensitivity of 0.94 or more and a specificity of 0.60 or less. Free downloadable versions in multiple languages are available at https://www.mocatest.org. Completion of a training and certification program or signing a disclaimer if you choose not to take the training is required to gain access to the test.

2. Decision-making capacity—Older adults with cognitive impairment commonly face serious medical decisions, and the clinicians involved in their care must ascertain whether the capacity exists to make medical decisions. To make a determination of capacity, the clinician should interview the patient using open-ended questions to assess the following four abilities: (1) **understanding** relevant information about the patient's condition, including the risks and benefits of the proposed intervention and the alternatives (including no intervention); (2) **expressing** a choice; (3) **appreciating** the relevant facts and how they relate to the patient's own situation; and (4) **reasoning** as demonstrated by comparing the consequences of the potential decisions.

Sensitivity must be used in applying these four components to people of various cultural backgrounds. *Decision-making capacity varies over time and is decision specific.*

B. Symptoms and Signs

Most patients with dementia can be identified by a primary care clinician after completion of a history (often requiring collateral information), a physical examination, and cognitive testing. The clinician can gather additional information about the type of dementia by asking about (1) the rate of progression of the deficits as well as their nature (including any personality or behavioral change); (2) the presence of other neurologic and psychiatric symptoms, particularly motor problems and psychotic symptoms; (3) risk factors for HIV; (4) family history of dementia; and (5) medications, with particular attention to recent changes.

The time of symptom onset must be established, but subtle, early symptoms are often apparent only in retrospect. Another event, such as an illness or hospitalization, may lead to new recognition of existing symptoms. Symptoms often accumulate over time, and *the nature of the earliest symptom is most helpful in forming the differential diagnosis.* The history should establish risk factors for dementia, including family history, other chronic illnesses, and vascular disease risk factors. Finally, it is important to document the patient's current capacity to perform basic and instrumental activities of daily living and to note the extent of decline from the premorbid level of function.

Indeed, *this functional assessment defines the presence and severity of dementia.*

Workup is directed at identifying any potentially *reversible* causes of dementia. However, such cases are rare. For a detailed description of the symptoms and signs of different forms of dementia, see Chapter 27.

C. Physical Examination

The neurologic examination emphasizes assessment of mental status but should also include evaluation for sensory deficits, previous strokes, parkinsonism, gait impairment, and peripheral neuropathy. The examination should focus on identifying comorbid conditions that may aggravate the individual's disability. A **neuropsychiatric evaluation** by a trained neuropsychologist or psychometrician may be helpful, particularly in cases with diagnostic uncertainty and to distinguish dementia from depression. The goals of such testing are to enhance localization by defining the cognitive domains that are impaired and to quantify the degree of impairment. There is no standard battery of tests, but several metrics are commonly used to assess the symptom types previously mentioned. Assessments are most accurate when a patient is well-rested, comfortable, and otherwise medically stable.

D. Laboratory Findings

For patients with dementia, laboratory studies should include a CBC and serum electrolytes, calcium, creatinine, glucose, TSH, and vitamin B_{12} levels. While hypothyroidism or vitamin B_{12} deficiency may contribute to the cognitive impairment, treating these conditions typically does *not* reverse the dementia. HIV and rapid plasma reagin (RPR) tests, a heavy metal screen, and liver biochemical tests may be informative in selected patients but are not part of routine testing. Analysis of CSF has previously been required for definitive diagnosis, but blood testing for Alzheimer disease via amyloid-β and tau proteins demonstrates high accuracy and is awaiting FDA approval. For a detailed description of laboratory findings, see Chapter 27.

E. Imaging

The American Academy of Neurology recommends neuroimaging (noncontrast head CT or MRI) in all patients with dementia while other experts limit routine use of neuroimaging to those patients more likely to have a structural cause of dementia (eg, subdural hematoma, tumor, previous stroke, or hydrocephalus). Those who are younger; those who have focal neurologic symptoms or signs, seizures, or gait abnormalities; and those with an acute or subacute onset are most likely to have positive findings and most likely to benefit from MRI scanning. In older patients with a more classic picture of Alzheimer disease for whom neuroimaging is considered, a noncontrast CT scan is sufficient. For a detailed description of imaging, see Chapter 27.

Differential Diagnosis

Older individuals experience occasional difficulty retrieving items from memory (usually word-finding difficulty) and experience a slowing in their rate of information processing. In the amnestic type of **mild cognitive impairment (MCI),** a patient describes memory problems, demonstrates mild deficits (most commonly in short-term memory) on formal testing, but the impairment does not significantly impact function. Annual dementia conversion rates vary from < 5–15%. An older patient with intact cognition but with severe impairments in vision or hearing may become confused in an unfamiliar medical setting and consequently may be falsely labeled as having dementia. See also Chapter 27 for more detail on differential diagnosis.

Treatment

Patients and families should be made aware of the Alzheimer's Association (http://www.alz.org) as well as the wealth of helpful community and online resources and publications available. **Caregiver support, education, and counseling** may prevent or delay nursing home placement. Education should include the manifestations and natural history of dementia as well as the availability of local support services, such as respite care. **Exercise** should be a component of treatment since evidence suggests physical activity may have beneficial effects on cognition and physical function, while limited evidence has found that intellectual engagement through a variety of nonpharmacologic interventions may have a modest positive impact on cognitive function. Patients with impaired hearing should be provided with **hearing aids**. **Maintaining an active role in the family and community** as practically as possible is likely to be beneficial, emphasizing activities in which the patient feels confident. Patients with neurodegenerative diseases have a limited capacity to regain lost skills; for example, memory drills in a patient with Alzheimer disease are more likely to lead to frustration than benefit, and studies show that computerized cognitive training does *not* improve cognition or function in patients with dementia.

A. Cognitive Impairment

1. Acetylcholinesterase inhibitors—Donepezil, galantamine, and rivastigmine are acetylcholinesterase inhibitors approved for the treatment of Alzheimer disease. These medications produce a modest improvement in cognitive function that is *not* likely to be detected in routine clinical encounters, and they have *not* convincingly been shown to delay functional decline or institutionalization. Compared to patients with Alzheimer disease, acetylcholinesterase inhibitors may yield similarly modest cognitive benefits in patients with vascular dementia or Lewy body dementia, but they should *not* be used in frontotemporal dementia because they may worsen behavioral problems. There is insufficient evidence to recommend their use in MCI to slow the progression toward dementia. See Chapter 27 for acetylcholinesterase inhibitor dosing details.

2. Memantine—In clinical trials, patients with moderate to severe Alzheimer disease have been shown to have statistical benefit from the use of memantine (5 mg orally daily to 10 mg twice daily), an *N*-methyl-D-aspartate (NMDA) antagonist, based on global assessment and behavioral scales. Long-term and meaningful functional outcomes are not well established, and evidence suggests *there is no clinically meaningful benefit to giving memantine in combination with an acetylcholinesterase inhibitor.* Evidence supporting the use of memantine in vascular and Lewy body dementia is similarly modest.

3. Immunotherapy targeting amyloid-β—Treatment with immunotherapy targeting amyloid-β should be done by or in consultation with dementia specialists. In 2021, aducanumab became the first FDA-approved monoclonal antibody for the treatment of MCI and mild dementia due to Alzheimer disease by targeting amyloid-β protein and promoting its clearance from the brain. Adoption of the medication was slow, and in January 2024, the manufacturer discontinued it. Lecanemab and donanemab are the two monoclonal anti-amyloid antibody treatments available in the United States that have FDA approval for the same indications as aducanumab. Both medications may modestly slow the progression of the disease, but uncertainty remains as to whether either medication will lead to meaningful clinical benefits. (See Table 4–1.)

Amyloid-related imaging abnormalities (ARIA), subclassified as edema (ARIA-E), hemorrhage (ARIA-H), or both, are known class effects of these medications and occur commonly. While most cases are asymptomatic, treatment-related symptoms can include headache, nausea, confusion, dizziness, and seizures; these symptoms usually resolved after stopping the medication. A small number of treatment-related deaths were attributed to both medications. Another recognized phenomenon noted is that anti-amyloid antibodies cause accelerated brain volume loss, but the clinical impact is unknown. In the clinical trials of lecanemab and donanemab, the overall discontinuation rates due to adverse events were 6.9% and 13.1%, respectively, and adverse event rates were higher with both treatments compared to placebo.

Because of the lack of racial and ethnic diversity and limited data on the oldest patients in clinical trials for both lecanemab and donanemab, questions remain about generalizability of the results to more diverse populations. Any patient living with suspected Alzheimer disease under consideration for monoclonal antibody treatment requires a thorough evaluation performed by a dementia specialist to assess eligibility including confirming amyloid presence on a PET scan or CSF biomarker evidence and should be counseled about the known benefits and risks. Those that are chosen for treatment require regular monitoring for ARIA using MRI.

B. Behavioral Problems

1. Nonpharmacologic approaches—Behavioral problems in patients with dementia are often best managed nonpharmacologically. Initially, it should be established that the problem is not unrecognized delirium, pain, urinary obstruction, fecal impaction, or other intercurrent illness. Determining whether the caregiver or institutional staff can tolerate the behavior is also helpful, since *it is often easier to find ways to accommodate to the behavior than to modify it.* If not, the caregiver should keep a brief log in which the behavior is described along with antecedent events and consequences. This may uncover patterns that delineate precipitants of the behavior or perhaps that the

Table 4–1. Anti-amyloid-β antibodies for Alzheimer disease treatment (listed in alphabetical order).

Medication	Relevant Clinical Trial Names	Dosing	Target Population	Primary Endpoint[1]	Outcomes	MRI Monitoring for ARIA[2]
Donanemab[3]	TRAILBLAZER-ALZ 2	700 mg intravenously every 4 weeks for three doses, then 1400 mg intravenously every 4 weeks	Patients with MCI or mild dementia due to AD	Change in the iADRS from baseline at 76 weeks	Slower decline in iADRS compared to placebo	Prior to initiation of treatment; at weeks 4, 12, 24, 52, and 76
Lecanemab[3]	Clarity AD	10 mg/kg intravenously every 2 weeks	Patients with MCI or mild dementia due to AD	Change in CDR-SB from baseline at 18 months	Slower decline in CDR-SB compared to placebo	Within 1 year prior to initiation of treatment; prior to fifth, seventh, and fourteenth infusions
Remternetug[4]	TRAILRUNNER-ALZ 1	Intravenous and subcutaneous formulations are being studied	Patients with MCI or mild dementia due to AD	Amyloid plaque clearance at 52 weeks	Study results expected in 2025	Not available

AD, Alzheimer disease; ARIA, amyloid-related imaging abnormalities; CDR-SB, Clinical Dementia Rating Scale-Sum of Boxes; iADRS, integrated Alzheimer Disease Scale; MCI, mild cognitive impairment.

[4] Undergoing phase 3 clinical trials.

behavior is somehow being rewarded. Caregivers are taught to use simple language when communicating with the patient, to break down activities into simple component tasks, and to use a "distract, not confront" approach when the patient seems disturbed by a troublesome issue. Additional steps to address behavioral problems include providing structure and routine, discontinuing all medications except those considered necessary, and correcting, if possible, sensory deficits.

2. Pharmacologic approaches—There is no clear consensus about pharmacologic approaches to the treatment of behavioral problems in patients who have not benefited from nonpharmacologic therapies. Pharmacologic treatment should be reserved for those patients who pose an imminent danger to others or themselves or when symptoms are substantially distressing to the patient.

Despite evidence of harm and recommendations against their use, antipsychotic medications have remained a mainstay for the treatment of behavioral disturbances, particularly agitation and aggression, largely because of the lack of alternatives. The atypical antipsychotic agents (eg, risperidone, olanzapine, quetiapine, aripiprazole, brexpiprazole) are usually the first choice because of an overall better side-effect profile compared to typical agents (eg, haloperidol) but should be used with caution in patients with vascular risk factors due to an increased risk of stroke; they can also cause weight gain, are associated with hyperglycemia in patients with diabetes, and are considerably more expensive. *Both typical and atypical antipsychotics increase the risk of mortality compared with placebo when used to treat older patients with dementia and behavioral disturbances.* Brexpiprazole was approved by the FDA in 2023 for agitation in Alzheimer disease. However, it carries a boxed warning that older people treated with antipsychotics have a higher risk of death. Starting and target dosages should be much lower than those used in schizophrenia (eg, risperidone, 0.25–2 mg orally; quetiapine, 12.5–25 mg orally).

Citalopram at a dose of 30 mg daily may improve symptoms of agitation; however, the maximum recommended dose is 20 mg daily for patients older than 60 years because of the risk of QT prolongation and associated dysrhythmia. Thus, while citalopram may be used to treat agitation, safe and effective dosing for patients older than age 60 has not been established. In the specific instance of patients with Lewy body dementia, treatment with acetylcholinesterase inhibitors has been shown to improve behavioral symptoms. Valproate medications have been used in the treatment of agitated and physically aggressive behavior, but studies demonstrate no identifiable benefit.

C. Driving

Although drivers with dementia are at an increased risk for motor vehicle accidents, many patients continue to drive safely well beyond the time of initial diagnosis, making the timing of when to recommend that a patient stop driving challenging.

There is no clear-cut evidence to suggest a single best approach to determining an individual patient's capability, and there is no accepted gold-standard test. The result is that clinicians must consider several factors upon which to base their judgment. For example, determining the severity of dementia can be useful. Patients with very mild or mild dementia according to the Clinical Dementia Rating Scale were able to pass formal road tests at rates of 88% and 69%, respectively. Experts agree that patients with moderately severe or more advanced dementia should be counseled to stop driving. Although not well studied, clinicians should also consider the effects of comorbid conditions (eg, visual impairment) and medications and the role each may play in contributing to the risk of driving by a patient with dementia. Assessment of the ability to carry out IADLs may also assist in the determination of risk. Finally, in some cases of mild dementia, referral may be needed to a driver rehabilitation specialist for evaluation. Although not standardized, this evaluation often consists of both off- and on-road testing. Experts recommend such an evaluation for patients with mild dementia, for those with dementia whose driving skills are newly impaired, and for those with significant deficits in cognitive domains (such as attention, executive function, and visuospatial skills).

Clinicians must also be aware of the reporting requirements in their individual jurisdictions. When a clinician has made the decision to report an unsafe driver to the Department of Motor Vehicles, he or she must consider the impact of a potential breach in confidentiality and must weigh and address, in advance, when possible, the consequences of the loss of driving independence.

D. Advance Financial Planning

Difficulty in managing financial affairs often develops early in dementia. Although expertise is not expected, clinicians should have some proficiency to address financial concerns. Just as clinicians counsel patients and families about advance care planning, the same should be done to educate about the need for advance financial planning and to recommend that patients complete a **durable power of attorney for finance matters (DPOAF)** while the capacity to do so still exists.

No gold-standard test is available to identify when a patient with dementia no longer has financial capacity. However, the clinician should be on the lookout for signs that a patient is either at risk for or experiencing financial incapacity. Because financial impairment can occur when dementia is mild, making that diagnosis should alone be enough to warrant further investigation. Questioning patients and caregivers about late, missed, or repeated bill payments, unusual or uncharacteristic purchases or gifts, overdrawn bank accounts, or reports of missing funds can provide evidence of suspected financial impairment. *Patients with dementia are also at increased risk for becoming victims of financial abuse*, and some answers to these same questions might also be signs of potential exploitation. When financial abuse is suspected, clinicians should be aware of the reporting requirements in their local jurisdictions.

▶ Prognosis

Average life expectancy after a diagnosis of Alzheimer disease typically ranges from 4–8 years and can depend on several factors, including age at the time of diagnosis. Other neurodegenerative dementias, such as Lewy body dementia, generally show more rapid decline. Hospice care is often appropriate for patients with end-stage dementia.

When to Refer

Referral for neuropsychological testing may be helpful to distinguish dementia from depression, to diagnose dementia in persons of poor education or high premorbid intellect, and to aid diagnosis when impairment is mild. For patients under consideration for treatment with novel anti-amyloid antibody therapy, clinicians should consult with a dementia specialist.

van Dyck CH et al. Lecanemab in early Alzheimer's disease. N Engl J Med. 2023;388:9. [PMID: 36449413]

2. Depression

ESSENTIALS OF DIAGNOSIS

- May manifest in older adults as physical symptoms (eg, fatigue, anhedonia) rather than symptoms of depressed mood.
- *Often undertreated in older adults.* Approximately one-third of those treated with an antidepressant will achieve remission, and two-thirds will need additional treatment.

General Considerations

Major depressive disorder has prevalence rates of approximately 2% among community-dwelling adults aged 55 years and older. Prevalence rises with increasing age as well as conditions such as chronic illness, multimorbidity, cognitive impairment, functional impairment, social isolation, and loneliness. The COVID-19 pandemic period also saw an increased prevalence of depression. *Major depressive disorder is less common in older adults than in younger adults, but depressive symptoms (not meeting criteria for major depressive disorder) are common and present in up to 15% of older adults.* Depression is more common among hospitalized and institutionalized elders. Older single men have the highest rate of completed suicides of any demographic group.

New incidence of depressive symptoms may be an early sign of cognitive impairment in older adults; therefore, evaluation of depression should include cognitive assessment. Older patients with depression and depressive symptoms who have comorbid conditions (eg, HF) are at higher risk for hospitalization, tend to have longer hospital stays, and have worse outcomes than patients without depression.

Clinical Findings

The **Patient Health Questionnaire-2 (PHQ-2)** is highly sensitive for detecting major depression in persons over age 65. Positive responses should be followed up with more comprehensive questionnaires, such as the PHQ-9.

Evaluation of depression should include a careful review of substances that can contribute to depressive symptoms, such as medications (eg, benzodiazepines) and alcohol/illicit drugs. A thorough review of the medical history is critical, since many medical problems can cause fatigue, lethargy, or hypoactive delirium, all of which may be mistaken for depression.

Treatment

First-line treatment is the same for older adults as it is for younger adults; psychotherapy and SSRI medications are the mainstays of treatment. Adjunctive treatment may include psychosocial interventions, increased physical activity, reduction of substance use (eg, alcohol), reduction of potentially contributing medications, or electroconvulsive therapy. In older patients with depressive symptoms who do not meet criteria for major depressive disorder, nonpharmacologic treatments are indicated. Among those with MCI or dementia, cognitive behavioral therapy (CBT) added to usual care probably increases depression remission and slightly reduces depression symptoms, based on a 2022 Cochrane review. Telehealth for mental health support is an important innovation in the field.

Choice of antidepressant agent is usually based on side-effect profile, cost, and patient-specific factors, such as presenting symptoms and comorbidities. SSRIs are used as first-line agents because they are relatively well-tolerated and have good evidence to support efficacy (see Table 28–6). Older adults are more susceptible to SSRI-induced hyponatremia, falls, and osteoporosis. SNRIs (eg, duloxetine and venlafaxine) lead to more adverse events versus placebo than do SSRIs. Regardless of the medication chosen, many experts recommend starting older adults at a relatively low dose, titrating to full dose slowly, and continuing for a longer trial (at least 8 weeks) before trying a different medication. Titration to full dose is critical to achieve efficacy of treatment. Of note, the maximum citalopram dose for adults older than 60 years is 20 mg orally daily, due to dose-dependent QT prolongation.

One-third of older adults achieve remission after adequate treatment with first-line SSRI treatment. For the remainder, referral to a mental health specialist is indicated. For those who do not achieve remission, augmentation therapy (eg, with lithium, methylphenidate, or aripiprazole) can enhance clinical response. Esketamine, the S-enantiomer of ketamine, is approved for treatment-resistant depression, but studies of its safety and efficacy did not include adults older than age 65. For patients with severe or catatonic depression, electroconvulsive therapy has high rates of efficacy (60–80%) and should be considered.

Pharmacologic treatment for the first episode of depression should continue for 1 year after remission. Clinicians and patients should share in decision-making regarding maintenance therapy for depression since risk of major depressive disorder recurrence is high. This decision should weigh how long-term pharmacotherapy may contribute to polypharmacy and adverse effects in the landscape of a patient's comorbidities and medication regimen.

When to Refer

- Any patient who might be considered for electroconvulsive therapy should be referred for psychiatric evaluation.
- Consider referral for patients who have mania, psychosis, catatonia, or treatment-resistant depression.

When to Admit

Recommend urgent psychiatric evaluation and admission for patients who have psychosis, suicidality, homicidality, catatonia, grave disability, or self-neglect.

Silva C et al. Depression in older adults during the COVID-19 pandemic: a systematic review. J Am Geriatr Soc. 2023;71:2308. [PMID: 37029710]

3. Delirium

ESSENTIALS OF DIAGNOSIS

- Rapid onset and fluctuating course.
- Primary deficit in attention rather than memory.
- May be hypo- or hyperactive.
- Dementia frequently coexists.

General Considerations

Delirium is described in the *DSM*-5 as a disturbance in attention and awareness of the environment that usually occurs acutely over a short period of time, represents a change from baseline, tends to fluctuate, and is accompanied by a change in cognition (see also Chapter 28). It is often the pathophysiologic consequence of an underlying general medical condition (eg, infection, coronary ischemia, hypoxemia, metabolic derangement) or the adverse effect of a medication. Delirium occurs in 29–64% of hospitalized older adults, persists in 25% or more, and is associated with worse clinical outcomes (higher in-hospital and post-discharge mortality, longer lengths of stay, delayed and limited recovery of physical function, greater probability of placement in a nursing facility).

The acutely agitated older patient often comes to mind when imagining delirium. However, such **hyperactive delirium** occurs less frequently than **hypoactive delirium** in hospitalized older adults and may be suspected only if the clinician notices new cognitive slowing or inattention.

Cognitive impairment is an important risk factor for delirium. Other risk factors include advanced age, functional impairment, severe illness, polypharmacy, use of psychoactive medications, sensory impairment, depression, volume depletion, and alcohol use disorder.

Clinical Findings

Several bedside instruments are available for the assessment of delirium. The **confusion assessment method (CAM)** requires (1) acute onset and fluctuating course and (2) inattention and *either* (3) disorganized thinking *or* (4) altered level of consciousness (https://oxfordmedicaleducation.com/geriatrics/cam/). The **3D CAM** (3-minute diagnostic CAM) is useful for clinical assessment of delirium in general medical and surgical patients (http://eddelirium.org/delirium-assessment/3d-cam/).

A key component of a delirium workup is review of medications because polypharmacy, the addition of a new medication, an increase in dose of a medication, or the discontinuation of a medication known to cause withdrawal symptoms are all associated with the development of delirium. Medications that are likely to increase the risk of delirium include sedative/hypnotics, anticholinergics, opioids, benzodiazepines, and H_1- and H_2-antihistamines.

Evaluation of most patients should include a CBC; BUN; serum electrolytes, creatinine, glucose, calcium, and liver biochemical tests; UA; and ECG. In selected cases, serum magnesium, medication levels, ABG measurements, blood cultures, CXR, urinary toxin screen, and lumbar puncture may be helpful. When delirium develops during a hospitalization in the absence of trauma or new localizing neurologic signs, a head CT is rarely revealing.

Prevention

The best evidence for prevention comes from nonpharmacologic multicomponent interventions. These components include improving cognition (frequent reorientation, activities, socialization with family and friends when possible), sleep (massage, noise reduction, minimizing interruptions at night), mobility (early initiation of rehabilitation services as appropriate), vision (visual aids and adaptive equipment), hearing (portable amplifiers or hearing aids, cerumen disimpaction), and hydration status (volume repletion). No medications have been consistently shown to prevent delirium or improve outcomes such as length of stay or mortality should delirium develop.

Treatment

Management of established episodes of delirium combines the elements of preventive interventions with reassurance and reorientation, treatment of underlying causes, eliminating unnecessary medications, and avoidance of indwelling catheters and restraints. *Antipsychotics offer little to no proven benefit and can cause harm.* For example, haloperidol and second-generation antipsychotics have not been found to reduce delirium severity or duration, hospital length of stay, or mortality when compared to placebo. QT interval prolongation can occur and is a potential risk for serious dysrhythmias. Benzodiazepines should be avoided except in the circumstance of alcohol or benzodiazepine withdrawal. In ventilated patients in the ICU setting, dexmedetomidine or propofol (or both) may also be useful alternatives to antipsychotic therapy in patients with delirium.

Most episodes of delirium clear in a matter of days after correction of the precipitant, but some patients suffer episodes of much longer duration, and a significant percentage never return to their former baseline level of functioning.

▶ When to Refer

If an initial evaluation does not reveal the cause of delirium or if entities other than delirium are in the differential diagnosis, referral to a geriatrician, neuropsychologist, neurologist, or geropsychiatrist should be considered.

▶ When to Admit

Patients with delirium of unknown cause should be admitted for an expedited workup if consistent with the patient's goals of care.

4. Immobility

Mobility limitations are common in older adults and are associated with increased rates of morbidity, hospitalization, disability, and mortality. Hospital-associated bed rest is a common precipitant of immobility and functional decline. Among hospitalized medical patients over age 70, about 10% experience a decline in function, and those who experience critical illness are particularly at high risk.

The hazards of bed rest in older adults are multiple, serious, quick to develop, and slow to reverse. Within days of being confined to bed, deconditioning of the cardiovascular system occurs. This deconditioning causes fluid shifts, decreased cardiac output, decreased peak oxygen uptake, increased resting heart rate, and postural hypotension. More striking changes occur in skeletal muscle, resulting in loss of strength and function. Pressure injuries, VTE, and falls are additional serious outcomes of immobility and deconditioning.

▶ Prevention & Treatment

Physical activity should be encouraged for all older adults, including during hospitalizations. Physical activity is associated with many health benefits in older adults. Structured physical activity programs may help reduce mobility-related disability among community-dwelling elders.

When immobilization cannot be avoided, several measures can be used to minimize its consequences. Avoiding restraints and discontinuing intravenous lines and urinary catheters will increase opportunities for early mobility. Graduated ambulation should begin as soon as it is feasible. Among hospitalized older adults, exercise protocols can improve functional outcomes. Prior to discharge, physical therapists can recommend appropriate exercises and assistive devices; after discharge, they can recommend home safety modifications and maintenance exercises. Severe functional disability impeding the patient's ability for independent self-care often leads to discharge to an acute or subacute rehabilitation facility. Recovery from illness-related deconditioning takes weeks to months, and in many cases, full recovery to the pre-illness physical condition does not occur. Evidence supports widespread implementation of **Acute Care for Elders units,** which protocolize delivery of the above preventive measures to prevent hospital-associated disability; however, there are only 43 such units in the United States.

Rogers SE et al. The current landscape of Acute Care for Elders units in the United States. J Am Geriatr Soc. 2022;70:3012. [PMID: 35666631]

5. Falls & Gait Disorders

Annually, about one-third of people over age 65 fall, and the frequency of falls increases markedly with advancing age. About 10% of falls result in serious injuries. *Complications from falls (eg, hip fracture, subdural hematoma) are the leading cause of death from injury in persons over age 65, and fall-associated mortality is increasing.*

Every older person should be asked about falls. Assessment of patients who fall should include measurement of postural blood pressure and pulse; cardiac examination; evaluations of strength, range of motion, cognition, and proprioception; and examination of feet and footwear. A thorough gait assessment should be performed in all older people. Gait and balance can be readily assessed by the **"Timed Up and Go Test,"** in which the patient is asked to stand up from a sitting position without use of hands, walk 10 feet/3 meters, turn around, walk back, and sit down. An older adult who takes 12.5 seconds or greater is considered at increased risk for falling. The ability to recognize common patterns of gait disorders is an extremely useful clinical skill to develop.

Table 4–2. Fall risk factors, targeted interventions, and best evidence for fall prevention (fall risk factors listed in alphabetical order).

To Consider for All Patients	
Exercise or physical therapy	Tai chi, gait training, balance training, strength training
Multifactorial intervention	Home safety assessment, medication review, review of specific conditions (below), advice on appropriate footwear, vision check, adaptive aids as appropriate, physical therapy or exercise as appropriate
Condition	**Targeted Intervention**
Environmental hazards	Removal or mitigation of hazards; installation of safety equipment (eg, grab bars)
Gait impairment	Gait training, assistive devices, balance or strengthening exercises
High-risk footwear	Education on appropriate footwear (eg, avoid slippers, high heels)
Impairment in leg or arm muscle strength or limb range of motion	Exercise with resistance bands or putty, with graduated increases in resistance
Impairment in transfer or balance	Balance exercises, training in transfers, environmental alterations (eg, grab bars)
Inability to get up after a fall	Medical alert system, physical therapy training for fall-prevention strategies
Osteoporosis	Bisphosphonate treatment to prevent first or recurrent fractures
Postural hypotension (> 20 mm Hg drop in systolic blood pressure, or systolic blood pressure < 90 mm Hg)	Behavioral recommendations, such as hand clenching, elevation of head of bed; discontinuation or substitution of high-risk medications
Use of benzodiazepine or sedative/hypnotic agent	Education about sleep hygiene; discontinuation or substitution of medications
Use of multiple prescription medications	Review of medications with a focus on discontinuation (deprescribing)
Vision impairment	Cataract surgery or other interventions as appropriate (eg, corrective lenses)

Causes of Falls

Balance and ambulation require a complex interplay of cognitive, neuromuscular, and cardiovascular function. With age, balance mechanisms can become compromised, reaction time slows, and postural sway increases. These changes predispose the older person to a fall when challenged by an additional insult to any of these systems.

Falls in older people are rarely due to a single cause, and effective intervention entails a comprehensive assessment of the patient's intrinsic deficits (eg, diseases and medications), the activity engaged in at the time of the fall, and environmental obstacles (Table 4–2).

Medication use is one of the most common, significant, and reversible causes of falling. A meta-analysis found that sedative/hypnotics, antidepressants, and benzodiazepines were the classes of medications most likely to be associated with falling. Polypharmacy has also been associated with increased fall risk. Other often overlooked but treatable contributors include postural hypotension (including postprandial, which peaks 30–60 minutes after a meal), insomnia, use of multifocal lenses, and urinary urgency.

Since most falls occur in or around the home, a **home safety evaluation** by a visiting nurse, physical therapist, or health care provider may be beneficial in identifying environmental obstacles.

Complications of Falls

The most common fall-related fractures are of the wrist, hip, and vertebrae. Osteoporosis significantly increases fracture risk and is vastly undertreated in older adults. Following hip fracture, older women experience a high mortality rate (approximately 20% in 1 year), particularly if they were debilitated prior to the time of the fracture. Fear of falling again is a common, serious, but treatable factor in the older person's loss of confidence and independence.

Chronic subdural hematoma is an easily overlooked complication of falls that must be considered in any older patient presenting with new neurologic symptoms or signs, including evidence of new cognitive impairment. Headache and known history of trauma may both be absent.

Prevention & Management

Exercise is the intervention that is most consistently reported to reduce the risk of falls. Balance focused exercises (eg, Tai Chi), gait, and strength training appear to be more effective for fall prevention than general exercise programs (Table 4–2). **Physical therapy** for gait training can help restore an individual's confidence and independence in ambulation, which can help prevent (and treat) falls.

Multifactorial interventions appear to have a small benefit in preventing falls. These interventions include an assessment of potentially modifiable risk factors and tailored interventions to reduce risk. Emphasis is placed on treating all contributory medical conditions, minimizing environmental hazards, and eliminating medications where the harms may outweigh the benefits (eg, sedative-hypnotics).

The USPSTF recommends *against* vitamin D supplementation to prevent falls in community-dwelling adults. Vitamin D supplementation might be considered for high-risk individuals (eg, institutionalized elders) on a case-by-case basis.

Osteoporosis treatment (both preventive and post-fracture) is essential to prevent first and recurrent fracture. First-line treatment with bisphosphonates is effective; for example, alendronate significantly reduces the risk of hip, vertebral and nonvertebral fracture in people with osteoporosis. Unfortunately, < 20% of people who sustain a fragility fracture receive osteoporosis treatment (this treatment failure is called the "osteoporosis care gap"; see Chapter 30 for more information).

Assistive devices, such as canes and walkers, are useful for many older adults but often are used incorrectly. Canes should be used on the "good" side. The height of walkers and canes should generally be at about the level of the wrist. Physical therapists are invaluable in assessing the need for an assistive device, selecting the best device, and training a patient in its correct use.

Eyeglasses, particularly bifocal or graduated lenses, may increase the risk of falls, especially in the early weeks of use. Patients should be counseled about the need to take extra care when new eyeglasses are being used.

Patients with repeated falls are often reassured by the availability of telephones at floor level, a mobile telephone on their person, a personalized fall detection system (eg, watch), or a lightweight radio call system.

When to Refer

Patients experiencing repeated falls should be referred for physical therapy, eye examination, and home safety evaluation.

When to Admit

Consider hospitalization for patients with new falls that are unexplained, particularly in combination with a change in the physical examination (eg, neurologic status) or with an injury/fracture requiring surgery.

6. Urinary Incontinence

ESSENTIALS OF DIAGNOSIS

- Involuntary loss of urine.
- **Stress incontinence:** leakage of urine upon coughing, sneezing, or standing.
- **Urge incontinence:** urgency and inability to delay urination.
- **Overflow incontinence:** variable presentation.

General Considerations

Urinary incontinence in older adults is common, and interventions can greatly improve patients' quality of life. Many do not voluntarily disclose their experiences with urinary incontinence to their health care providers, possibly due to embarrassment or the belief that it is a normal part of aging. A simple question about involuntary leakage of urine is a reasonable annual screen: *"Do you have a problem with urine leaks or accidents?"*

Classification

A. Transient Causes

The mnemonic "DIAPPERS" represents categories of "transient" urinary incontinence.

1. Delirium—A clouded sensorium impedes recognition of both the need to void and the location of the nearest toilet. Delirium is the most common cause of incontinence in hospitalized patients.

2. Infection—Symptomatic UTI can cause or contribute to urgency and incontinence. Asymptomatic bacteriuria does not.

3. Atrophic urethritis and vaginitis—Atrophic urethritis and vaginitis can usually be diagnosed by the presence of vaginal mucosal telangiectasia, petechiae, erosions, erythema, or friability.

4. Pharmaceuticals—Medications are one of the most common causes of transient incontinence. Typical offending agents include diuretics, anticholinergics, psychotropics, opioid analgesics, α-blockers (in women), α-agonists (in men), and calcium channel blockers.

5. Psychological factors—Severe depression with psychomotor retardation may impede the ability or motivation to reach a toilet.

6. Excess urinary output—Excess urinary output may overwhelm the ability of an older person to reach a toilet in time. In addition to diuretics, common causes include excess fluid intake; metabolic abnormalities (eg, hyperglycemia, hypercalcemia, diabetes insipidus); and peripheral edema.

7. Restricted mobility—If mobility cannot be improved, access to a urinal or commode (eg, at the bedside) may improve continence.

8. Stool impaction—This is a common cause of urinary incontinence in hospitalized or immobile patients. A clinical clue to its presence is the onset of both urinary and fecal incontinence.

B. Established Causes

Causes of "established" incontinence should be addressed after any "transient" causes have been managed appropriately.

1. Detrusor overactivity (urge incontinence)—Detrusor overactivity refers to uninhibited bladder contractions that cause leakage. It is the most common cause of established incontinence in older adults, accounting for two-thirds of cases. Women will report leakage associated with a strong and sudden urge to urinate that cannot be forestalled. In men, the symptoms are similar, but detrusor overactivity commonly coexists with urethral obstruction from benign prostatic hyperplasia. Because detrusor overactivity also may be due to bladder stones or tumor, the abrupt onset of unexplained urge incontinence should be investigated by urine cytology and cystoscopy.

2. Urethral incompetence (stress incontinence)—Urethral incompetence is the second most common cause of established urinary incontinence in older women. In men, it commonly occurs after radical prostatectomy. Stress incontinence is characterized by instantaneous leakage of urine in response to an increase in intra-abdominal pressure. It can coexist with detrusor overactivity causing "mixed" incontinence. Typically, urinary loss occurs with laughing, coughing, or lifting heavy objects. To test for stress incontinence, have the patient relax the perineum and cough vigorously (a single cough) while standing with a full bladder. Instantaneous leakage indicates stress incontinence.

3. Overflow incontinence—Urethral obstruction (due to prostatic enlargement, urethral stricture, bladder neck contracture, or prostatic cancer) is a more common cause of established incontinence in men than women. It can present as dribbling incontinence after voiding, urge incontinence due to detrusor overactivity, or overflow incontinence due to urinary retention. Detrusor underactivity is less common but can also cause overflow incontinence. It may be idiopathic or have an identifiable cause including medications and sacral lower motor nerve dysfunction. When it causes incontinence, detrusor underactivity is associated with urinary frequency, nocturia, and frequent leakage of small volumes.

Treatment

A. Transient Causes

Each identified transient cause should be treated regardless of whether an established cause coexists.

B. Established Causes

1. Detrusor overactivity—The cornerstone of treatment is **bladder training.** Patients start by voiding on a schedule based on the shortest interval recorded on a bladder record. They then gradually lengthen the interval between voids by 30 minutes each week using relaxation techniques to postpone the urge to void. Lifestyle modifications, including weight loss and caffeine reduction, may also improve incontinence symptoms. **Pelvic floor muscle ("Kegel") exercises** can reduce the frequency of incontinence episodes when performed correctly and sustained. For cognitively impaired patients and nursing home residents who are unable to manage on their own, **timed and prompted voiding** initiated by caregivers is effective.

If behavioral approaches prove insufficient, pharmacotherapy with β_3-agonists or antimuscarinic agents can be considered. Efficiency and safety profiles are comparable in both groups, with fewer anticholinergic adverse drug effects reported in patients taking β_3-agonists. Mirabegron, at 20–50 mg by mouth daily, and vibegron, at 75 mg by mouth daily, are FDA-approved β_3-agonists for overactive bladder symptoms.

FDA-approved antimuscarinic agents include short-acting tolterodine, 1–2 mg orally twice daily; long-acting tolterodine, 2–4 mg orally daily; short-acting oxybutynin, 2.5–5 mg orally two or three times daily; long-acting oxybutynin, 5–15 mg orally daily; oxybutynin transdermal patch, 3.9 mg/day applied twice weekly; oxybutynin 10% topical gel, 100 mg applied daily; fesoterodine, 4–8 mg orally once daily; trospium chloride, 20 mg orally once or twice daily; long-acting trospium chloride, 60 mg orally daily; darifenacin, 7.5–15 mg orally daily; and solifenacin, 5–10 mg orally daily. They are commonly available, have low-cost generic options, come in short-acting and long-acting formulations, and can be combined with β_3-agonists for synergistic effects. Potential adverse drug effects to consider include cognitive impairment, dry mouth, constipation, and urinary retention.

Women who have persistent symptoms despite an adequate trial of initial treatment, or who are unable to tolerate pharmacotherapy options, may be referred to urologists or urogynecologists for alternative options. Other possible treatment approaches include percutaneous or transcutaneous tibial nerve stimulation and botulinum toxin type A injection into the detrusor muscle. Symptom relief from botulinum toxin injections has been reported to last 6–12 months; possible adverse effects include urinary retention and the need for self-catheterization.

In men with both benign prostatic hyperplasia and detrusor overactivity and with postvoid residual of 150 mL or less, an antimuscarinic agent added to an α-blocker may provide additional relief of lower urinary tract symptoms.

2. Urethral incompetence (stress incontinence)— **Lifestyle modifications** include limiting caffeine and fluid intake and may be helpful for those with mixed stress/urge incontinence; strong evidence supports weight loss in women with BMI of 30 or more. **Pelvic floor therapy** is effective for women with mild to moderate stress incontinence. Instruct the patient to pull in the pelvic floor muscles and hold for 6–10 seconds and to perform three sets of 8–12 contractions daily. Benefits may not be seen for 6 weeks. **Pessaries** or **vaginal cones** may be helpful in some women but should be prescribed only by providers who are experienced with using these modalities. No medications are approved for the treatment of stress incontinence, and a clinical practice guideline from the American College of Physicians recommends against pharmacologic treatment. Patients experiencing symptoms despite initial approaches should be evaluated for **surgical treatments.** Midurethral sling procedures, with their rapid recovery times, high cure rates, and low risk of complications, have become the standard surgeries for stress incontinence in older women.

3. Overflow incontinence—Most men with overflow incontinence from obstructive uropathy will first undergo bladder decompression with intermittent or indwelling catheterization followed by initiation of α-blocking agents (eg, terazosin, 1–10 mg orally daily; prazosin, 1–5 mg orally twice daily; or tamsulosin, 0.4–0.8 mg orally daily taken 30 minutes after a meal). Finasteride, 5 mg orally daily, can provide additional benefit in men with an enlarged prostate. If medical therapy fails to allow for adequate bladder emptying, surgical decompression can be an option. A variety of nonsurgical techniques make decompression feasible even for frail patients. For the nonoperative candidate with urinary retention, intermittent or indwelling catheterization are options. For the patient with a poorly contractile bladder, augmented voiding techniques (eg, double voiding, suprapubic pressure) can prove effective. If further emptying is needed, intermittent or indwelling catheterization is the only option. Antibiotics should be used only for symptomatic UTI or as prophylaxis against recurrent symptomatic infections in a patient using intermittent catheterization; they should not be used as prophylaxis in a patient with an indwelling catheter.

When to Refer

- Men with urinary obstruction who do not respond to medical therapy should be referred to a urologist.
- Women who do not respond to pelvic floor therapy, medical treatment, or both should be referred to a urogynecologist or urologist.

7. Involuntary Weight Loss

General Considerations

Aging, even in the absence of disease, is associated with reduced appetite. Involuntary weight loss affects substantial numbers of older adults. Most studies of involuntary weight loss in community-dwelling older adults define it as the loss of 5% of body weight in 6 months or 10% of body weight in 1 year.

Clinical Findings

The many potential causes of involuntary weight loss include medical conditions (60–70%; eg, cancer, chronic HF) and psychiatric conditions (10–20%; eg, depression), but in up to 25%, the cause of weight loss cannot be identified. Social factors, such as food insecurity, financial hardship, or both, should be investigated. The clinical evaluation should search for symptoms and signs that could point to a potential cause (eg, abdominal pain to peptic ulcer disease; tachycardia to hyperthyroidism). When the history, physical examination, and basic laboratory studies do not suggest a possible diagnosis, additional evaluation (eg, total body CT scan) is usually low yield.

Treatment

Initial treatment should focus on identifying medical causes of involuntary weight loss while also addressing and improving social barriers, such as social isolation and lack of access to food. Social meals can improve intake and nutrition. Oral nutritional supplements of 200–1000 kcal/day can increase weight and improve outcomes in malnourished hospitalized older adults but have *not* been shown to have benefits in community-dwelling older adults. Megestrol acetate as an appetite stimulant has *not* been shown to increase lean body mass or lengthen life among elders and has significant side effects. Mirtazapine is often used for older adults with comorbid depression; however, effects on weight gain remain equivocal. For patients with advanced dementia, percutaneous liquid artificial nutrition ("tube feed") is *not* recommended, but rather assiduous hand feeding may allow maintenance of weight and provide more comfort.

8. Pressure Injury

ESSENTIALS OF DIAGNOSIS

- Examine at-risk patients on admission to the hospital and daily thereafter.
- Pressure injury is classified into one of six categories:
  - Stage 1: Non-blanchable erythema of intact skin
  - Stage 2: Partial-thickness skin loss with exposed dermis
  - Stage 3: Full-thickness skin loss
  - Stage 4: Full-thickness skin and tissue loss
  - Unstageable: Obscured full-thickness skin and tissue loss
  - Deep tissue: Persistent non-blanchable, deep red, maroon, or purple discoloration of intact skin

General Considerations

The National Pressure Injury Advisory Panel defines pressure injuries as damage to the skin and underlying tissue from pressure in combination with shear and friction forces, usually over a bony prominence or related to a medical device. The term "pressure ulcer" was changed to "pressure injury" to more accurately reflect that the skin is intact in stage 1 and deep tissue injury, since the word "ulcer" implies that the skin has opened. Deep tissue and unstageable pressure injuries are included in the six pressure injury stages. An area of purple or maroon discolored intact skin or blood-filled blister is characteristic of deep tissue injury, sometimes preceded by tissue that is painful, firm, mushy, boggy, warmer, or cooler compared with adjacent tissue. Ulcers in which the base is covered by slough (yellow, tan, gray, green, or brown) or eschar (tan, brown, or black) are considered unstageable. Most pressure injuries develop during an acute illness. The primary risk factor for pressure injuries is immobility. Other contributing risk factors include reduced tissue perfusion, reduced sensory perception, increased moisture, and poor nutritional status.

Older adults should be assessed for their risk of developing pressure injuries, utilizing risk assessment instruments such as the **Braden Scale** and the **Norton score**. These tools should be used in conjunction with clinical judgment since each may cover a limited range of risk factors and each depends on the skills of the examiner.

Prevention

Using specialized support surfaces (including mattresses, beds, and cushions), patient repositioning, optimizing nutritional status, reducing shear and friction forces, and being mindful of skin integrity are strategies that have been shown to reduce pressure injury. In general, advanced supportive surfaces are superior to standard hospital beds in preventing and managing pressure injuries, but there is no clear advantage of one support surface over another.

Evaluation

Evaluation of pressure injuries should include the patient's risk factors and goals of care; injury stage, size, and depth; absence or presence (and type) of exudate; appearance of the wound bed and possible surrounding infection; and any sinus tracking, undermining, or tunneling.

Treatment

High-quality evidence that rigorously examines the effectiveness of various treatments remains limited. Clinicians should therefore focus on the principles of wound care, including pressure reduction, removing necrotic debris, and maintaining a moist wound bed to promote formation of granulation tissue and healing. The type of dressing recommended depends on the location and depth of the wound, whether necrotic tissue or dead space is present, and the amount of exudate (Table 4–3). Pressure-reducing devices (eg, air-fluid beds and low-air-loss beds) are associated with improved healing rates. Although poor nutritional status is a risk factor for the development of pressure injury, the evidence that nutritional supplementation helps correct pressure injury is limited.

Institutions should designate a wound care expert or team to select a streamlined wound care product line with simple guidelines. In a patient with end-stage disease who is receiving end-of-life care, appropriate treatment might be directed toward palliation only (including minimizing dressing changes and odors) rather than efforts directed at healing.

Complications

Bacteria contaminate all chronic pressure injuries with skin loss, but it can be difficult to identify those wounds that are infected. Suspicion for infection should rise if there is pain, increased or foul-smelling wound drainage, erythema of the skin around the wound, or if the wound will not heal. Fever and leukocytosis are other indicators of systemic infection but are not always present. Culture from a superficial swab adds little valuable diagnostic information. For nonhealing infected wounds without evidence of systemic involvement, topical antiseptics (eg, silver sulfadiazine) are recommended and may need to be accompanied by debridement of necrotic tissue. When systemic infections such as cellulitis and osteomyelitis are present, oral or parenteral antibiotics are warranted and medication choice should be guided by tissue culture, but obtaining this can be painful and it is not always readily available.

Table 4–3. Pressure injury dressings and other measures.

Injury Type	Dressing Type and Considerations
Stage 1	Barrier ointment Polyurethane film
Stage 2	Hydrocolloid dressings Semipermeable foam dressing Polyurethane film Hydrogel
Stages 3 and 4	For highly exudative wounds, use highly absorptive dressing or packing, such as calcium alginate; negative pressure wound therapy or vacuum-assisted wound closure also can be considered Wounds with necrotic debris should be debrided Debridement can be autolytic, enzymatic, mechanical, or surgical Shallow, clean wounds can be dressed with hydrocolloid wafers, semipermeable foam, hydrogels, or polyurethane film Deep wounds can be packed with gauze; if the wound is deep and highly exudative, an absorptive packing should be used
Heel injury	Do not remove eschar on heel pressure injury because it can help promote healing (eschar in other locations should be debrided)
Unstageable	Debride if appropriate before deciding on further therapy
Deep tissue injury	Offload pressure to the affected area Consider barrier ointment

When to Refer

- Pressure injuries that are large or nonhealing should be referred to a plastic or general surgeon or dermatologist for biopsy, debridement, and possible skin grafting.
- For hospitalized patients or residents of skilled nursing facilities in whom pressure injuries develop, early involvement of a wound care specialist is crucial.

When to Admit

Patients with pressure injury should be admitted if the primary residence is unable to provide adequate wound care or pressure reduction, or if the wound is infected or requires complex or surgical care.

Siotos C et al. Burden of pressure injuries: findings from the Global Burden of Disease Study. Eplasty. 2022;22:e19. [PMID: 35873067]

9. Pharmacotherapy & Polypharmacy

ESSENTIALS OF DIAGNOSIS

- Older adults experience more adverse medication events than younger patients. Evaluate for dose reduction or medication avoidance based on kidney function, comorbidities, and other medication use.
- The AGS Beers Criteria list is useful for identifying high-risk medications for older adults. Particular caution/avoidance should be used in prescribing benzodiazepines and other sedative-hypnotic medications.

General Considerations

Polypharmacy refers to the condition of taking or being prescribed a multitude of prescription and nonprescription medications. More adverse drug events occur in older adults compared to younger patients for many reasons, including changing drug metabolism in the kidney or liver or both, drug interaction with comorbid conditions, and interactions between multiple medications. Polypharmacy itself is associated with adverse health outcomes, including falls, impaired cognition, hospitalizations, and death.

Medication metabolism is often impaired in older adults due to decreased GFR, reduced hepatic clearance, and changes in body composition (eg, lean body mass). Most emergency hospitalizations for adverse medication events among older adults result from commonly prescribed medications used alone or in combination.

Precautions in Prescribing Medications

Most medications prescribed for chronic disease management should be initiated at the low end of the usual adult dosage range, with slow increases in dosage until a therapeutic level is reached or intolerable side effects develop. At the same time, it is imperative that a medication's therapeutic dose be achieved, since older adults are at risk for undertreatment of conditions such as depression, if the starting dose is not increased with careful monitoring.

Optimal medication adherence is less likely with increasing numbers of pills and doses, high cost, and poor communication about medication changes as well as expected benefits and side effects; other factors affecting adherence include cognitive impairment, insurance issues, and psychosocial barriers. When possible, the clinician should simplify both dosing schedules with the fewest number of pills and doses (combination formulations can be useful in this regard, though perhaps complicate future dose adjustments) as well as modes of administration (eg, oral, ocular, transdermal, subcutaneous, inhalational). Other helpful medication management techniques include use of a single pharmacy, use of pillboxes or pharmacy-packaged medication sets, clarity about the prescriber of each medication (and ideally use of fewer prescribers), infrequent medication changes, and clear instructions about all medication changes using the "teach-back" method of patient communication. Clinicians should ask patients about their ability to afford their medications, and counsel patients about strategies for cost containment.

The patient or caregiver should bring in all medications at each visit for accurate **medication reconciliation** and instruction on medication use, dosage, frequency of administration, and possible adverse effects. Patients should also bring all supplements and over-the-counter medications used, including analgesics and sleep aids. Medication reconciliation is particularly important if the patient sees multiple clinicians. Clinicians should be aware of the "prescribing cascade" in which a medication is prescribed to counter the side effect of another medication.

The risk of toxicity goes up with the number of medications prescribed. Certain combinations of medications (eg, warfarin and many antibiotics, ACE inhibitors and NSAIDs, opioids and sedative-hypnotics) are likely to cause drug-drug interactions and should be monitored carefully.

Trials of medication discontinuation (deprescribing) should be considered when the original indication is unclear or the patient is having side effects. Medication discontinuation is particularly important in patients with limited life expectancy who may be experiencing increasing burdens from polypharmacy and modest, if any, benefits from the medication (eg, bisphosphonates, antilipemics). Clinical tools such as **"STOPP/START"** and the **AGS Beers Criteria** can inform safe medication prescribing for older adults.

When to Refer

- Refer patients with polypharmacy or poor medication adherence to a clinical pharmacist, when available.
- Refer homebound patients with poor medication adherence and suboptimal chronic disease management to a home health nurse for medication reconciliation and teaching.

10. Vision Impairment

Visual impairment due to age-related refractive error ("presbyopia"), macular degeneration, cataracts, glaucoma, or diabetic retinopathy is associated with several negative physical and mental health outcomes. These include falls, impaired mobility, and reduced quality of life. The 2022

USPSTF updated evidence report concluded that there was no direct evidence for better visual outcomes with screening in primary care. However, the American Academy of Ophthalmology recommends a complete eye examination every 1–2 years after age 65. Eye examinations should certainly be prioritized for patients with new or recurring falls, changes in vision, and conditions with risk of eye complications (eg, diabetes mellitus, thyroid disease). Patients with significant visual loss should be referred to low-vision community programs for support and assessment for assistive devices.

Chou R et al. Screening for impaired visual acuity in older adults: updated evidence report and systematic review for the US Preventive Services Task Force. JAMA. 2022;327:2129. [PMID: 35608842]

11. Hearing Impairment

Hearing loss in older adults is common yet undertreated. *Over one-third of persons older than age 65 and half of those older than age 85 have some degree of hearing loss.* Hearing loss is associated with social isolation, depression, disability, dementia and accelerated cognitive decline, hospitalization, and nursing home placement. Hearing loss is undertreated because it is underrecognized by clinicians and hearing assistive devices are expensive and may not be covered by insurance.

Although the USPSTF found insufficient evidence for routine hearing screening, clinicians should periodically ask patients about hearing loss and refer them to audiology if hearing loss is suspected. A reasonable clinical screen is to ask patients if they have noticed any hearing impairment. Those who answer “yes” should be referred for audiometry. For those who answer “no” but in whom hearing loss is still suspected, further in-office screening can be performed using the **whispered voice test.** To determine the degree to which hearing impairment interferes with functioning, the provider may ask patients if they become frustrated when conversing with family members, have challenges understanding conversations, are embarrassed when meeting new people, or have difficulty watching television. Caregivers or family members can provide important collateral information regarding potential hearing loss and the impact of hearing loss on social interactions.

Hearing loss assistive devices and technology include hearing aids, cochlear implants, sound amplification for telephones and televisions, speech to text software, smart phone applications, hearing loops, and alerting devices to inform hearing-impaired people of an event such as a fire alarm. Hearing amplification and cochlear implantation improve hearing-related quality of life and reduce depressive symptoms. *Hearing aid use has been associated with lower dementia prevalence.* Compliance with hearing amplification can be a challenge because of the high device cost, dissatisfaction with performance, and stigma associated with hearing aid use. Newer digital devices may perform better but are considerably more expensive. In 2022, the FDA issued a new rule supporting over-the-counter sale of hearing aids for mild to moderate hearing loss without the need for a medical examination or prescription, in order to lower cost and expand access to such technology. For people with severe hearing loss, an audiologist and medical evaluation is recommended. Cochlear implantation is an underutilized treatment for profound hearing loss that improves understanding of speech and improves quality of life.

For those with milder hearing loss or who do not pursue hearing aids for a variety of reasons, portable sound amplifiers (eg, “pocket talkers”) are useful over-the-counter and low-cost hand-held devices. Such devices are helpful in facilitating communication with hearing-impaired patients in clinical settings. Clinicians should develop skills in successful communication with people who have hearing impairment, such as facing toward patients when speaking, speaking at a moderate pace and in a low tone, and practicing the “teach-back” method to assess that information was adequately transmitted.

12. Elder Mistreatment & Self-Neglect

Elder abuse is defined as “acts whereby a trusted person causes or creates risk of harm to an older adult” **Self-neglect** is the most common form of elder abuse and occurs among all demographic strata. In the United States, about 10% of adults over age 60 have experienced some sort of abuse or neglect in the previous year. Financial abuse is on the rise, and older adults with cognitive impairment are particularly vulnerable. Each year, at least 5% of elders are victims of financial abuse or scams.

Elder abuse risk factors include limited social support and poor physical health. Clues to the presence of elder mistreatment or self-neglect include physical signs on examination such as lacerations or bruises in unusual locations or that cannot be explained; fractures in sites other than the wrist, hip, or vertebrae; or dehydration or malnutrition. Carefully note behavior changes in the presence of the caregiver, delays between injury occurrence and treatment seeking, inconsistencies between an observed injury and its associated explanation, lack of appropriate clothing or hygiene, and unfilled prescriptions. Elder abuse and self-neglect can cause many health consequences, such as long-term care placement, anxiety, depression, and death.

The USPSTF has found no evidence that screening for abuse or neglect causes harm and does not recommend for or against screening. Clinicians caring for older adults should maintain a high index of suspicion and meet with patients without the presence of caregivers on occasion. In these encounters, clinicians can ask questions about the

Table 4–4. Phrases and actions that may be helpful in situations of suspected abuse or neglect.

Questions for the Older Patient

1. Has anyone hurt you?
2. Are you afraid of anybody?
3. Is anyone taking or using your money without your permission?

Questions for the Caregiver

1. Are your relative's needs more than you can handle?
2. Are you worried that you might hit your relative?
3. Have you hit your relative?

If abuse is suspected

Tell the patient that you are concerned, want to help, and will call Adult Protective Services for further assistance

Document any injuries

Document the patient's words

Document whether the patient has decision-making capacity using a tool such as "Aid to Capacity Evaluation"

caregiver relationship, and directly question about possible mistreatment and neglect, if suspected (Table 4–4).

When self-neglect is suspected, it is critical to establish whether a patient has decision-making capacity regarding the suspected neglectful behavior. A patient who has full decision-making capacity should be provided help and support but can choose to live in conditions of self-neglect, providing that the public is not endangered by their actions. In contrast, more aggressive intervention is recommended for a patient who lacks decision-making capacity and lives in conditions of self-neglect. Such interventions include reporting to county-specific Adult Protective Services and arranging in-home help, conservatorship, and placement in a supervised setting.

When to Refer

- Refer older adults suffering from suspected elder abuse or self-neglect to **Adult Protective Services**, as required by law in most states (consult the National Adult Protective Services Association, https://www.napsa-now.org/)
- Refer to a mental health professional and neurologist for evaluation of those cases in which decision-making capacity is unclear, neuropsychiatric testing would be useful, or if untreated mental illness is suspected to play a role in self-neglect.

When to Admit

- Admit older adults who would be unsafe in the community when an alternative plan cannot be put into place in a timely manner. In cases of self-neglect, surrogate decision-makers need to be identified, and conservatorship may need to be pursued for safe discharge planning.

PALLIATIVE CARE

DEFINITION & SCOPE

Palliative care is medical care focused on improving quality of life for people living with serious illness. Serious illness is defined as "a condition that carries a high risk of mortality, negatively impacts quality of life and daily function, and/or is burdensome in symptoms, treatments or caregiver stress." Palliative care addresses physical and psychological symptoms, helps ensure that care aligns with patients' preferences and goals, and supports patients and their loved ones who are facing serious illness. Randomized studies have shown that palliative care provided alongside life-prolonging treatment throughout the course of a serious illness can reduce symptoms, improve quality of life, and even prolong life in some situations. Palliative care can be provided at any age or stage of serious illness, inpatient or outpatient, and alongside life-prolonging or curative treatment. On the other hand, hospice is a service provided near the end of life to patients with a prognosis of < 6 months who have chosen to forgo further life-prolonging treatments.

All clinicians should have basic skills to care for people with serious illness, including routinely identifying and taking initial steps to manage symptoms, communicating about prognosis and eliciting patients' preferences for care, and helping identify and address sources of distress in patients and their care partners.

PALLIATION OF COMMON NONPAIN SYMPTOMS

Numerous physical symptoms can occur in the setting of serious illness—pain, dyspnea, nausea and vomiting, constipation, fatigue, and delirium are among the most common physical symptoms. Pain is discussed separately within this chapter. Treatment of depression and anxiety is discussed briefly in this chapter and extensively in Chapter 28. This chapter focuses primarily on the pharmacologic management of symptoms and also recognizes the benefits of many integrative practices for symptom control, including acupuncture and mindfulness.

Dyspnea

Dyspnea is the subjective experience of difficulty breathing and may be characterized as shortness of breath, breathlessness, or tightness in the chest. Up to half of people at the end of life experience dyspnea.

Treatment of dyspnea is first directed at the underlying cause (see Chapter 9), assuming this care is consistent with a patient's goals. When disease-directed treatments for dyspnea are not sufficient or desired, dyspnea can be managed symptomatically with opioids. Starting doses are typically lower than what is necessary for the relief of pain. *Immediate-release* liquid morphine given orally (2–5 mg sublingually every 4 hours as needed) or intravenously (1–2 mg every 2 hours as needed) can treat dyspnea effectively. *Sustained-release* morphine given orally at a dose of 15 mg once or twice daily is safe and effective for most patients with frequent or chronic dyspnea. Supplemental oxygen may be useful for a patient who is *hypoxic,* but oxygen is *not* helpful for dyspnea in patients who are not hypoxic. Noninvasive ventilation (eg, bilevel positive airway pressure [BIPAP], high-flow oxygen via nasal cannula) can be helpful when ventilation is compromised, assuming there are no contraindications. Moving air from an open window or fan also can provide relief for dyspneic patients.

For patients with dyspnea and associated anxiety, nonpharmacologic relaxation techniques, such as mindfulness, meditation, and guided imagery, may be beneficial. Benzodiazepines may be useful adjuncts for treatment of dyspnea-related anxiety but should be used with caution, especially in combination with opioids, as they can increase risk of mortality.

Simon ST et al; BETTER-B Consortium. Practice review: pharmacological management of severe chronic breathlessness in adults with advanced life-limiting diseases. Palliat Med. 2024;38:1079. [PMID: 39264397]

Nausea & Vomiting

The management of severe, frequent nausea can require proactive dosing of medications (ie, scheduled around the clock rather than as needed) as well as multiple medications targeting more than one of the major mechanisms of nausea and vomiting (see Chapter 17). Medications for nausea and vomiting are summarized in Table 5–1. Additionally, integrative medicine practices for treatment of nausea that are supported by evidence include ginger, inhaled isopropyl alcohol, acupuncture, and hypnosis. Medical cannabis and dronabinol (2.5–20 mg orally every 4–6 hours) also can be helpful in the management of nausea and can boost appetite.

Malignant bowel obstructions can cause nausea and vomiting that is particularly challenging to ameliorate. In those cases, nasogastric suction may provide rapid, short-term relief, H_2-blocking medications (eg, famotidine 20–60 mg orally daily) can reduce gastric secretions, steroids (eg, dexamethasone 8 mg daily) can be used to decrease swelling associated with the tumor to relieve the obstruction, and somatostatin analogs (eg, octreotide 600 mcg/day) may be tried to decrease gastrointestinal secretions and motility, though evidence for their benefit is limited. In refractory cases, a venting gastrostomy tube may be needed to provide symptomatic relief.

Table 5–1. Pharmacologic management of nausea and vomiting.

Medication Class	Medications and Dosing	Pathophysiologic Causes of Nausea, with Check Mark (√) Indicating Mechanisms of Each Medication Class				
		Toxins (eg, Chemotherapy, Infection)	Vestibular Disturbance	Gastrointestinal Dysmotility or Disturbance	Anticipation or Sensory Triggers	Increased Intracranial Pressure
5-HT3 antagonists	Ondansetron (4–8 mg orally or intravenously four times a day) Granisetron patch (3.1 mg transdermally daily) Mirtazapine (7.5–45 mg orally nightly)	√	√	√	√	√
Dopaminergic antagonists	Olanzapine (2.5–10 mg orally nightly) Prochlorperazine (5–10 mg orally or intravenously four times a day or 25 mg per rectum twice daily) Metoclopramide (5–10 mg orally or intravenously four times a day)	√		√		
Antihistaminic or anticholinergic	Diphenhydramine (12.5–25 mg orally or intravenously every 8 hours) Scopolamine (1.5-mg patch every 3 days)		√			
Neurokinin-1 receptor antagonists	Aprepitant (125 mg orally on day 1, 80 mg on days 2–3)	√				
Benzodiazepines	Lorazepam (0.5–1.0 mg orally every 6–8 hours)				√	
Corticosteroids	Dexamethasone (4 mg two to four times a day)			√		√
Acid suppressants	Famotidine (20–60 mg orally daily) Omeprazole (20 mg twice daily) (also available as orally dissolving tablet)			√		

Constipation

Constipation is a common problem in seriously ill patients, particularly given the frequent use of opioids, low intake of fluids and food, physical inactivity, and changes in strength and mobility that can affect toileting. Clinicians should inquire about hard, infrequent, or difficult-to-pass stools, since constipation is a preventable and treatable cause of discomfort (see Chapter 17). Sometimes, mild constipation may be prevented or relieved if patients increase their activity and intake of fluids. Simple considerations, such as privacy, regular undisturbed toilet time, and a bedside commode rather than a bedpan, may be helpful.

Constipation from opioid use—*A prophylactic bowel regimen with a stimulant laxative (eg, senna or bisacodyl) should be offered whenever opioids are prescribed.* Table 17–4 lists other agents (including osmotic laxatives such as polyethylene glycol and lactulose) that can be added as needed, especially for firm or hard stools. Docusate, a stool softener, is *not* recommended because it does not add benefit beyond stimulant laxatives in seriously ill patients. In the setting of slowed peristalsis in opioid-induced constipation, bulk-forming laxatives, like psyllium, should be avoided. Peripherally acting mu-receptor antagonists (eg, naloxegol 12.5–25 mg orally daily and methylnaltrexone 8–12 mg subcutaneously every other day) are recommended to treat laxative-refractory opioid-induced constipation. Lubiprostone or prucalopride also can be used. Suppositories (eg, bisacodyl 10 mg per rectum) and enemas (eg, tap water or saline) should be combined with oral medications in cases of severe constipation (ie, no bowel movement in > 3 days) or when use of oral medications is limited by vomiting. Patients who report being constipated and then have diarrhea may be passing liquid stool around impacted stool. Such patients should have a rectal examination to assess for impaction; if it is present, manual disimpaction can be the quickest way to provide relief.

Fatigue

Fatigue is the most common complaint among people with cancer, heart failure, and other serious illnesses. Screening for and treating factors that contribute to fatigue is important (eg, insomnia, pain, depression, medication adverse effects, anemia, hypothyroidism, hypogonadism, and malnutrition). For nonspecific fatigue, a gradual increase of physical activity and physical rehabilitation may be most effective. There is strong evidence for exercise (eg, 150 minutes of aerobic exercise per week), yoga, and cognitive-behavioral therapy (CBT) to treat cancer-related fatigue. Psychostimulants (eg, methylphenidate 2.5–10 mg orally in the morning and mid-day as needed, modafinil 100–200 mg orally in the morning) and American ginseng (*Panax quinquefolius*) can be used to manage cancer-related fatigue, but evidence for their effectiveness is weaker. American ginseng may have an estrogenic effect and may impact the efficacy of anticoagulant medications. Corticosteroids can be beneficial but are most appropriate for patients with a short prognosis given their myriad side effects, which are most problematic with long-term use. Caffeine also can help some patients.

Stone P et al. Management of fatigue in patients with advanced cancer. Curr Treat Options Oncol. 2023;24:93. [PMID: 36656503]

Delirium & Agitation

Many seriously ill patients experience delirium—a waxing and waning in level of consciousness and cognition that develops over a short time course and is manifested by disorientation, sleep-wake cycle disruptions, psychomotor disturbances (eg, lethargy, restlessness), and mood disturbances (eg, fear, anxiety). Delirium may be hyperactive, hypoactive, or mixed. Hyperactive delirium at the end of life has also been called **terminal restlessness** and can be highly distressing to patients and families.

Common reversible causes of delirium include infections, urinary retention, constipation, anticholinergic medications, pain, and sleep disruption; these should be addressed when they are found. There is no strong evidence that dehydration causes, or that hydration relieves, delirium. Nonpharmacologic measures—including modifying the environment to make it calming and safe, ensuring a clear distinction between day and night, and frequently reassuring and reorienting patients to where they are and what is happening—are the cornerstones of delirium treatment. Ramelteon, a melatonin agonist, 8 mg/day orally has been shown to prevent delirium in seriously ill, older, hospitalized patients. The use of scheduled neuroleptics (risperidone or haloperidol) in patients with moderate delirium has been shown to *increase* delirium and mortality compared to placebo. *Thus, neuroleptic agents generally should be avoided in this setting.* However, when agitated delirium is severe and poses a significant safety risk or quality of life concern, neuroleptics (eg, quetiapine 12.5–25 mg orally at bedtime or haloperidol 1–2 mg orally, subcutaneously, intramuscularly, or intravenously every 6 hours as needed) may be used to mildly sedate the patient. Although benzodiazepines can worsen delirium and generally should be avoided, they may be used when deeper sedation is needed to achieve comfort or relieve suffering near the end of life, including in the setting of terminal restlessness. Such sedation may be achieved with midazolam (0.5–5 mg/h subcutaneously or intravenously) or with barbiturates (eg, phenobarbital 200 mg orally or rectally).

Heijltjes MT et al. Physicians opinion and practice with the continuous use of sedatives in the last days of life. J Pain Symptom Manage. 2022;63:78. [PMID: 34333097]

Depression & Anxiety

The management of mood symptoms, such as depression and anxiety, is an important aspect of palliative care and is described in detail in Chapter 28. Feelings of hopelessness, worthlessness, or anhedonia help distinguish depression from the low energy and other vegetative symptoms that are common in advanced illness. *Despite the significant sadness and grief that can be associated with facing a serious illness, clinical depression is not normal and should be treated.* Notably, coexisting depression can worsen outcomes in numerous serious illnesses.

In choosing a medication to treat depression or anxiety, it is important to consider whether it can achieve multiple effects for coexisting symptoms. For instance, serotonin norepinephrine reuptake inhibitors (SNRIs) are often preferred over SSRIs for patients with neuropathic pain in addition to depression. Mirtazapine can help with mood as well as with nausea and insomnia. When prognosis is short, it is important to use medications that render effects quickly. Therefore, for patients who have prominent fatigue in the setting of depression, a psychostimulant such as methylphenidate (2.5–10 mg orally at 8:00 AM and a second dose at 2:00 PM) or dextroamphetamine (2.5–7.5 mg orally at 8:00 AM and a second dose at 2:00 PM) can be started along with a traditional antidepressant medication to provide initial symptom relief while the benefits of SSRI or SNRI antidepressants take effect over 4–6 weeks. The stimulant can then be stopped or continued based on the patient's response to the stimulant, preferences, and prognosis. There is also emerging evidence for the benefits of psychedelic-assisted therapy (eg, with psilocybin or ketamine) for depression and anxiety, including at the end of life. Ketamine is approved with restrictions for treatment-resistant depression.

Generally, best outcomes result from the combination of pharmacologic and behavioral treatments for depression and anxiety. Cognitive behavioral therapy and acceptance and commitment therapy are two evidence-based psychotherapeutic frameworks that are commonly used for people with depression, anxiety, or both. Additionally, there is good evidence for the benefits of mindfulness for depression and anxiety. A meta-analysis found that mindfulness-based interventions were associated with reductions in anxiety for at least 6 months. Many online and mobile applications can support people to develop and practice mindfulness skills.

COMMUNICATION

Prognostication

Most patients with serious illness, and their loved ones, want accurate prognostic information. This information is necessary for patients to be able to make informed decisions, typically influences the choices they make and how they spend their time, and—when delivered skillfully—does not negatively impact patient well-being.

However, determining and communicating prognosis is not easy. Studies have shown that clinicians' estimates of prognosis are often inaccurate and generally overly optimistic. Many people with cancer do not understand when the treatments they are on are palliative rather than curative. Other common causes of death—including heart disease, stroke, chronic lung disease, and dementia—have even more variable trajectories and difficult-to-predict prognoses than most cancers. Nonetheless, clinical experience, epidemiologic data, and prediction tools (eg, the Palliative Performance Scale, found with other tools at http://eprognosis.ucsf.edu) may be used in combination to offer patients more realistic estimates of prognosis. Clinicians can also ask themselves "Would I be surprised if this patient died in the next year?" If the answer is "no," then the clinician should plan for a discussion of prognosis and goals of care. Recognizing that patients may have different preferences about when and how they receive prognostic information, clinicians should ask for permission before discussing prognosis, saying something like, *"I have information about what's likely to come with your illness. Would you like to talk about this?"* Additionally, it can be helpful to understand how patients want to receive this information with a statement such as, *"Some people prefer to hear information directly. Other people want information filtered through others, or don't want to hear certain information such as how much time they might have left to live. What are your preferences about receiving information about your illness and what is likely to come in the future?"* Palliative care communication resources, such as VitalTalk, offer detailed guidance around discussing prognosis (https://www.vitaltalk.org/guides/discussing-prognosis/).

Canavan ME et al. Systemic anticancer therapy at the end of life—changes in usage pattern in the immunotherapy era. JAMA Oncol. 2022;8:1847. [PMID: 36264566]

Communication in the Care of Seriously Ill Patients

Communication skills are vitally important when caring for seriously ill patients and can be improved through training. High-quality communication is associated with greater satisfaction and care that is more often concordant with patients' wishes. Clinicians must be proficient at delivering sensitive information and supporting the people who hear it (Table 5–2). Resources are available to support clinicians around serious illness communication (https://www.vitaltalk.org/, https://www.ariadnelabs.org/serious-illness-care/), and evidence suggests that communication checklists and guides can be helpful. When the clinician and patient do not speak the same language fluently, the use of a professional interpreter is critical to facilitate clear communication.

Table 5–2. Suggestions for the delivery of serious news.

Choose an appropriate place, time, and group of attendees.
Clinicians pre-meet and set an agenda for the conversation.
Begin with introductions and consent to review the news.
Assess the patient and family's perspectives and what they already know or have been told.
Provide clinical information. Be brief and direct; avoid jargon and euphemisms. Pause frequently to check for understanding.
Leave space for silence and expression of emotions. Compassionately attend to emotions that arise.
Allow sufficient time for processing and collaborative decision-making, whenever possible.
Briefly summarize the conversation and next steps. Ensure a plan to address questions that arise.

Manz CR et al. Long-term effect of machine learning-triggered behavioral nudges on serious illness conversations and end-of-life outcomes among patients with cancer: a randomized clinical trial. JAMA Oncol. 2023;9:414. [PMID: 36633868]

Advance Care Planning & Advance Directives

Advance care planning as defined by an international Delphi panel is *"a process that supports adults at any age or stage of health in understanding and sharing their personal values, life goals, and preferences regarding future medical care. The goal of advance care planning is to help ensure that people receive medical care that is consistent with their values, goals, and preferences during serious and chronic illness."* Clinicians should encourage all patients—ideally well before the end of life—to consider their preferences, appoint a surrogate decision-maker, talk to that person and to their clinicians about their preferences for current and future care, and document their wishes. Most patients with a serious illness have already thought about how they hope the end of their life will go, want to discuss their wishes with their clinician, want the clinician to bring up the subject of advance care planning, and feel better for having had discussions. Patients who have such discussions with their clinicians are more satisfied with their clinician, are less likely to die in a hospital, are more likely to utilize hospice care, and are perceived by their family as having a better quality of life at the end of life. The loved ones of patients who engage in advance care planning discussions are also less likely to suffer from depression during bereavement.

Advance directives are written or oral statements made by patients when they are competent, which are intended to guide care should they lose the capacity to make and communicate their own decisions. While oral statements about these matters are ethically binding, they are not legally binding in all states. State-specific advance directive forms are available from a number of sources, including the National Hospice Palliative Care Organization (https://www.caringinfo.org/planning/advance-directives/). Through an advance directive, patients can assign a **Durable Power of Attorney for Health Care (DPOA-HC)**, a surrogate decision-maker who is to use "substituted judgment" to decide *what patients would have wanted* when the patient has become unable to make and communicate their own decisions. In the absence of a designated surrogate, clinicians usually turn to family members or next of kin and, in rare cases, the courts. There are numerous resources that can guide people to create an advance directive, such as online at https://prepareforyourcare.org.

Hickman SE et al. The care planning umbrella: the evolution of advance care planning. J Am Geriatr Soc. 2023;71:2350. [PMID: 36840690]

McMahan RD et al. What clinicians and researchers should know about the evolving field of advance care planning: a narrative review. J Gen Intern Med. 2024;39:652. [PMID: 38169025]

Resuscitation Preferences

Because the "default" in US hospitals is that patients will undergo cardiopulmonary resuscitation (CPR) in the event of cardiopulmonary arrest, as part of advance care planning, clinicians should elicit patient preferences about CPR upon hospital admission as well as at other times when cardiac arrest seems like a distinct possibility. Only about 17% of all patients who undergo CPR in the hospital survive to hospital discharge; among people with multisystem organ failure, metastatic cancer, and sepsis, the likelihood of survival to hospital discharge following CPR is much lower. Clinicians must describe CPR clearly, avoiding overly frightening or benign language that might unduly sway a patient's decision, and must inform patients about the possible sequelae of CPR if they do survive, including neurologic disability and need for other invasive interventions (such as intubation and mechanical ventilation). Patients may ask their hospital clinician to write an order that CPR not be attempted should they experience cardiac arrest. Although this order initially was referred to as a **"DNR" (do not resuscitate)** order, many clinicians prefer the term **"DNAR" (do not attempt resuscitation)** to emphasize that resuscitation is not always successful. Some clinicians and institutions use the term **"Allow Natural Death"** instead, which is particularly appropriate for situations in which death is imminent.

For patients with very short prognoses, decisions about CPR may be best understood as *not about whether they will live, but about how they will die*. Clinicians should correct the misconception that not doing CPR is tantamount to "withdrawing care" or "letting someone die." While respecting the patient's right to make the decisions, clinicians should offer recommendations about DNAR orders that are grounded in their understanding of the patient's values and priorities, taking care to not be influenced by their own biases and prejudices in this process. Providing such recommendations can protect dying patients and their families from feelings of guilt and from the added grief associated with having unrealistic hopes. Clinicians should also discuss which interventions will be continued and which started to promote comfort, rather than focusing only on which interventions will be stopped or withheld. For patients with an implanted cardioverter defibrillator, clinicians must also address turning off the defibrillator, while leaving the pacemaker function on, as death approaches to prevent the distressing situation of the defibrillator discharging during the dying process.

Physician (or Medical) Orders for Life-Sustaining Treatment (POLST or MOLST) or **Physician (or Medical) Orders for Scope of Treatment (POST or MOST)** forms are active orders, including for resuscitation, that complement advance directives and can guide care for patients especially in the setting of an emergency. They document care preferences in a standard way that is transferrable across all care settings—home, hospital, and care facilities. They are available in most states within the United States and are appropriate for patients with a serious illness, frailty, a short (roughly < 1 year) prognosis, or a combination of these conditions.

Ethical Considerations

Clinicians' care of seriously ill patients is guided by the same ethical and legal principles that inform other types of medical care. Foremost among these are truth-telling, nonmaleficence, beneficence, autonomy, confidentiality, and procedural and distributive justice. *Important ethical principles may come into conflict when caring for patients with serious illness.* For example, many treatments that promote beneficence and autonomy, such as surgery or bone marrow transplantation, may end up violating the clinician's commitment to nonmaleficence; thus, balancing the benefits and risks of treatments is an important ethical responsibility in palliative care.

In most cases, clinicians, patients, and families agree on decisions to stop or forego life-sustaining interventions, and most disagreements between families and clinicians can be resolved with good communication. However, when there is persistent disagreement between patients or family members and clinicians, it is recommended that the clinicians consult with an institutional ethics committee. In rare cases, clinicians may determine unilaterally that a particular intervention—such as CPR or dialysis in end-stage multisystem organ failure—offers no realistic possibility of benefit and thus need not be offered even when it is requested by a patient or family. Because such unilateral actions potentially violate the autonomy of the patient, clinicians should *rarely* resort to them. Clinicians must use caution in invoking "futility," since strict futility is rare and what constitutes futility is often a matter of controversy and subject to bias. Patients and their surrogates have the same right to stop unwanted medical treatments once begun as they do to refuse those treatments initially.

Psychological, Social, & Spiritual Aspects of Care

Illness and dying are not exclusively biomedical processes. They are human experiences with profound psychological, interpersonal, and existential meanings. For many people with serious illness, the prospect of impending death stimulates a deep assessment of their identity, relationships, values and priorities, the meaning and purpose of their life, and their legacy. Some individuals may grow through illness and, by offering presence, encouraging reflection, and providing support, clinicians may be a catalyst for this growth.

A. Psychological Considerations

Near the end of life, anticipatory grief is common. In 1969, Dr. Elisabeth Kübler-Ross identified five psychological reactions or patterns of emotions seen in grief: denial and isolation, anger, bargaining, depression, and acceptance. Many patients will experience these reactions throughout the course of a serious illness, but generally not in an orderly progression. In addition to these five reactions are the challenges of anxiety and fear of the unknown. Straightforward information, attentive listening, reassurance when appropriate, and validation may help patients with these psychological challenges. *Patients and families rank emotional support as one of the most important aspects of end-of-life care.* Meaning-centered psychotherapy and group psychotherapy are effective for treating emotional distress at the end of life. See above under "Palliation of Common Nonpain Symptoms" and Chapter 28 for a description of the pharmacologic treatment of depression in the setting of serious illness.

Clinicians caring for seriously ill patients can also serve as facilitators or catalysts for hope. While hope for a particular outcome such as cure may decline, hope can be refocused on *what is still possible*. Even if a patient hopes for a "miracle," clinicians can share that hope while simultaneously encouraging more likely hopes, including hope for comfort, connection with loved ones, meaning-making, and spiritual growth. With such questions as, "*When you look to the future, what do you hope for?*" clinicians can explore meaningful and realistic goals and then develop plans to achieve them.

B. Social Considerations

In the face of serious illness, patients should be encouraged to attend to personal, professional, and logistical obligations. These tasks include completing important work or personal projects, distributing possessions, writing a will, and making funeral and burial arrangements, as desired. Some people find meaning in writing an "ethical will" that documents their wisdom and lessons learned (see also information about "legacy," below). The prospect of death often prompts people to examine the quality of their interpersonal relationships and to begin the process of saying goodbye. Concern about estranged relationships or "unfinished business" and interest in reconciliation may become paramount at this time. Financial concerns can be a significant source of distress, particularly given the rising costs of caregiving, which many people with serious illness require. Referrals to social workers can help identify potential resources or strategies to address these concerns.

C. Spiritual & Existential Considerations

As people near the end of life, spiritual and existential considerations often include attempts to understand the meaning of one's life, one's place in the universe, and one's legacy.

Perhaps because of preoccupation with biologic aspects of treatment or lack of training, clinicians frequently ignore their patients' spiritual concerns or reflexively refer these important issues to chaplains or other spiritual care providers. However, existential considerations are central to the well-being of people with serious illness and should be the concern of all clinicians caring for them.

Unlike physical ailments, such as infections and fractures, which usually require a concrete intervention to be treated, a patient's spiritual and existential concerns are often best addressed through a clinician's devoted attention, active listening, and bearing witness, rather than attempts to "fix" problems. Clinicians can inquire about the patient's spiritual well-being and ask whether the patient wishes to discuss existential concerns. For example, asking, *"How are your spirits?"* or *"Are you at peace?"* communicates that the clinician is interested in the patient's whole experience and provides an opportunity for the patient to share perceptions about his or her inner life.

Legacy work and dignity therapy have been shown to be effective in improving spiritual well-being and quality of life. Clinicians can ask patients to recall what they are proudest of to promote a sense of value and dignity. Opportunities for storytelling give patients a chance to verbalize what is meaningful to them and to leave something of themselves behind, with the promise of being remembered by loved ones. Consider inviting patients to share their life stories with family members, make an audio or video recording, assemble a photo album or scrapbook, or write or dictate autobiographical vignettes.

Wilkie DJ … Rabow M et al. Engaging mortality: effective implementation of dignity therapy. J Palliat Med. 2024;27:176. [PMID: 37676977]

Cultural Considerations

Various religious, ethnic, and cultural traditions can influence a patient's style of communication, comfort in discussing particular topics, expectations about illness, dying, and medical interventions, and preferences about disposition of remains. While there are differences in beliefs regarding advance care planning, withdrawal of life-sustaining interventions, autopsy, organ donation, and hospice care among patients of different demographic groups, clinicians should be careful not to make assumptions about any individuals. Being curious about and respectful of each person's unique values, beliefs, and traditions are important responsibilities of the clinician caring for seriously ill patients. A clinician may ask a patient, *"What do I need to know about you and your beliefs that will help me take the best care of you?"* and *"How do you make decisions in your family?"*

Clinicians must also appreciate that palliative care is susceptible to the same explicit and implicit biases documented in other medical specialties. Humility, self-reflection, and continual learning are key to the practice of palliative care. It is also imperative that palliative care practitioners work actively to identify and rectify injustice in the medical system, including racism, sexism, class discrimination, and homophobia.

Koffman J et al. Researching minoritised communities in palliative care: an agenda for change. Palliat Med. 2023;37:530. [PMID: 36271636]

Caring for the Family & Other Care Partners

In caring for seriously ill patients, clinicians must appreciate the central role played by family, friends, and other loved ones (sometimes called "caregivers" or "care partners"). Family and other informal care partners, most often women, provide the bulk of care for seriously ill patients, yet their work is often not adequately acknowledged, supported, or compensated. They can simultaneously struggle with physical caregiving responsibilities, care coordination challenges, and financial burdens. Care partners also experience higher rates of anxiety, depression, grief, chronic illness, and even mortality. However, palliative care has been shown to reduce depression, complicated grief, and posttraumatic stress disorder in care partners.

Clinicians treating people with serious illness should provide care not only for patients but also for the patient's care partners. It is important to hold family meetings so that all members can hear from clinicians, understand the patient's values and preferences, and be heard. Acknowledging and respecting the role of care partners, and soliciting their perspectives, questions, and concerns, can be powerful. It is important to offer care partners an opportunity to meet with members of the medical team separately from the patient, which can be particularly meaningful when the informational preferences and needs of the care partner differ from those of the patient. Video telemedicine can allow care partners to participate in meetings even if they are unable to be physically present.

CARING FOR PATIENTS AT THE END OF LIFE

Annually, > 3 million people die in the United States and approximately 61 million die worldwide. Caring for patients at the end of life is an important responsibility and can be deeply meaningful for clinicians. The end of life is defined as that time when death is expected within hours to a few months and can no longer be significantly forestalled by medical intervention. At the end of life, palliative care can do much to relieve distress and promote comfort and quality of life. For many patients at the end of life, palliative care becomes the primary focus of care.

Counseling Patients Approaching the End of Life

Patients' experiences at the end of life are influenced by their expectations about how they will die and their sense of the meaning of death. Many fear how they will die more than death itself. Patients report fears of dying in pain or of suffocation, loss of control, indignity, isolation, and being a burden to their families. These anxieties can be ameliorated with attentive palliative care.

Death is often regarded by clinicians, patients, and families as a failure and an enemy to be battled rather than as an inevitability and a normal part of life. As a result, many people in the United States die in hospitals or long-term care facilities even though they may have wished otherwise. However, there is a trend toward fewer deaths in hospitals and more deaths at home or in other community settings. In 2017, deaths at home in the United States surpassed hospital deaths for the first time in about a century, with 31% of people dying at home.

Relieving suffering, providing support, and helping patients make the most of their final stage of life should be the foremost considerations, even when patients continue to pursue treatment for potentially reversible disease processes. Patients at the end of life and their care partners identify many factors as important to quality end-of-life care, including managing pain and other symptoms, avoiding unwanted invasive treatments, preserving dignity, having a sense of control, minimizing burdens on others, and strengthening relationships with loved ones. However, because there is a wide variation between people in terms of what they value most at the end of life, it is critical that clinicians ask patients about their priorities and preferences.

Additionally, it is important that clinicians caring for patients at the end of life pledge that they will care for the patient throughout the final stage of life, which can help curb the patients' fear and sense of isolation. *The promise of nonabandonment is a central principle of end-of-life care.* No matter what happens, clinicians can be a guide during uncertain times, a resource for practical problem-solving, and a witness to the patient's experiences. Dying patients need their clinicians to offer their presence—not necessarily the ability to solve all problems but rather a commitment to recognize and receive the patients' difficulties and experiences with respect and empathy. At its best, the patient–clinician relationship can be a covenant of compassion and affirmation of common humanity.

Chochinov HM. Intensive caring: reminding patients they matter. J Clin Oncol. 2023;41:2884. [PMID: 37075272]

Hospice

In the United States, hospice is a specific type of palliative care service that is available to patients with a prognosis of 6 months or less (a criterion for eligibility under the Medicare hospice benefit) who want to prioritize comfort and not pursue life-prolonging treatments. In the United States in 2021, nearly half of people who died use hospice, most at home where they were cared for by their family and other care partners with support from visiting hospice staff. Less often, hospice care is provided in residential facilities, nursing homes, and hospitals. As is true of all types of palliative care, hospice emphasizes individualized attention for patients and care partners, and uses an interdisciplinary team approach with nurses, social workers, chaplains, personal care attendants, physicians, and others working together. When patients enroll in hospice, the hospice team typically takes over their medical care entirely and patients generally do not continue to see their preexisting medical providers for scheduled visits. Hospice is rated highly by families and has been shown to increase patient satisfaction and to improve care partner bereavement. A study of bereaved family caregivers demonstrated higher opinions of end-of-life care provided by home hospice teams compared with end-of-life care provided in nursing homes, in hospitals, or at home without hospice care.

Despite evidence suggesting that hospice care does not shorten length of life, hospice care tends to be engaged late, often within weeks of death. Many people wait to enroll in hospice until they have decided with certainty that they no longer wish to pursue life-prolonging treatments. Patients can be encouraged to enroll in hospice while they are still deciding about further life-prolonging treatment attempts (eg, upcoming clinical trials) and can *disenroll from hospice* if they decide to pursue them.

Nutrition & Hydration

People with serious illness often lose their appetite, and most stop eating and drinking in their final days. Clinicians should explain to families that people who are dying are not "starving to death." Rather, the cessation of eating and drinking is a normal part of the dying process. The ketonemia caused by not eating can produce a sense of mild euphoria and analgesia. However, carbohydrate intake even in small amounts (such as that provided by 5% intravenous dextrose solution) blocks ketone production and may blunt the effects of ketosis. The sensation of thirst can usually be reduced by moistening the mouth with ice chips, swabs, or popsicles.

Although the normal process of diminishing oral intake is very common in seriously ill people, it can be distressing to families who may associate the offering of food with loving care and lack of eating with starvation. In response, patients and families often ask about supplemental hydration or enteral or parenteral nutrition. *Artificial nutrition and hydration generally do not benefit those at the end of life (including patients with end-stage cancer or dementia) and rarely achieve patient and family goals.* Intravenous hydration may increase oropharyngeal secretions that can be difficult to manage, pulmonary edema, and third-spacing and thus is not indicated unless a patient has severe or symptomatic dehydration. Enteral feeding may cause nausea and diarrhea and increase risk of aspiration. Parenteral nutrition imposes risks of line infection, electrolyte imbalance, and burden from blood draws used to monitor the treatment, in additional to the potential harms caused by the fluid delivered. Additionally, artificial hydration and nutrition for delirious patients may lead to the use of physical or chemical restraints to prevent lines or tubes from being dislodged.

Decisions about artificial nutrition and hydration are not simply medical and may have deep social and cultural significance for patients, care partners, and clinicians. Eliciting perceived goals of artificial nutrition and hydration, correcting misperceptions, offering comprehensive support to patients and care partners, and allowing sufficient time to make decisions can help patients and care partners make sound decisions. Care partners can be encouraged to express their love and care for patients in ways other than through artificial nutrition or hydration (eg, using ice chips or swabs to relieve symptomatic xerostomia). Individuals at the end of life have the right to voluntarily refuse nutrition and hydration.

Bower KL et al. Ethical implications of nutrition therapy at the end of life. Curr Gastroenterol Rep. 2023;25:69. [PMID: 36862286]

Withdrawal of Life-Prolonging Treatments

Informed and competent patients, or their surrogates, are allowed to refuse or stop life-sustaining treatments. The withdrawal of life-sustaining treatments, such as mechanical ventilation, must be done carefully to avoid patient suffering and distress for those in attendance. Clinicians should educate the patient and family about the expected course of events after withdrawal of life-sustaining treatments, and what can be expected regarding the approximate timing of death. Loved ones should be offered the opportunity to be at the bedside during the process of withdrawing life-sustaining intervention whenever possible. Sedating and analgesic agents should be administered to ensure patient comfort prior to any life-prolonging treatments being withdrawn, even if they contribute to respiratory depression or hypotension. The ethical **Principle of Double Effect** argues that hastening of an imminent death is acceptable if it comes as the known but unintended consequence of a primary intention to provide comfort and relieve suffering. When communicating with patients and their care partners, using language like "transitioning to comfort-focused care" and "stopping interventions that artificially sustain life" is preferred to using the phrase "withdrawing care," since the latter term may be perceived as entirely stopping the provision of care and attention.

Akdeniz M et al. Ethical considerations at the end-of-life care. SAGE Open Med. 2021;9:20503121211000918. [PMID: 33786182]

Care of the Actively Dying Patient

Signs of approaching death (eg, alterations in breathing patterns, skin changes, and changes in mental status) should be recognized and shared with loved ones so they can be prepared. Loved ones can be encouraged to speak gently to and around the dying person, with the assumption that dying people might still have the ability to hear even when they cannot respond. Retained oropharyngeal and respiratory secretions are common in actively dying patients, and the sound caused by these (a "death rattle") can be distressing to families, but they are not thought to be uncomfortable to patients as they are not typically associated with other signs of distress. Turning the patient can decrease the sound and decreasing intravenous fluids also can help. There is no evidence that medications decrease secretions meaningfully, and deep suctioning should be avoided since it can cause discomfort.

Medical Aid in Dying

Medical aid in dying (MAID) is the legally sanctioned process in some regions by which patients who have terminal illness with a prognosis of 6 months or less and decisional capacity may request and receive prescriptions from a clinician for a lethal dose of medications that the patients can *self-administer* for the purpose of ending their life. While terminology for this process varies, the term "physician-assisted suicide" is discouraged because it is not considered suicide and patients who are actively suicidal from mental illness are *not* eligible for MAID in the United States.

Although public and state support for MAID has grown in the United States, this remains an area of contention and debate. As of 2024, MAID has been legalized with careful restrictions and specific procedures for residents in 10 US states (Oregon, Washington, Montana, Vermont, California, Colorado, Hawaii, New Jersey, Maine, and New Mexico) as well as the District of Columbia. Internationally, MAID (and/or euthanasia, which is the administration of a lethal dose of medication by a clinician) is legal in a growing number of countries (the Netherlands, Belgium, Luxembourg, Switzerland, Austria, Spain, Colombia, Canada, Germany, New Zealand, and Australia). US laws permitting MAID require physician certification of a terminal disease with a prognosis of 6 months or less and require the individual to be competent to make and communicate their own health care decisions at that time, to be an adult resident of the state, and to be physically capable of self-administering the medication through an enteral route. Any clinician that hears a request for MAID should be familiar with the law governing it in their area.

Requests for MAID are relatively rare, and the use of these medications leads to about 0.3% of all deaths in the United States. *Requests for MAID are generally motivated by a desire to have control in the dying process and preserve dignity, rather than by intolerable pain or other symptoms.* In the United States, most patients requesting it are male, white, college-educated, and receiving hospice care.

Each clinician must decide their personal approach to caring for patients who ask about MAID. Regardless of the clinician's feelings about the intervention, the clinician should respond initially by *exploring the patient's reasons for making the inquiry*. During the dialogue, the clinician should inform the patient about their options (including palliative care, hospice care, symptom management, and psychosocial and spiritual support) and provide reassurance that people typically can be made comfortable around the end of life. For clinicians who object to MAID on moral or ethical grounds, documentation of the request and referral to another clinician to field the request is appropriate.

Patel T. Clinician responses to legal requests for hastened death: a systematic review and meta-synthesis of qualitative research. BMJ Support Palliat Care. 2021;11:59. [PMID: 32601150]

TASKS AFTER DEATH

After the death of a patient, the clinician is called upon to perform a number of tasks, both required and recommended. The clinician must do an examination to confirm the death, compassionately and directly inform the family of the death, inquire about preferences regarding autopsy, complete a death certificate, and contact an organ procurement organization, as indicated. Providing words of sympathy and support, time for questions, and, for people who die in the hospital or other health care facility, a quiet private room for the family to grieve is also important.

Pronouncement & Death Certificates

In the United States, state policies direct clinicians to confirm the death of a patient in a formal process called "pronouncement." The diagnosis of death is typically easy to make, and the clinician need only verify the absence of spontaneous respirations and cardiac activity by auscultating for each for 1 minute. A note describing these findings, the time of death, and that the family has been notified is entered in the patient's medical record. In many states, when a patient whose death is expected dies outside of the hospital (eg, at home), nurses may be authorized to report the death over the telephone to a physician who assumes responsibility for signing the death certificate within 24 hours. While the pronouncement may sometimes seem like an awkward and unnecessary formality, both clinicians and families may use the ritual as an opportunity to begin to emotionally process the death of the patient. Clinicians may use this time to reassure the patient's loved ones at the bedside that the patient died peacefully and that all appropriate care had been given, when this is the case.

Physicians are legally required to accurately report the underlying cause of death on the death certificate and to report certain deaths to the coroner. The physician should be specific about the major cause of death being the condition without which the patient would not have died (eg, "decompensated cirrhosis") and its contributory cause (eg, "hepatitis B and hepatitis C infections") as well as any associated conditions (eg, "acute kidney injury"). It is not appropriate to write "cardiac arrest" as the cause of death. In cases where MAID is pursued, clinicians should document the patient's underlying terminal illness that qualified them for the prescription (eg, "metastatic pancreatic cancer"). "Medical aid in dying" should not be written anywhere on the death certificate.

Autopsy & Organ Donation

Discussing the options of autopsy and organ donation with patients prior to death is a good practice when possible, as it promotes patient autonomy and lessens the responsibilities of distressed family members during the period immediately following the death. In the United States, federal regulations require that a designated representative of an organ procurement organization be the one to approach family members about organ donation because organ transplant personnel are typically more experienced than treating clinicians at counseling family members about organ donation. While most people in the United States support the donation of organs, organ transplantation is severely limited by the availability of donor organs. Many families of donors feel it is gratifying to contribute so meaningfully to the lives of others, even through death.

Even with the use of sophisticated diagnostic tests, an autopsy can provide families important information about the cause of their loved one's illness and death, which can help with closure and can advance medical knowledge. Despite the benefits of autopsies, autopsy rates in US hospitals are only approximately 5%. Families decline autopsies because of unwarranted fears about disfigurement of the body or delay of the funeral, and some say they were not asked. It is important to educate families that pathologists can perform autopsies without interfering with funeral plans and take care to limit the impact on the appearance of the deceased.

Scarl R et al. The hospital autopsy: the importance in keeping autopsy an option. Autops Case Rep. 2022;12:e2021333. [PMID: 35252044]

Bereavement Care

Comprehensive end-of-life care includes following up with surviving loved ones after the patient has died. Contacting loved ones provides the clinician with an opportunity to express respects for the deceased patient and the loved ones that cared for the patient, assuage guilt loved ones may have, assess how loved ones are coping, provide education about the normal grieving process, and screen for complicated grief. Clinicians should recommend bereavement support groups and counseling as needed. Some clinical teams also send a card or make a telephone call months after the patient's death, on the anniversary of the death, or both, so that loved ones know that they and the deceased patient have not been forgotten and supportive services remain available to them.

After a patient dies, clinicians also grieve. Some deaths may cause feelings of sadness, loss, guilt, or remorse. A first step toward processing and ameliorating these feelings is recognizing them. *Each clinician should develop personal or communal practices to support them through difficult emotions.* Taking time for reflection, sharing stories and feelings with colleagues, engaging in rituals, and protecting time for other self-care practices may be helpful. Attending the funeral of a patient who has died can be a satisfying personal experience that is generally appreciated by families.

Lichtenthal WG et al. Investing in bereavement care as a public health priority. Lancet Public Health. 2024;9:e270. Erratum in: Lancet Public Health. 2024;9:e281. [PMID: 38492580]

Clinician Self-Care

Many clinicians find caring for patients with serious illness to be one of the most rewarding aspects of medical practice. Working with this population, however, is intense and can invoke difficult emotions. Clinicians must be able to tolerate uncertainty, ambiguity, powerlessness, and the limitations of modern medicine. They may find themselves considering their own eventual mortality. Clinicians should strive to recognize and attend to their own needs, build and strengthen resiliency skills, and advocate for sustainable health care systems, in order to avoid being overburdened, overly distressed, or emotionally depleted by this work.

PAIN MANAGEMENT

TAXONOMY OF PAIN

The International Association for the Study of Pain (IASP) defines pain as "an unpleasant sensory and emotional experience associated with, or resembling that associated with, actual or potential tissue damage."

Acute pain resolves within the expected period of healing and is self-limited.

Chronic pain persists beyond the expected period of healing and is itself a disease state. In general, chronic pain is defined as extending beyond 3–6 months.

Cancer pain is in its own special category because of the unique ways neoplasia and its therapies (such as surgery, chemotherapy, immunotherapy, or radiation therapy) can lead to burdensome pain.

Pain at the end of life entails measures to alleviate suffering that may take priority over promoting restoration of function.

Pain is a worldwide burden; across the globe, *one in five adults suffers from pain*. In 2010, members from 130 countries signed the Declaration of Montreal stating that *access to pain management is a fundamental human right*. The first CDC guidelines on opioid prescribing for chronic pain, including chronic noncancer pain, cancer pain, and pain at the end of life, were published in 2016, and continue to be updated. Notably, in 2022, the CDC opioid prescribing guidelines were revised with increased flexibility for opioid prescriptions.

Centers for Disease Control and Prevention (CDC). Opioid Prescribing Resources. 2022. Department of Health and Human Services. Pain Management Best Practices. Pain management best practices inter-agency task force report. 2022. Accessed August 20, 2024. https://www.cdc.gov/overdose-prevention/hcp/clinical-guidance/

ACUTE PAIN

Management of acute pain depends on comprehending the type of pain (**somatic, visceral,** or **neuropathic**) and on understanding the risks and benefits of potential therapies. At times, treating the underlying cause of the pain (eg, dental caries) may be all that is needed, and pharmacologic therapies may not be required for additional analgesia. On the other hand, not relieving acute pain can have consequences beyond the immediate suffering. Inadequately treated acute pain can develop into chronic pain in some patients. This transition from acute to chronic pain ("chronification" of pain) depends on the pain's cause, type, and severity and on the patient's age, psychological status, and genetics, among other factors. Chronic pain leads to significant societal costs beyond the individual's experiences of suffering, helplessness, and depression. Increased intensity and duration of acute pain may be correlated with a higher incidence of chronic pain, and regional anesthesia, ketamine, gabapentinoids, and cyclooxygenase (COX) inhibitors may be helpful for prevention of chronic postsurgical pain. These approaches are particularly important given concerns that exposure to opioids in the perioperative period can lead to chronic opioid dependence.

The Oxford League Table of Analgesics is a useful guide; it lists the number-needed-to-treat for specific doses of various medications to relieve acute pain. NSAIDs, including COX inhibitors, have the lowest number-needed-to-treat. Delivery routes for these medications include oral, intramuscular, intravenous, intranasal, rectal, and transdermal. The primary limitation in use of the COX inhibitors is their side effects of gastritis; kidney dysfunction; bleeding; and cardiovascular adverse events, such as hypertension, MI, and stroke. Like most pharmacologic therapies, COX inhibitors have a "ceiling" effect, meaning that beyond a certain dose, there is no additional benefit.

Acetaminophen (paracetamol) is effective as a sole agent, or in combination with an NSAID or an opioid in acute pain. Its mechanism of action remains undetermined but is thought to act centrally through mechanisms such as the prostaglandin, serotonergic, and opioid pathways. It is one of the most widely used and best tolerated analgesics; its primary limitation is hepatoxicity when given in high doses or to patients with underlying impaired liver function.

Patient-controlled analgesia (PCA) (including postoperatively) with intravenous morphine, hydromorphone, or another opioid can achieve analgesia faster and with less daily medication requirement than with standard "as needed" or even scheduled intermittent dosing. PCA can also be used with oral analgesic opioid medications and with both opioids and local anesthetics via neuraxial delivery in the epidural and intrathecal spaces. The goal of PCA is to maintain a patient's plasma concentration of opioid in the "therapeutic window," between the minimum effective analgesic concentration and a toxic dose.

In order to prevent prolonged inappropriate opioid use and opioid use disorder, **multimodal analgesia** (including regional anesthesia) has been employed to decrease the need for postoperative opioids. Patients may undergo either neuraxial anesthesia with an epidural catheter, for example, or regional anesthesia with a nerve block with or without a catheter. These techniques are effective for management of both intraoperative pain and postoperative pain and can diminish the need for both intraoperative and postoperative opioids.

CHRONIC NONCANCER PAIN

Chronic noncancer pain may begin as acute pain that then fails to resolve and extends beyond the expected period of healing; it may also arise from a primary disease state, rather than as the residual symptom from another condition. Common examples of chronic noncancer pain include chronic low-back pain and arthralgias (often somatic in origin), chronic abdominal pain and pelvic pain (often visceral in origin), chronic headaches, chronic (persistent) postoperative pain, peripheral neuropathy, and postherpetic neuralgia (neuropathic origin). Chronic noncancer pain is common, with both international and US estimates of prevalence of approximately 20% in adults.

Chronic noncancer pain requires interdisciplinary management. Generally, no one therapy by itself is sufficient to manage such chronic pain. Physical or functional therapy and cognitive behavioral therapy have been shown to be the most effective for treating chronic noncancer pain, but other modalities including pharmacologic therapy, interventional modalities, and complementary/integrative approaches are useful in caring for affected patients.

Chronic low-back pain, a common type of chronic noncancer pain, causes more disability globally than any other condition. Evidence-based practice does *not* support the use of prolonged opioid therapy for chronic low-back pain.

CANCER PAIN

Cancer pain is unique in cause and in therapies. Cancer pain consists of both acute pain and chronic pain from the neoplasm itself as well as from the therapies associated with it, including surgery, chemotherapy, radiation, and immunotherapy. In addition, patients with cancer pain may also have acute or chronic non–cancer-related pain, a possibility that should not be overlooked.

Cancer pain includes **somatic pain** (eg, neoplastic invasion of tissue), **visceral pain** (eg, painful hepatomegaly from liver metastases), **neuropathic pain** (eg, neoplastic invasion of sacral nerve roots), or **pain from a paraneoplastic syndrome** (eg, peripheral neuropathy). Chemotherapy can cause peripheral neuropathies, radiation can cause neuritis or skin allodynia, surgery can cause persistent postsurgical pain such as postmastectomy or postthoracotomy pain syndromes, and immunotherapy can cause arthralgias.

Patients with cancer pain may have multiple reasons for pain and thus benefit from a comprehensive and multimodal strategy. The **WHO Analgesic Ladder** suggests starting medication treatment with nonopioid analgesics, then weak opioid agonists, followed by strong opioid agonists. While opioid therapy can be helpful for the majority of patients living with cancer pain, therapy must be individualized depending on the patient, their family, and the clinician. For example, if patients are experiencing sedation and cognitive dysfunction from opioids, interventional therapies such as nerve blocks and implantable devices may be an option, weighing their risks and costs against their potential benefits. Alternatively, in dying patients, provided there is careful documentation of continued, renewed, or accelerating pain, use of opioid doses exceeding those recommended as standard for acute (eg, postoperative) pain is acceptable. Furthermore, for ongoing cancer pain, a long-acting opioid analgesic can be given around the clock with a short-acting opioid medication as needed for "breakthrough" pain.

One of the unique challenges in treating cancer pain is that it is often a "moving target," with disease progression and improvements or worsening pain directly stemming from chemotherapy, radiation, or immunotherapy. Therefore, *frequent adjustments may be required to any pharmacologic regimen*. Interventional approaches such as celiac plexus neurolysis and intrathecal therapy are well studied and may be appropriate for both analgesia and reduction of side effects from systemic medications. Radiation therapy (including single-fraction external beam treatments) may decrease the extent of both primary and metastatic disease and may treat the associated pain.

PAIN AT THE END OF LIFE

Pain is what many people say they fear most about dying, and pain at the end of life is consistently undertreated. Up to 75% of patients dying of cancer, HF, COPD, AIDS, or other diseases experience pain. In the United States, the Joint Commission includes pain management standards in its reviews of health care organizations and mandates that each hospital have a designated leader in pain management.

The risk-to-benefit ratio changes in end-of-life pain management. Harms from the use of opioid analgesics, including even death, eg, from respiratory depression (rare), are perhaps less of a concern in patients approaching the end of life. In all cases, clinicians must be prepared to use appropriate doses of opioids in order to relieve this distressing symptom for these patients. In the hospice setting, greater use of opioids is actually associated with decreased mortality.

PRINCIPLES OF PAIN MANAGEMENT

The experience of pain is unique to each person and influenced by many factors, including the patient's prior experiences with pain, meaning given to the pain, emotional stresses, and family and cultural influences. A brief means of assessing pain and evaluating the effectiveness of analgesia is to ask the patient to rate the degree of pain along a **numeric or visual pain scale** (Table 5–3), assessing trends over time. This should be complemented with discussions around function (or limitations thereof). Clinicians should ask about the nature, severity, timing, location, quality, and aggravating and relieving factors of the pain.

General guidelines for diagnosis and management of pain are recommended for the treatment of all patients with pain, but clinicians must comprehend that such guidelines may not be suited for every individual. Because of pain's complexity, it is important to understand benefits and risks of treatment for each patient. *Distinguishing between nociceptive (somatic or visceral) and neuropathic pain is essential to proper management since therapies differ.*

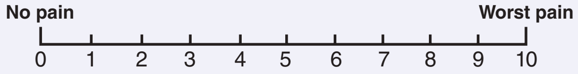
In addition, while clinicians should seek to diagnose the underlying cause of pain and then treat it, they must balance the burden of diagnostic tests or therapeutic interventions with the patient's condition. For example, single-fraction radiation therapy for painful bone metastases or nerve blocks for neuropathic pain may obviate the need for ongoing treatment with analgesics and their side effects. Regardless of decisions about seeking and treating the underlying cause of pain, every patient should be offered *prompt* pain relief.

The aim of effective pain management is to meet specific goals, such as preservation or restoration of function or quality of life, and this aim must be discussed between clinician and patient, as well as their family. For example, some patients may wish to be completely free of pain even at the cost of significant sedation, while others will wish to prioritize maximal cognitive functioning at the expense of complete pain control.

Whenever possible, the *oral route of analgesic administration* is preferred because it is easier to manage at home, is not itself painful, and imposes no risk from needle exposure. In unique situations, or near the end of life, transdermal, subcutaneous, rectal, and intravenous routes of administration are used; intrathecal administration is used when necessary.

Table 5–3. Pain assessment scales.

A. Numeric Rating Scale Verbal Intensity

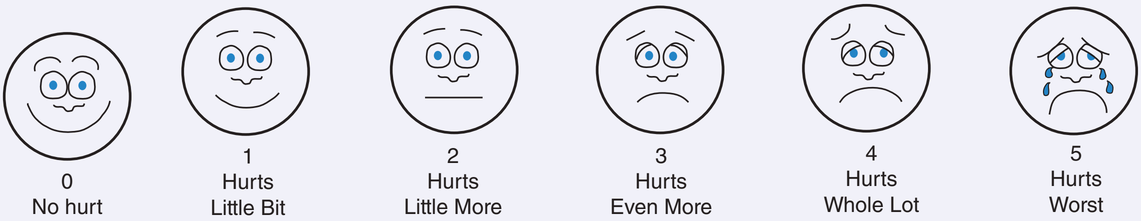


None, mild, moderate, severe
(0), (1–4), (5–6), (7–10)

B. Numeric Rating Scale Translated into Word and Behavior Scales

Pain Intensity	Word Scale	Nonverbal Behaviors
0	No pain	Relaxed, calm expression
1–2	Least pain	Stressed, tense expression
3–4	Mild pain	Guarded movement, grimacing
5–6	Moderate pain	Moaning, restlessness
7–8	Severe pain	Crying out
9–10	Excruciating pain	Increased intensity of above

C. Wong-Baker FACES Pain Rating Scale[1]



[1] Especially useful for patients who cannot read English (and for pediatric patients).

Wong-Baker FACES Foundation (2015). Wong-Baker FACES® Pain Rating Scale. Retrieved with permission from http://www.WongBakerFACES.org.

Finally, pain management should not automatically indicate opioid therapy. While some individuals fare better with opioid therapy in specific situations, this does not mean that opioids are the answer for every patient. There are situations when opioids actually worsen the quality of life for individuals, due to a lack of adequate analgesic effect or due to their side effects.

Barriers to Good Care

One barrier to good pain control is that many clinicians have limited training and clinical experience with pain management and thus are reluctant to attempt to manage severe pain. Lack of knowledge about the proper selection and dosing of analgesic medications carries with it attendant and typically exaggerated fears about the side effects of pain medications. Consultation with a palliative care or pain management specialist may provide additional expertise.

Just as pain is a subjective experience of individual patients, the assessment and treatment of pain by individual providers is also subjective and often reflects the same social biases and prejudices observed in the greater society. Racial disparities in pain treatment encompass the entire continuum of care from pediatric ED visits to the most advanced neuromodulation therapies. These disparities are associated with prejudices and false beliefs of providers throughout the medical training continuum. Vigilance at identifying institutional as well as individual biases and prejudices and taking appropriate corrective actions is critical to the equitable treatment of all patients in pain.

Jones MR et al. Racial and socioeconomic disparities in spinal cord stimulation among the Medicare population. Neuromodulation. 2021;24:434. [PMID: 33723896]

PHARMACOLOGIC PAIN MANAGEMENT STRATEGIES

Pain generally can be well controlled with nonopioid and opioid analgesic medications, complemented by nonpharmacologic adjunctive and interventional treatments. For mild to moderate pain, acetaminophen, aspirin, and NSAIDs (also known as COX inhibitors) may be sufficient. For moderate to severe pain, especially for those with acute pain, short courses of opioids are sometimes necessary; for those with cancer pain or pain from advanced, progressive serious illness, opioids are generally required and interventional modalities should be considered. In all cases, the choice of an analgesic medication must be guided by careful attention to the physiology of the pain, the patient's goals, and the benefits and risks of the particular analgesic being considered.

ACETAMINOPHEN & NSAIDS

Table 5–4 provides comparison information for acetaminophen, aspirin, the COX-2 inhibitor celecoxib, and other NSAIDs. An appropriate dose of acetaminophen may be just as effective an analgesic and antipyretic as an NSAID but without the risk of GI bleeding or ulceration. Acetaminophen can be given at a dosage of 500–1000 mg orally every 6 hours, not to exceed 4000 mg/day maximum for short-term use. Total acetaminophen doses should not exceed 3000 mg/day for long-term use or 2000 mg/day for older patients and for those with liver disease. Hepatotoxicity is of particular concern because of how commonly acetaminophen is also an ingredient in various over-the-counter medications and because of failure to account for the acetaminophen dose in combination acetaminophen-opioid medications such as Vicodin or Norco. The FDA has limited the amount of acetaminophen available in some combination analgesics (eg, in acetaminophen plus codeine preparations).

NSAIDs, including aspirin, are antipyretic, analgesic, and anti-inflammatory. Aspirin is dosed at 325–650 mg orally every 4 hours; GI irritation and bleeding are side effects that are lessened with enteric-coated formulations and by concomitant use of PPI medication. Bleeding, allergy, and an association with Reye syndrome in children and adolescents further limit its use.

Treatment with NSAIDs via COX-1 inhibition increases the risk of GI bleeding 1.5 times; the risks of bleeding and nephrotoxicity are both increased in elderly patients. Ketorolac is a COX-1 inhibitor with high analgesic potency. GI bleeding and ulceration may be prevented with either the concurrent use of PPIs (eg, omeprazole, 20–40 mg orally daily) or the use of celecoxib (100 mg orally daily to 200 mg orally twice daily), the only COX-2 inhibitor available. However, due to COX-2 inhibition, celecoxib is associated with higher risk of CVD. All NSAIDs can lead to fluid retention, kidney injury, and exacerbations of HF and should be used with caution in patients with these conditions. Topical formulations of NSAIDs (such as diclofenac 1.3% patch or 1% gel), placed over the painful body part for treatment of musculoskeletal pain, are associated with less systemic absorption and fewer side effects than oral administration and are likely underutilized in patients at risk for GI bleeding.

Pergolizzi JV et al. Can NSAIDs and acetaminophen effectively replace opioid treatment options for acute pain? Expert Opin Pharmacother. 2021;22:1119. [PMID: 33689517]

OPIOIDS

See also Chapter 48.

Opioid Mechanism of Action and Metabolism

Opioid medications mimic the pharmacologic properties of endogenous opioid peptides and activate the primary opioid receptors (μ, δ, and κ). Different opioid medications activate the different opioid receptors to varying degrees. Any substance that causes analgesia via binding an opioid receptor and is reversed by naloxone is referred to as an "opioid." This broad class of drugs includes alkaloids derived from the extract of a poppy plant (eg, codeine, morphine), semisynthetic opioids (eg, oxycodone, buprenorphine), and synthetic opioids (eg, methadone, fentanyl).

Table 5–4. Acetaminophen, aspirin, and useful NSAIDs and COX inhibitors. (Listed in alphabetical order.)

Medication (Proprietary)	Usual Dose for Adults Based on Total Body Weight	Comments[1]
Acetaminophen (Ofirmev)	≥ 50 kg: 1000 mg intravenously every 6–8 hours	
Acetaminophen or paracetamol[2] (Tylenol, Datril, etc)	≥ 50 kg: 325–500 mg orally every 4 hours or 500–1000 mg orally every 6 hours, up to 2000–4000 mg/day < 50 kg: 10–15 mg/kg every 4 hours orally; 15–20 mg/kg every 4 hours rectally, up to 2000–3000 mg/day	Not an NSAID because it lacks peripheral anti-inflammatory effects. Equivalent to aspirin as analgesic and antipyretic agent. Limit dose to 4000 mg/day in acute pain. Limit dose to 2000 mg/day in older patients and those with liver disease. Be mindful of multiple sources of acetaminophen from combination analgesics, cold remedies, and sleep aids.
Aspirin[3]	≥ 50 kg: 325–650 mg orally every 4 hours < 50 kg: 10–15 mg/kg every 4 hours orally; 15–20 mg/kg every 4 hours rectally	Available also in enteric-coated oral form that is more slowly absorbed but better tolerated.
Celecoxib[2] (Celebrex)	≥ 50 kg: 200 mg orally once daily (OA); 100–200 mg orally twice daily (RA) < 50 kg: 100 mg orally once or twice daily	COX-2 inhibitor. No antiplatelet effects. Lower doses for older adults who weigh < 50 kg. Lower incidence of endoscopic GI ulceration than NSAIDs. Not known if true lower incidence of GI bleeding. Celecoxib is contraindicated in sulfonamide allergy.
Diclofenac, patch (Flector)	1.3% topical patch applied twice daily	Apply patch to most painful area.
Diclofenac gel (Voltaren)	1% gel 2–4 g four times daily	Available OTC. Topical formulation may result in fewer side effects than oral formulations.
Diclofenac (Voltaren, Cataflam, Zorvolex, others)	≥ 50 kg: 50–75 mg orally two or three times daily; 1% gel 2–4 g four times daily	Increased risk of hepatotoxicity. Enteric-coated product; slow onset. Topical formulations may result in fewer side effects than oral formulations.
Diclofenac sustained release (Voltaren-XR, others)	≥ 50 kg: 100–200 mg orally once daily	
Etodolac (Lodine, others)	≥ 50 kg: 200–400 mg orally every 6–8 hours	
Ibuprofen (Caldolor)	≥ 50 kg: 400–800 mg intravenously every 6 hours as needed (max 3.2 g/day)	
Ibuprofen (Motrin, Advil, Rufen, others)	≥ 50 kg: 400–800 mg orally every 6 hours as needed < 50 kg: 10 mg/kg orally every 6–8 hours	Relatively well tolerated and inexpensive.
Indomethacin (Indocin, Indometh, others)	≥ 50 kg: 25–50 mg orally two to four times daily	Increased risk of dose-related toxic effects, especially GI and bone marrow effects.
Ketorolac tromethamine	≥ 50 kg: 10 mg orally every 4–6 hours to a maximum of 40 mg/day orally	Short-term use (< 5 days) only; otherwise, increased risk of GI side effects.
Ketorolac tromethamine[4]	≥ 50 kg: 30–60 mg every 6 hours intramuscularly or intravenously as needed	Intramuscular or intravenous NSAID as alternative to opioid. Lower doses for elderly. Short-term use (< 5 days) only.
Magnesium salicylate (various)	≥ 50 kg: 325–650 mg orally every 6 hours	
Meloxicam (Mobic)	≥ 50 kg: 7.5 mg orally every 12 hours	Intermediate COX-2/COX-1 ratio similar to diclofenac.
Nabumetone (Relafen)	≥ 50 kg: 500–1000 mg orally once daily (max dose 2000 mg/day)	May be less ulcerogenic than ibuprofen, but overall side effects may not be less.
Naproxen (Naprosyn, Anaprox, Aleve [OTC], others)	≥ 50 kg: 250–500 mg orally every 6–8 hours < 50 kg: 5 mg/kg every 8 hours	Generally well tolerated. Lower doses for elderly.

COX, cyclooxygenase; OA, osteoarthritis; OTC, over the counter; RA, rheumatoid arthritis.

[1] The adverse effects of headache, tinnitus, dizziness, confusion, rashes, anorexia, nausea, vomiting, GI bleeding, diarrhea, nephrotoxicity, visual disturbances, etc, can occur with any of these drugs. Tolerance and efficacy are subject to great individual variations among patients. Note: All NSAIDs can increase serum lithium levels.

[2] Acetaminophen and celecoxib lack antiplatelet effects.

[3] May inhibit platelet aggregation for 1 week or more and may cause bleeding.

[4] Has the same GI toxicities as oral NSAIDs.

Opioids are primarily metabolized by the liver via phase I (cytochrome P450 isoenzyme 3A4 and 2D6) and phase II (glucuronidation) processes. Some opioid medications need to be metabolized to an active metabolite to produce analgesia (eg, codeine, a prodrug, metabolizes to morphine), while others are pharmacologically active and have active metabolites (eg, morphine metabolizes to morphine-6-glucuronide, an active metabolite). Cytochrome P450 allelic variants can predispose patients to being rapid or poor opioid metabolizers, affecting how they respond to various opioid medications. *Age-related changes in hepatic function predispose older individuals to adverse side effects from opioids, including delirium, falls, fractures, and respiratory depression.* Hepatic impairment will also affect plasma concentrations of opioids and their metabolites in a complex manner.

Most opioids are eliminated primarily in the urine, so opioid clearance is affected by kidney function. GFR typically decreases with age and can lead to an accumulation of active metabolites and consequent toxicity. For example, meperidine is metabolized to normeperidine and its accumulation can result in neurotoxicity (seizures) in older adults or those with renal impairment.

When initiating opioid therapy clinicians should "start low and go slow," particularly in patients with older age, liver disease, decreased kidney function, and higher total body fat. In addition, initially prescribing immediate-release opioid formulations is more desirable since these agents can be titrated down more rapidly in case of adverse reactions, and because long-acting formulations are associated with increased risk of overdose.

Vearrier D et al. Clinical pharmacology, toxicity, and abuse potential of opioids. J Clin Pharmacol. 2021;61 Suppl 2:S70. [PMID: 34396552]

Principles of Opioid Management & CDC Guidelines

Opioids, if prescribed, are just one component of a patient's pain management plan and are not appropriate for all pain situations. Nonpharmacologic treatments (eg, exercise, psychological intervention, other treatments) and nonopioid medications (eg, NSAIDs, SNRIs, gabapentinoids) are associated with improvements in pain and function that are comparable to improvements associated with opioid use for acute and chronic pain. In fact, a 12-month randomized trial of stepped therapy using opioid versus nonopioid medications for chronic musculoskeletal pain (SPACE trial) found increased pain intensity in the opioid treatment group. Observational studies suggest that *opioid use for acute pain is associated with subsequent long-term use, and there is a lack of robust evidence to support long-term opioid use for chronic noncancer pain.* Utilization of high dosages of opioids over time can result in **opioid-induced hyperalgesia** (enhanced pain to noxious stimuli) and **allodynia** (pain from stimuli that typically do not provoke pain), possibly secondary to upregulation and sensitization of NMDA (*N*-methyl-D-aspartate) receptors in the nervous system. Weaning opioids can be a difficult experience for patients and providers. An increase in suicidal ideation and risk of opioid overdose may occur around an opioid taper. Observational studies suggest opioid use is associated with increased risk of fracture and falls, OUD, overdose, mortality, and MI in a dose-dependent fashion. There is no known reliable way to predict who will experience harm from opioid use.

A. CDC Guidelines for Prescribing Opioids

In 2022, the CDC released updated guidelines for prescribing opioids for outpatients with pain. These guidelines are summarized in Table 5–5 and reviewed below. Of note, the 2022 CDC guidelines are meant for outpatients with acute, subacute, and chronic noncancer pain. They are *not* meant to be applied to patients with pain related to cancer, sickle cell disease, or palliative or end-of-life care.

Before starting opioid therapy, clinicians should have a frank conversation with the patient about the risks and realistic expected benefits of opioid use. Before prescribing and periodically during opioid therapy, clinicians should review the patient's prescribed controlled substance history in their **state prescription drug monitoring program.** When starting opioid therapy, providers should prescribe immediate-release opioids instead of extended-release opioids, since patients have a *higher risk of overdose with extended-release opioids* and no difference in pain or function is seen when using immediate-release versus extended-release opioids. When initiating opioids in opioid-naïve patients, the lowest effective dose should be used (Table 5–6). Caution should be used if prescribing opioids for a patient concurrently taking benzodiazepines or CNS depressant medications (eg, sedative hypnotics, muscle relaxants, gabapentinoids), since risk of respiratory depression may outweigh benefits. ***Naloxone** should be offered to patients prescribed opioids, especially those at increased risk of overdose (including patients prescribed > 50 morphine mg equivalents [MME]* [Table 5–7] *with concurrent benzodiazepine prescription, with loss of tolerance, or with history of sleep apnea, prior overdose, or substance use disorder).*

B. Acute Pain

The 2022 CDC guideline for prescribing opioids defines **acute pain** as lasting < 1 month. Nonopioid therapies are at least as effective as opioids for managing many types of acute pain. Thus, nonopioid treatments should be optimized, and opioids only considered if benefits will outweigh the risks of opioid use. If opioids are needed to treat acute pain, for example after a major surgery, providers should prescribe no more than the expected duration of pain severe enough to necessitate opioid use. If continuing opioids for acute pain, the provider should reassess the patient at least every 2 weeks and seriously weigh the benefit and risk before deciding to continue opioid therapy for longer than 1 month. The updated CDC guidelines no longer have a specific recommendation on duration of treatment. However, when considering duration of opioid treatment for acute pain, it is important to remember that opioid efficacy for pain management wanes over a short period of time, that opioid use for acute pain is associated

Table 5–5. 2022 CDC clinical practice guideline for prescribing opioids for pain.

	Guideline
	Recommendations are for prescribing opioids for outpatients with pain, excluding pain related to sickle cell disease, cancer, palliative care, and end-of-life care.
Determining whether to initiate opioids	Acute pain: nonopioid therapies are at least as effective as opioids for many acute pain conditions. Maximize use of nonpharmacologic and nonopioid pharmacologic therapies, and only consider opioids if benefits are anticipated to outweigh risks. Subacute and chronic pain: nonopioid therapies are preferred. Maximize use of nonpharmacologic and nonopioid pharmacologic therapies, and only consider opioids if benefits to pain and function are anticipated to outweigh risks. Before initiating opioid therapy, clinicians should discuss realistic benefits and known risks of opioid therapy. Subacute and chronic pain: before starting opioid therapy, clinicians should work with patients to establish treatment goals for pain and function and consider how opioid therapy will be discontinued if benefits do not outweigh risks.
Opioid selection and dosage	When starting opioid therapy, clinicians should prescribe immediate-release opioids instead of extended-release/long-acting opioids. When starting opioids in opioid-naïve patients, prescribe the lowest effective opioid dose. If opioids are continued for subacute/chronic pain, clinicians should use caution when prescribing at any dosage, should carefully evaluate benefits and risks when considering dose increase, and should avoid increasing dose above levels likely to yield diminishing returns relative to risk. Patients already receiving opioid therapy: clinicians should carefully weigh benefits and risks and exercise care when changing opioid dosage. • If benefits outweigh risks—clinicians should work with patient to optimize nonopioid therapies while continuing opioid therapy. • If benefits do not outweigh risks—clinicians should optimize other therapies and work closely with patients to gradually taper to lower dosages or, if warranted, appropriately taper and discontinue opioids. • Unless there are indications of a life-threatening issue (eg, impending overdose), opioid therapy should not be discontinued abruptly or rapidly reduced from higher dosages.
Deciding duration of initial opioid prescription and conducting follow-up	For acute pain, prescribe no greater than quantity needed for expected duration of pain severe enough to require opioids. Evaluate benefits and risks within 1–4 weeks of starting opioids (for subacute or chronic pain) or of any dose escalation. Clinicians should regularly reevaluate benefits and risks of continued opioid therapy with patient.
Assessing risk and addressing potential harms of opioid use	Before starting and periodically during opioid therapy, clinicians should evaluate risk for opioid-related harms and discuss with the patient. Clinicians should work with the patient on a plan to mitigate risk including offering naloxone. Review the patient's history of controlled substance use through their state's prescription drug monitoring program before initiating and periodically during opioid therapy. Consider benefits and risks of urine toxicology testing when prescribing opioids for subacute or chronic pain (to assess for prescribed and non-prescribed controlled substances). Use particular caution when prescribing opioids and benzodiazepines (and other central nervous system depressants) concurrently. Manage or arrange treatment for opioid use disorder (OUD) with evidence-based medications. Detoxification without OUD medications is not recommended due to risk for resuming drug use, overdose, and overdose death.

Adapted from Dowell D, Ragan KR, Jones CM, Baldwin GT, Chou R. CDC Clinical Practice Guideline for Prescribing Opioids for Pain – United States, 2022. MMWR Recomm Rep 2022;71(No. RR-3):1-95. DOI: http://dx.doi.org/10.15585/mmwr.rr7103a1

Clinical practice guideline definition: Acute pain, duration < 1 month; Subacute pain, duration 1–3 months; Chronic pain, duration > 3 months.

with long-term use in observational studies, that there is *no robust evidence* that long-term opioid use improves pain or function, and that long-term opioid use can increase the risk of OUD and overdose.

C. Subacute Pain and Chronic Pain

The 2022 CDC guideline for prescribing opioids defines **subacute** or **unresolved acute pain** as that persisting for 1–3 months, and **chronic pain** as that lasting > 3 months. Nonpharmacologic therapies and nonopioid medications should be optimized and are the preferred treatment for subacute and chronic pain. It is important to remember that opioids are *not* first-line treatment for chronic or subacute pain, and providers should utilize nonopioid treatments in most circumstances. If, after carefully weighing risks and benefits, a decision is made to start opioid therapy, providers should work with patients to determine treatment goals around pain and function and create a strategy to discontinue opioid treatment if benefits no longer outweigh risks.

Table 5–6. Opioids. (Listed in alphabetical order, within classes.)

Medication (Proprietary Name)	Routes of Administration and Available Doses	Approximate Equianalgesic Dose (compared to morphine 30 mg orally or 10 mg intravenously/subcutaneously)[1]	Usual Starting Dose in an Opioid-Naïve Patient Based on Weight
Opioid Agonists[2,3]			
Buprenorphine[4] *(not for long-term use)*	*Parenteral* (intravenous, intramuscular)	Not available	≥ 50 kg: 300 mcg intravenously slowly once, may be repeated after 30–60 minutes after initial dose; then 300 mcg every 6–8 hours as needed for acute pain
Buprenorphine (Butrans)	*Transdermal:* 5 mcg/h, 7.5 mcg/h, 10 mcg/h, 15 mcg/h, 20 mcg/h	Not available	≥ 50 kg: opioid-naïve patients or patients taking < 30 mg morphine equivalents/day—5-mcg/h patch every 7 days Patients taking 30–80 mg morphine equivalents/day—consider 10 mcg/h every 7 days Patients taking > 80 mg morphine equivalents/day—could consider 20 mcg/h every 7 days, **but may not provide adequate analgesia; consider other analgesics** May increase by 5–10 mcg/h with a minimum titration interval of 72 hours Maximum: 20 mcg/h every 7 days
Buprenorphine (Belbuca)[4] *(note: buccal and sublingual formulations are associated with dental adverse events)*	*Buccal strips:* 75 mcg, 150 mcg, 300 mcg, 450 mcg, 600 mcg, 750 mcg, 900 mcg	Not available	≥ 50 kg: opioid-naïve patients or patients taking < 30 mg morphine equivalents/day–75 mcg buccally once daily or, if tolerated, every 12 hours for ≥ 4 days, then increase to 150 mcg every 12 hours Patients taking 30–89 mg of morphine equivalents/day – 150 mcg every 12 hours Patients taking 90–160 mg of morphine equivalents/day – 300 mcg every 12 hours Patients taking >160 mg of morphine equivalents/day – **may not provide adequate analgesia; consider use of an alternate analgesic** May titrate by 150 mcg every 12 hours no more frequently than every 4 days. Maximum: 900 mcg every 12 hours; 450 mcg every 12 hours in opioid naïve patients
Fentanyl *(note: for use in ICU or closely monitored settings)*	*Parenteral* (intravenous, intramuscular): 50 mcg/mL	*Parenteral:* 50–100 mcg	≥ 50 kg: 12.5–50 mcg intravenously every 3–5 minutes until pain relieved, then every 30–60 minutes as needed for acute pain; 50–100 mcg intramuscularly every 1–2 hours as needed for acute pain < 50 kg: 0.5–1 mcg/kg intravenously every 1–2 hours as needed for acute pain; max 50-mcg/dose
Fentanyl (Actiq) *(not available in the United States)*	*Lozenge:* 200 mcg, 400 mcg, 600 mcg, 800 mcg, 1200 mcg, 1600 mcg	Not available	*Initial dose for breakthrough cancer pain:* ≥ 50 kg: 200 mcg consumed orally over 15 minutes; may repeat × 1 after 30 minutes if inadequate relief *(wait at least 4 hours before treating another episode; max 4 doses/day)*

Fentanyl (buccal: Fentora) (sublingual spray: Subsys – Not available in the United States) *(note: do not convert from other fentanyl formulations on a mcg-per-mcg basis)*	*Buccal:* 100 mcg, 200 mcg, 400 mcg, 600 mcg, 800 mcg	Not available	*Initial dose for breakthrough cancer pain:* ≥ 50 kg: 100-mcg buccal tab; may repeat × 1 after 30 minutes if inadequate relief *(wait at least 4 hours before another dose)*
Fentanyl[12] (Duragesic)	*Transdermal:* 12.5 mcg/h, 25 mcg/h, 37.5 mcg/h, 50 mcg/h, 62.5 mcg/h, 75 mcg/h, 87.5 mcg/h, 100 mcg/h	Initial doses: Conversion to fentanyl patch is based on total daily dose of oral morphine[2] (45 mg morphine/24 hours is approximately equivalent to 12-mcg/h fentanyl patch)	Note: it is safer to underestimate daily fentanyl requirement and provide breakthrough pain relief with immediate release opioid during initiation. Do not titrate fentanyl patch more frequently than every 3 days.
Hydromorphone[5] (Dilaudid)	*Oral:* 2 mg, 4 mg, 8 mg	*Oral:* 6 mg	*Oral:* ≥ 50 kg: 1–2 mg every 4–6 hours as needed < 50 kg: 0.03–0.06 mg/kg every 4–6 hours as needed
Hydromorphone[5] (Dilaudid)	*Parenteral* (intravenous, intramuscular, subcutaneous): 0.5 mg/0.5 mL, 1 mg/mL, 2 mg/mL, 4 mg/mL	*Parenteral:* 1 mg	*Parenteral:* ≥ 50 kg: 0.2 mg every 3–4 hours as needed < 50 kg: 0.015 mg/kg every 3–6 hours as needed
Hydromorphone extended release[12]	*Oral:* 8 mg ER, 12 mg ER, 16 mg ER, 32 mg ER	*Oral:* 6 mg	*Oral, initial dose:* ≥ 50 kg: Estimated total daily oral hydromorphone dose based on current daily short-acting opioid use. Once-daily administration. Not for use in opioid-naïve patients.
Levorphanol	*Oral:* 2 mg, 3mg	*Oral:* 2 mg	*Oral, initial dose:* 1–2 mg every 6–8 hours as needed
Meperidine[6] (Demerol)	*Oral:* 50 mg	*Oral:* 300 mg	*Oral:* Not recommended
Meperidine[6] (Demerol)	*Parenteral* (intravenous, intramuscular, subcutaneous): 25 mg/mL, 50 mg/mL, 75 mg/mL, 100 mg/mL	*Parenteral:* 100 mg	*Parenteral:* ≥ 50 kg: 50–100 mg every 3 hours; not to exceed 600 mg/24 hours < 50 kg: 0.8 mg/kg every 3–4 hours; not to exceed 50–75 mg/dose *(Note: NOT recommended for the treatment of acute pain due to potential for neurotoxicity, especially in older adults or patients with kidney disease)*
Methadone[7,12]	*Oral tab:* 5 mg, 10 mg *Soln:* 5 mg/5 mL, 10 mg/5 mL, 10 mg/mL	*Oral:* 7.5 mg *(Caution: conversion varies depending on magnitude of daily opioid use. See Table 5–7.)*	*Oral, initial dose:* ≥ 50 kg: 2.5 mg every 8–12 hours *(Increase dose not more frequently than every 3–5 days)*
Methadone[7,12]	*Parenteral:* 10 mg/mL	*Parenteral:* 4 mg *(Caution: conversion varies depending on magnitude of daily opioid use. See Table 5–7.)*	*Parenteral:* ≥ 50 kg: 1–2 mg every 8 hours < 50 kg: 0.1 mg/kg every 6–24 hours
Morphine[5] immediate release	*Oral:* 15 mg, 30 mg (tablets); 10 mg/5 mL, 20 mg/5 mL, 100 mg/5 mL (solution) *Rectal:* 5 mg, 10 mg, 20 mg, 30 mg (suppositories)	*Oral:* 30 mg	*Oral:* ≥ 50 kg: 4–8 mg every 3–4 hours as needed < 50 kg: 0.3 mg/kg every 3–4 hours as needed *Rectal:* 10 mg per rectum every 4 hours as needed
Morphine[5] immediate release (morphine sulfate, various)	*Intravenous:* varies	*Parenteral (intravenous):* 10 mg	*Parenteral (intravenous):* ≥ 50 kg: 1–4 mg every 3–4 hours < 50 kg: 0.05 mg/kg every 3–4 hours

(*continued*)

Table 5–6. Opioids. (Listed in alphabetical order, within classes.) (continued)

Medication (Proprietary Name)	Routes of Administration and Available Doses	Approximate Equianalgesic Dose (compared to morphine 30 mg orally or 10 mg intravenously/subcutaneously)[1]	Usual Starting Dose in an Opioid-Naïve Patient Based on Weight
Morphine controlled release, 12 hour[12] (MS Contin)	*Oral (tablets):* 15 mg ER, 30 mg ER, 60 mg ER, 100 mg ER, 200 mg ER	*Oral:* 30 mg	*Oral, initial dose:* ≥ 50 kg: Not for use in opioid-naïve patients. Initial dose should be based on current daily opioid use divided into dosing every 8–12 hours.
Morphine extended release, 24 hour[12] (Kadian)	*Oral (capsules):* 10 mg ER, 20 mg ER, 30 mg ER, 45 mg ER, 50 mg ER, 60 mg ER, 75 mg ER, 80 mg ER, 90 mg ER, 100 mg ER, 120 mg ER	*Oral:* 30 mg	*Oral, initial dose:* ≥ 50 kg: Not for use in opioid-naïve patients. Initial dose should be based on current daily opioid use. Dose given every 24 hours.
Oxycodone (Roxicodone, others)	*Oral:* *(capsules):* 5 mg *(tablets):* 5 mg, 10 mg, 15 mg, 20 mg, 30 mg *(solution):* 5 mg/5 mL, 100 mg/5 mL	*Oral:* 20 mg	*Oral, initial dose:* ≥ 50 kg: 5–10 mg every 4–6 hours as needed < 50 kg: 0.1–0.2 mg/kg every 4–6 hours as needed
Oxycodone controlled release[12] (OxyContin)	*Oral:* *(tablets):* 10 mg ER, 15 mg ER, 20 mg ER, 30 mg ER, 40 mg ER, 60 mg ER, 80 mg ER	*Oral:* 20 mg	Not for use in opioid-naïve patients. Dosing should be based on current daily opioid use. Dose given every 12 hours.
Oxycodone ER[12] tamper-resistant capsules (Xtampza ER)	*Oral (capsules):* 9 mg ER, 13.5 mg ER, 18 mg ER, 27 mg ER, 36 mg ER	Oral: 20 mg	Not for use in opioid-naïve patients. Dosing should be based on current daily opioid use. Dose given every 12 hours.
Oxymorphone[5,8] oral, immediate release	*Oral (tablets):* 5 mg, 10 mg	*Oral:* 10 mg	*Oral, initial dose:* ≥ 50 kg: 5–10 mg every 6 hours as needed
Oxymorphone[5,8,12] oral, extended release	*Oral (tablets):* 5 mg ER, 7.5 mg ER, 10 mg ER, 15 mg ER, 20 mg ER, 30 mg ER, 40 mg ER	*Oral:* 10 mg	Not for use in opioid-naïve patients. Dosing should be based on current daily opioid use. Dose given every 12 hours. May increase dose every 3–7+ days.
Combination Opioid Agonist–Nonopioid Preparations			
Codeine[9,10] (with acetaminophen; other combinations also available)	*Oral (tablets):* Acetaminophen/codeine: 300 mg/15 mg, 300 mg/30 mg, 300 mg/60 mg Codeine: 15 mg, 30 mg, 60 mg	*Oral:* 200 mg codeine	*Oral:* ≥ 50 kg: 15–60 mg codeine every 4–6 hours as needed; maximum total daily dose 360 mg/day < 50 kg: 0.5–1 mg/kg codeine every 6–12 hours *(Note: contraindicated in patients < 12 years old, and in patients 12–18 years old after tonsillectomy/adenoidectomy or at risk for respiratory depression)*
Codeine[9]	*Parenteral (not available in the United States)*		≥ 50 kg: 30–60 mg codeine phosphate every 4–6 hours intramuscularly/subcutaneously < 50 kg: Not recommended
Hydrocodone[8] (with acetaminophen)[11] (Hydrocodone also available as a tablet in combination with ibuprofen 200 mg)[11]	*Oral (solution):* 7.5 mg/325 mg per 15 mL, 10 mg/325 mg per 15 mL *Oral (tablets):* 5 mg/325 mg, 7.5 mg/325 mg, 10 mg/325 mg (various formulations)	30 mg hydrocodone	*Oral: Based on hydrocodone content* ≥ 50 kg: 5–10 mg every 4–6 hours as needed < 50 kg: 0.1–0.2 mg/kg hydrocodone every 4–6 hours as needed

Oxycodone (with acetaminophen)[10,11]	*Oral (tablets):* 2.5 mg/325 mg, 5 mg/325 mg, 7.5 mg/325 mg, 10 mg/325 mg *Oral (solution):* 5 mg/325 mg per 5 mL, 10 mg/300 mg per 5 mL	20 mg oxycodone	*Oral, initial dose:* ≥ 50 kg: 5–10 mg oxycodone every 4–6 hours as needed < 50 kg: 0.1–0.2 mg/kg oxycodone every 4–6 hours as needed
Combination Opioid Agonist–Norepinephrine Reuptake Inhibitor Preparations			
Tapentadol (Nucynta)	*Oral (tablets):* 50 mg, 75 mg, 100 mg	75 mg	*Oral, initial doses:* ≥ 50 kg: 50–100 mg every 4–6 hours as needed; maximum daily dose 600 mg
Tapentadol, extended release[12] (Nucynta ER)	*Oral:* 50 mg ER, 100 mg ER, 150 mg ER, 200 mg ER, 250 mg ER		*Oral:* ≥ 50 kg: 50 mg ER every 12 hours; can increase by 50-mg increments twice daily every 3+ days to dose of 100–250 mg ER twice daily; maximum total daily ER dose 500 mg/day
Tramadol (Ultram)	*Oral (tablets):* 50 mg, 100 mg *Oral (solution):* 5 mg/mL	150 mg	*Oral, initial dose:* ≥ 50 kg: Start 25–50 mg every 6 hours as needed; limit of 400 mg/day or 300 mg/day in patients > 75 years old
Tramadol extended release[12] (ConZip ER capsules)	*Oral (tablets):* 100 mg ER, 200 mg ER, 300 mg ER		*Extended release is for use in patients already taking tramadol IR for > 1 week.* Dosing should be based on current daily tramadol use. Dose given every 24 hours.

[1] Published tables vary in the suggested doses that are equianalgesic to morphine. Clinical response is the criterion that must be applied for each patient; titration to clinical efficacy is necessary. Because there is not complete cross-tolerance among these drugs, it is usually necessary to use a lower than equianalgesic dose initially when changing drugs and to retitrate to response.

[2] Conversion is conservative; therefore, do not use these equianalgesic doses for converting back from fentanyl patch to other opioids because they may lead to inadvertent overdose. Patients may require breakthrough doses of short-acting opioids during conversion to transdermal fentanyl.

[3] Several significantly more potent formulations of buprenorphine are available but generally reserved for the treatment of opioid use disorder with or without comorbid constant pain, most often by pain management or addiction specialists: a sublingual tablet or a sublingual film (Suboxone and others) in which the buprenorphine is combined with naloxone; a subdermal implant of buprenorphine alone (Probuphine); and a subcutaneous depot injection (Sublocade). Each of these is used in maintenance treatment to reduce problematic use of other opioids.

[4] Note, buprenorphine can precipitate withdrawal in patients already receiving opioids. In opioid-experienced patients, taper current opioids to 30 mg/day oral morphine equivalent prior to starting buccal buprenorphine. Thereafter, buprenorphine dosing schedule depends on prior current oral morphine equivalent:
< 30 mg/day, 75 mcg buccally every 12 hours;
30–89 mg/day, 150 mcg buccally every 12 hours;
90–160 mg/day, 300 mcg buccally every 12 hours;
In all patients, use same dose escalation and maximum dose as shown for opioid-naïve patients.

[5] *Caution:* For morphine and hydromorphone, rectal administration is an alternative route for patients unable to take oral medications. Equianalgesic doses may differ from oral and parenteral doses. A short-acting opioid should normally be used for initial therapy.

[6] Not recommended for the treatment of pain due to potential neurotoxicity and availability of safer alternatives, especially in patients with kidney disease or older patients. Doses listed are for brief therapy of acute pain only.

[7] Methadone conversion varies depending on the equivalent total daily dose of morphine. Consult with a pain management or palliative care expert for conversion.

[8] *Caution:* Recommended doses do not apply to adult patients with kidney or liver impairment or other conditions affecting drug metabolism.

[9] *Caution:* Individual doses of codeine above 60 mg often are not appropriate because of diminishing incremental analgesia with increasing doses but continually increasing nausea, constipation, and other side effects.

[10] *Caution:* Doses of aspirin and acetaminophen in combination products must also be adjusted to the patient's body weight.

[11] *Caution:* Monitor total acetaminophen dose carefully, including any OTC use. Total acetaminophen dose maximum is 3 g/day. If liver impairment or heavy alcohol use, maximum is 2 g/day. Available dosing formulations of these combination medications are being adjusted to reflect increased caution about acetaminophen toxicity. Acetaminophen doses in a single combination tablet or capsule is limited to ≤ 325 mg.

[12] Extended-release opioid formulations are not recommended for use in opioid-naïve patients.

Table 5–7. Morphine milligram equivalent (MME) doses for commonly prescribed opioids. (Listed in alphabetical order, after morphine.)

Opioid	Conversion Factor
Morphine	1
Codeine	0.15
Fentanyl transdermal (in mcg/h)	2.4
Hydrocodone	1
Hydromorphone	4
Methadone[1]	
1–20 mg/day	4
21–40 mg/day	8
41–60 mg/day	10
≥ 61–80 mg/day	12
Oxycodone	1.5
Oxymorphone	3
Tapentadol[2]	0.4
Tramadol[2]	0.2

TO CALCULATE MMEs: Multiply the dose for each opioid by the conversion factor to determine the dose in MMEs. As an example: tablets containing hydrocodone 5 mg and acetaminophen 325 mg taken four times a day would contain a total of 20 mg of hydrocodone daily, equivalent to $20 \times 1 = 20$ MME daily. Or another example: Extended-release tablets containing oxycodone 10 mg taken twice a day contain a total of 20 mg of oxycodone daily, equivalent to $20 \times 1.5 = 30$ MME daily.

Note the following precautions: (1) All doses are in mg/day except for fentanyl, which is in mcg/hour. (2) Equianalgesic dose conversions are only estimates and cannot account for individual variability in genetics and pharmacokinetics. (3) Do not use the calculated dose in MMEs to determine the doses to use when converting one opioid to another; when converting opioids, the new opioid is typically dosed at a substantially lower dose than the calculated MME dose to avoid accidental overdose due to incomplete cross-tolerance and individual variability in opioid pharmacokinetics. (4) Use particular caution with methadone dose conversions because methadone has a long and variable half-life, and peak respiratory depressant effect occurs later and lasts longer than peak analgesic effect. (5) Use particular caution with fentanyl because it is dosed in mcg/hour instead of mg/day, and its absorption is affected by heat and other factors. (6) These conversion factors should not be applied to dosage decisions related to management of opioid use disorder.

[1] Methadone conversion uses different conversion ratios depending on dose.

[2] Tapentadol is a mu-receptor agonist and norepinephrine reuptake inhibitor. Tramadol is a mu-receptor agonist and norepinephrine and serotonin reuptake inhibitor. MMEs are based on degree of mu-receptor agonist activity; however, it is unknown whether tapentadol or tramadol is associated with overdose in the same dose-dependent manner as observed with medications that are sole mu-receptor agonists.

Adapted from Dowell D et al. CDC clinical practice guideline for prescribing opioids for chronic pain—United States, 2022. MMWR Recomm Rep. 2022;71(No. RR 3):31; by the CDC from Von Korff M et al. De Facto long-term opioid therapy for noncancer pain. Clin J Pain. 2008;24:521 and Nielsen S et al. Pharmacoepidemiol Drug Saf. 2016;25:733; Jutkiewicz EM et al. Table 23-4. Opioid Analgesics. In: Brunton LL et al, eds. *Goodman & Gilman's: The Pharmacological Basis of Therapeutics,* 14th ed. McGraw Hill Education; 2023. Accessed November 28, 2024. https://accessmedicine.mhmedical.com/content.aspx?bookid=3191&sectionid=269719481

Caution should be used when prescribing opioids at any dosage, and providers should avoid increasing the dose above levels likely to increase the risk to patients compared with the expected benefit. After initiating opioid treatment or any dose escalation, clinicians should reassess the benefits and risk to the patient within 1–4 weeks, and regularly thereafter. Before prescribing and at least annually, providers should consider **urine toxicology testing**. Test results should be used to increase patient safety and improve patient care (by assessing for prescribed or nonprescribed controlled substance use, or both, especially combinations that increase risk of overdose), not for punitive reasons.

D. Patients Already Receiving Opioid Therapy

Receiving and caring for a patient who has been started on opioids by another provider can be a complex and stressful situation for both patient and provider. The 2022 CDC guideline has a recommendation for this specific situation, starting with carefully considering the benefits and risks of continuing opioid therapy. If benefits outweigh risks, providers should optimize nonopioid therapies while continuing opioid therapy. If benefits do not outweigh risks, providers should optimize nonopioid therapies and work with the patient to gradually taper opioids to lower doses, with a goal to possibly discontinue opioids depending on the patient's circumstance. The CDC guideline recommends against rapidly tapering high-dose opioids or abruptly discontinuing opioids unless the patient has warning signs of an impending overdose (eg, confusion, sedation, slurred speech). Opioid taper or cessation is associated with increased nonprescribed heroin and other opioid use, increased emergency department and hospital visits, and higher rates of overdose, mental health crises, and overdose mortality (up to three times higher mortality in a 2019 retrospective study). **Opioid risk reduction practices** (eg, opioid consent process, prescription drug program monitoring, urine toxicology testing, overdose education, naloxone distribution, assessment of pain and function) should be considered and may be legally required in some jurisdictions while prescribing opioids.

E. Patients with Chronic Pain and OUD

Opioid use disorder (OUD) is characterized by a cluster of cognitive, behavioral, and physiologic symptoms indicating *continued use of opioids despite significant related problems*. Patients are diagnosed with OUD by meeting at least 2 of 11 symptoms outlined in the *DSM-5* that describe craving, loss of control, and drug use despite adverse consequences (Table 48–1). See Chapter 48, Substance Use Disorder, for details on diagnosis and treatment of OUD.

Managing patients with concomitant OUD and chronic pain can be complex. As with any patient with chronic pain, nonopioid and nonpharmacologic therapies should be optimized. Patients should be screened for OUD routinely. Per the 2022 CDC guideline, clinicians should provide or arrange *treatment of OUD with evidence-based medications (eg, buprenorphine usually with naloxone or methadone—both FDA approved medications for treatment of OUD)*. Buprenorphine has been associated with lower pain scores and higher quality of life in patients with OUD and chronic pain. Methadone and buprenorphine have long half-lives and have been shown to decrease withdrawal syndromes, opioid cravings, illicit drug use, overdose, overdose death, and all-cause mortality in patients with OUD even when used without psychosocial interventions. The CDC guideline recommends against detoxification without these medications. Providers should identify treatment resources for OUD in their community and obtain a waiver to prescribe buprenorphine for OUD (especially if working in communities with limited treatment capacity for OUD).

F. Cancer-related Pain

The 2022 CDC practice guideline for prescribing opioids is not meant to be applied to patients with cancer-related pain. Patients with cancer should be screened for pain at every clinic visit. Moderate to severe cancer-related pain can be treated with an opioid. Morphine is often used as first-line treatment; in an open-label RCT for moderate cancer pain, it produced more adequate analgesia than weak opioids (eg, codeine). Opioid switching (opioid rotation) may be appropriate when patients have inadequately managed pain or unacceptable side effects. A four-arm, phase 4 RCT reported improved pain relief and decreased side effects in 50% of patients who switched opioids after suboptimal response to initial opioid treatment. There is moderate evidence to support **epidural or intrathecal opioid administration** for cancer-related pain (eg, through an implanted intrathecal pump). This therapy requires access to a specialist pain management clinic. Nonpharmacologic pain interventions and self-management pain strategies also should be encouraged. Consider consulting with a palliative care team or pain management specialist early, especially for patients who may have more difficulty with pain management.

Opioid therapy in patients with concurrent cancer-related pain and OUD can be complicated. Both cancer-related pain and OUD should be treated as adequately as possible. Medications for treatment of OUD, such as methadone and buprenorphine-naloxone, should be continued. Depending on the individual patient's situation and prognosis, medications for treatment of OUDs could be administered in split dosing (rather than daily dosing), a full agonist opioid (eg, morphine) could be added in addition to the medications for treatment of OUD, or full agonist opioids could be switched to buprenorphine or methadone. Interdisciplinary management with addiction psychiatry, palliative care, chronic pain management, and primary care teams is often beneficial.

G. Pregnant Patients

Opioid use during pregnancy has been associated with stillbirth, poor fetal growth, and preterm delivery in observational studies and may lead to neonatal abstinence syndrome in some cases. However, the American College of Obstetricians and Gynecologists (ACOG) has emphasized that concern for **neonatal abstinence syndrome**, a treatable condition, should not be a reason to avoid treating acute pain in pregnant patients. For acute pain, the lowest effective opioid dose should be prescribed for no longer than the expected duration of pain requiring opioids. For pregnant patients with chronic pain, ACOG recommends employing strategies to minimize opioid use. The 2022 CDC guidelines recommend management by continuing medications for treatment of OUDs (buprenorphine, methadone) for pregnant patients with OUD rather than withdrawal of the opioid. If considering tapering opioids in a pregnant patient, providers should consult appropriate experts because of the risk to the patient and fetus if the patient develops withdrawal.

H. Neuropathic Pain

Currently, there is no high-level evidence that supports the use of opioids in the long-term management of neuropathic pain. Instead, opioids have been found to have significantly more adverse effects when compared to nonopioid, neuropathic medications (Table 5–8).

Coffin PO et al. Primary care management of long-term opioid therapy. Ann Med. 2022;54:2451. [PMID: 36111417]

Cuménal M et al. The safety of medications used to treat peripheral neuropathic pain, part 2 (opioids, cannabinoids, and other drugs): review of double-blind, placebo-controlled, randomized clinical trials. Expert Opin Drug Saf. 2021;20:51. [PMID: 33103931]

Dowell D et al. CDC Clinical Practice Guideline for prescribing opioids for pain—United States, 2022. MMWR Recomm Rep. 2022;71:1. [PMID: 36327391]

Ganguly A et al. Cancer pain and opioid use disorder. Oncology (Williston Park). 2022;36:535. [PMID: 36107782]

Adverse Effects of Opioids

Common adverse effects of opioids include constipation, nausea, sedation, pruritus, physical dependence, opioid use disorder, hormonal disturbance and sexual dysfunction (especially hypogonadism in men), respiratory depression, and CNS depression. Core strategies to decrease adverse effects include dose reduction, opioid rotation, and symptom management. *Opioid-induced respiratory depression constitutes a medical emergency and must be managed appropriately.*

Although potentially fatal, respiratory depression can be rapidly reversed by the opioid receptor antagonist naloxone. There is moderate evidence that naloxone, when administered appropriately, can decrease opioid overdose–related mortality. *The CDC recommends coprescribing naloxone in patients who are receiving opioid doses of ≥ 50 MME/day, who have a respiratory condition, who are concomitantly prescribed benzodiazepines, who have a history of substance use disorder, or who are otherwise at high risk for overdose.* Prefilled nasal sprays (4-mg or 8-mg doses for intranasal administration) and syringe kits (2-mg or 5-mg doses for intramuscular injection) can be distributed to patients on opioid therapy. Naloxone kits may contain two doses, so a repeat dose can be given every 2–3 minutes until emergency help arrives. To avoid precipitating opioid withdrawal, the medication is titrated with the objective of improving the patient's respiratory function, rather than arousal. Naloxone-induced withdrawal can lead to cardiovascular events (increases in heart rate, mean arterial pressure, and cardiac index). Larger-dose naloxone kits have

Table 5–8. Pharmacologic management of neuropathic pain. (Listed in alphabetical order, within classes.)

Medication[1]	Starting Dose	Typical Dose	Number Needed to Treat[2]
Tricyclic Antidepressants[3,4]			
Amitriptyline	10–25 mg orally at bedtime	10–150 mg orally at bedtime	2.1
Desipramine	12.5 mg orally at bedtime	12.5–250 mg orally at bedtime (can be divided into two doses)	2.1
Nortriptyline	10–25 mg orally at bedtime	10–150 mg orally at bedtime	2.1
Calcium Channel $\alpha_2\delta$ Ligands			
Gabapentin[5]	100–300 mg orally once to three times daily	300–1200 mg orally three times daily	6.5
Pregabalin[6]	25 mg orally once daily	50–150 mg orally three times daily	4.5
Selective Serotonin Norepinephrine Reuptake Inhibitors[4]			
Duloxetine	60 mg orally daily	60–120 mg orally daily	5.1
Venlafaxine[7]	37.5–75 mg orally daily divided into two or three doses	150–225 mg orally daily divided into two or three doses	
Opioids	(see Table 5–6)	(see Table 5–6)	2.6
Topical and Other Medications			
Capsaicin	0.04% or 0.075% cream; 8% patch	0.04% or 0.075% cream applied three or four times daily or 8% patch applied twice daily	6.2
Diclofenac transdermal	1.3% patch or 1% gel	Patch applied twice daily or gel applied three times daily	
Lidocaine transdermal	4% patch applied for a maximum of 12 hours	4% or 5% patch 1–3 patches applied daily for a maximum of 12 hours; available OTC	
Tramadol hydrochloride[8]	50 mg orally four times daily	100 mg orally two to four times daily	4.9

[1] Begin at the starting dose and titrate up every 4 or 5 days. Within each category, drugs listed in order of prescribing preference.

[2] Data from Moulin D et al; Canadian Pain Society. Pharmacologic management of chronic neuropathic pain: revised consensus statement from the Canadian Pain Society. Pain Res Manag. 2014;19:328.

[3] Begin with a low dose. Use the lowest effective dose. Pain relief may be achieved at doses below antidepressant doses, thereby minimizing adverse side effects.

[4] Do not combine TCAs with SNRIs (or SSRIs) to avoid serotonin syndrome.

[5] Common side effects include nausea, somnolence, and dizziness. Must adjust dose for kidney impairment.

[6] Common side effects include dizziness, somnolence, peripheral edema, and weight gain. Must adjust dose for kidney impairment.

[7] *Caution:* Can cause hypertension and ECG changes. Consider obtaining baseline ECG and monitor.

[8] Tramadol is classified by the DEA as a Schedule IV controlled substance.

been created to combat overdose deaths related to the even more potent illicit synthetic opioids (eg, carfentanil), but their use is associated with a higher risk of opioid withdrawal.

Opioid-induced constipation is the most common adverse effect of opioids. Opioids bind to mu receptors in the GI tract and decrease bowel motility and mucosal secretions in a dose-related fashion. Ideally, patients treated with opioids should have a bowel movement at least every 24–48 hours. Initial recommendations for management of opioid-induced constipation should include patient education, increased dietary fiber, adequate hydration, and regular physical activity. Additionally, osmotic laxatives (eg, Miralax) can be given with a stimulant laxative (eg, senna). Newer peripherally acting mu receptor antagonists (eg, naldemedine, naloxegol, methylnaltrexone) block the GI actions of opioids without decreasing the opioid's analgesic effects and are recommended if laxatives fail.

Opioid-induced nausea likely develops secondary to direct stimulation of the chemoreceptor trigger zone, to vestibular sensitivity, or to decreased GI motility. Management options include dopamine antagonists (eg, prochlorperazine), prokinetic agents (eg, metoclopramide), serotonin antagonists (eg, ondansetron), or antihistamines (eg, diphenhydramine, promethazine, meclizine). All of these agents have side effects that must be carefully monitored.

Sedation or decreased cognition most commonly occurs with initiation of opioid therapy or dose escalation. Dose reduction should be attempted first before pursuing pharmacologic intervention. Pharmacologic management options include methylphenidate; however, high-level evidence supporting its use for this indication is lacking.

Pruritus occurs in 2–10% of patients given opioids, possibly secondary to peripheral histamine release. Management options include an opioid rotation, dose reduction, diphenhydramine, and cool compresses.

ALMouaalamy N. Opioid-induced constipation in advanced cancer patients. Cureus. 2021;13:e14386. [PMID: 33850679]

Centers for Disease Control and Prevention (CDC). Stop overdose. Lifesaving naloxone. Accessed January 11, 2025. https://www.cdc.gov/stop-overdose/caring/naloxone.html

Payne ER et al. Comparison of administration of 8-milligram and 4-milligram intranasal naloxone by law enforcement during response to suspected opioid overdose — New York, March 2022–August 2023. MMWR Morb Mortal Wkly Rep 2024;73:110. [PMID: 38329911]

Basics of Opioid Monitoring

Prior to the initial opioid prescription, it is prudent to clearly define the underlying condition, diagnostic workup, nonopioid therapeutic management plan, and intended length of prescription. Ideally, the prescriber should determine how the opioid prescription fits into a broader comprehensive pain management plan.

The 2022 CDC guidelines for prescribing opioids recommend evaluating benefits and risks of opioid use within 1–4 weeks of initiating an opioid or escalating an opioid dose, as well as regularly during opioid therapy. Standardized assessments such as the **"PEG" scores** may be used at initial and follow-up visits to gauge the efficacy of treatment (Table 5–9). Meaningful improvement has been defined as 30% improvement in scores for both pain and function.

There is weak to moderate evidence to support the efficacy of some risk management strategies when prescribing opioids such as urine toxicology testing, prescription drug monitoring programs, and treatment agreements or "contracts." The 2022 CDC guidelines recommend *discussing realistic benefits and known risks of opioid therapy before initiating opioid treatment.* Providers should create functional goals to evaluate treatment benefit. Additionally, before starting opioid treatment, an exit strategy should be developed and ready if opioid therapy is unsuccessful.

The 2022 CDC guidelines recommend checking **prescription drug monitoring program** data before initiating opioids for any patient, and at least every 3 months or more frequently for patients on long-term opioid therapy. Prescription drug monitoring program data can be used to determine if a patient is taking an opioid dosage or medication combination that puts them at risk for overdose. Prescription drug monitoring program information should be discussed with the patient and used to make decisions around patient safety and treatment.

Table 5–9. PEG score to gauge benefit from long-term opioid use.

During the past week:
1. What number best describes your *P*ain? 0 = no pain to 10 = worst pain imaginable
2. What number best describes how much your pain interfered with your *E*njoyment of life? 0 = no interference to 10 = complete interference
3. What number describes how much pain interfered with your *G*eneral activity? 0 = no interference to 10 = complete interference

To calculate PEG score, average scores from questions 1 through 3. Adapted from US Dept of Health and Human Services, Office of Disease Prevention and Health Promotion. PEG: A three-item scale assessing pain intensity and interference. https://odphp.health.gov/hcq/trainings/pathways/assets/pdfs/PEG_scale.pdf

The CDC recommends that all patients receiving long-term opioid therapy have urine toxicology tests before initiating opioids and at least annually. Patients should understand that urine drug tests may be conducted randomly and repeatedly during treatment. Providers should discuss unexpected results with the patient in a nonjudgmental manner. Toxicology tests should not be used in a punitive manner, and clinicians should not dismiss patients from their care on the basis of these results.

Before initiating and periodically during opioid treatment, providers should **evaluate risk for opioid-related harms** (eg, assess alcohol and other substance use, screen for mental health and substance use disorder). **Naloxone** should be offered to patients taking opioids, especially those at increased risk for overdose. This includes patients with a history of overdose, substance use disorder, sleep apnea/sleep-disordered breathing, patients taking ≥ 50 MME/day, patients taking benzodiazepines or other CNS depressants, and patients who have lost tolerance and may return to higher opioid doses (eg, patients released from prison or undergoing opioid taper).

Asamoah-Boaheng M et al. Interventions to influence opioid prescribing practices for chronic noncancer pain: a systematic review and meta-analysis. Am J Prev Med. 2021;60:e15. [PMID: 33229143]

Dowell D et al. CDC Clinical Practice Guideline for prescribing opioids for pain—United States, 2022. MMWR Recomm Rep. 2022;71:1. [PMID: 36327391]

Weaning from Opioids

The goals during opioid tapers are to work with the patient to minimize symptoms and signs of withdrawal, and to mitigate risk of overdose and mental health crises during the wean. *Common symptoms and signs of withdrawal include anxiety, craving, tachycardia, vomiting, diarrhea, and mydriasis.* Opioid tapers may improve pain management and long-term patient safety, but they are precarious times when patients may be at higher risk for overdoses and mental health crises. A 2021 retrospective cohort study of patients originally prescribed at least 50 MME found an increased adjusted incident rate ratio (aIRR) of 1.28 for overdose events in patients during tapering periods compared with nontapering periods. Tapering was associated with an increased aIRR of 1.74 for mental health crises compared with nontapering periods.

Traditionally, a 10% decrease in opioid dosage *per week* was considered reasonable. However, a slower approximately 10% decrease in opioid dosage *per month* may be better tolerated and may result in an increased patient retention in the taper. Providers should work with patients during the taper to determine its speed; some tapers may take months to years. Per the 2022 CDC guideline for opioid prescribing, a more rapid taper should only be considered if there is a life-threatening issue such as an impending overdose. Additional psychosocial support should be offered to the patient and nonopioid measures to manage pain (eg, physical therapy, cognitive behavioral therapy, adjuvant nonopioid analgesics) should be maximized during the period of weaning.

Fishbain DA. Opioid tapering/detoxification protocols, a compendium: narrative review. Pain Med. 2021;22:1676. [PMID: 33860319]

MEDICATIONS FOR NEUROPATHIC PAIN

When taking a patient's history, pain descriptions such as "burning," "shooting," "pins and needles," or "electricity" and pain associated with numbness suggest neuropathic pain. Studies are mixed regarding efficacy of opioids for neuropathic pain. However, a number of nonopioid medications have been found to be effective in randomized trials (Table 5–8). Successful management of neuropathic pain often requires the use of more than one effective medication. Since these medications bind to receptors on a large variety of neurons, they often have CNS side effects. These side effects often limit reaching therapeutic doses and may be the reason for higher numbers needed to treat (Table 5–8) compared with NSAIDs.

The calcium channel $\alpha_2\delta$ ligands gabapentin and pregabalin are first-line therapies for neuropathic pain. Neither medication has significant medication interactions. However, they can cause sedation, dizziness, ataxia, and GI side effects. Both gabapentin and pregabalin require dose adjustments in patients with kidney dysfunction. Gabapentin should be started at low dosages of 100–300 mg orally once daily and titrated upward by 100–300 mg/day every 4–7 days by adding additional doses throughout the day, with a typical effective dose of 1800–3600 mg/day in three divided doses. Pregabalin should be started at 40–150 mg/day in two or three divided doses. If necessary, the dose of pregabalin can be titrated upward to 300–600 mg/day in two or three divided doses. Both medications are relatively safe in accidental overdose and may be preferred over tricyclic antidepressants (TCAs) for a patient with a history of HF or arrhythmia or if there is a risk of suicide.

The SNRIs duloxetine and venlafaxine also are first-line treatments for neuropathic pain. Patients should be advised to take duloxetine on a full stomach because nausea is a common side effect. Duloxetine may provide increased benefit for neuropathic pain up to a total daily dose of 120 mg (beyond the 60-mg limit for depression). SNRIs generally should not be combined with other serotonin or norepinephrine uptake inhibitors, but they can be combined with gabapentin or pregabalin. Lower doses of venlafaxine have more serotonin than norepinephrine activity; therefore, higher doses may be required to treat neuropathic pain. Because venlafaxine can cause hypertension and induce ECG changes, patients with cardiovascular risk factors should be carefully monitored when starting this medication. Desvenlafaxine, the active metabolite of venlafaxine, also is available and may be tolerated better than venlafaxine.

TCAs are another class of medications for neuropathic pain that work through the norepinephrine and serotonin pathways. Among the TCAs that are effective for neuropathic pain, nortriptyline and desipramine are preferred over amitriptyline because they cause less orthostatic hypotension and have fewer anticholinergic effects. Start with a low dosage (10–25 mg orally daily) and titrate upward in 10-mg increments every 4 or 5 days aiming to use the lowest effective dose and to titrate up to a maximum of ≤ 50–100 mg daily. It may take several weeks for a TCA to have its full analgesic effect for neuropathic pain. Because TCAs and SNRIs both work through the serotonin and norepinephrine pathways, they generally should not be coprescribed, particularly due to concerns for the serotonin syndrome. Additionally, to avoid the serotonin syndrome, both TCAs and SNRIs should not be used in patients already on an SSRI.

Topical medications, such as lidocaine 5% patch and capsaicin 8% patches, are considered second-line therapies. The lidocaine 5% patch is particularly effective in postherpetic neuralgia and may be effective in other types of localized neuropathic pain. Due to its relatively minimal adverse effects, it is commonly used despite being considered second line. Topical lidocaine 4% patches and cream are available over the counter.

Medical cannabis strains high in cannabidiol have proven efficacy for some types of neuropathic pain.

Pedowitz EJ et al. Management of neuropathic pain in the geriatric population. Clin Geriatr Med. 2021;37:361. [PMID: 33858616]

ADJUVANT PAIN MEDICATIONS & TREATMENTS

While polypharmacy is generally avoided, it can be appropriate to combine lower doses of multiple pain medications to avoid intolerable medication side effects of one or two medications at higher doses.

For metastatic bone pain, the anti-inflammatory effect of NSAIDs can be helpful. Furthermore, bisphosphonates (such as pamidronate and zoledronic acid) and receptor activator of NF-κ-B ligand (RANKL) inhibitors (such as denosumab) may relieve such bone pain, although they are generally more useful for prevention of bone metastases than for analgesia.

Corticosteroids, such as dexamethasone, prednisone, and methylprednisolone, can be helpful for patients with headache due to increased intracranial pressure, pain from spinal cord compression, metastatic bone pain, and neuropathic pain due to invasion or infiltration of nerves by tumor. Because of the side effects of long-term corticosteroid administration, they are most appropriate for short-term use and in patients with end-stage disease. Low-dose intravenous, oral, buccal, and nasal ketamine has been used successfully for neuropathic and other pain syndromes refractory to opioids, although research data are limited.

PSYCHOLOGICAL, PHYSICAL, & INTEGRATIVE THERAPIES

Psychological Therapy

Nonpharmacologic and noninterventional therapies are valuable in treating pain. In fact, *cognitive behavioral therapy and physical or functional therapy have been shown to be the most effective for management of chronic pain*. In multiple randomized, controlled studies, cognitive behavioral therapy has been proven effective as a primary evidence-based treatment for chronic pain. Because mood and psychological issues play an important role in the patient's perception of and response to pain, psychotherapy, support groups, prayer, and pastoral counseling also can help in pain management. Other psychological approaches include biofeedback, meditation, framing, guided imagery, and cognitive distraction. Depression and anxiety, which may be instigated by chronic pain or may alter the response to pain, should be treated aggressively with antidepressants and anxiolytics.

Darnall BD et al. Comparison of a single-session pain management skills intervention with a single-session health education intervention and 8 sessions of cognitive behavioral therapy in adults with chronic low back pain: a randomized clinical trial. JAMA Netw Open. 2021;4:e2113401. [PMID: 34398206]

Hadley G et al. CBT and CFT for chronic pain. Curr Pain Headache Rep. 2021;25:35. [PMID: 33791876]

Physical Therapy & Other Physical Interventions

Physical therapy is a mainstay of chronic pain management and encompasses several modalities, including strength training, manual therapy, and massage.

Physical therapy is useful for neuropathic pain and musculoskeletal pain. For example, if there is a cervical radiculopathy, the position and posture of individual neck muscles may exacerbate the narrowing of the neuroforamina or nerves may become entrapped within hypertrophied muscles, leading to neuropathic pain. Therefore, functional rehabilitation through physical therapy may address multiple types of pain.

Physical therapy for management of low-back pain may involve "core stabilization." Bounded by the diaphragm and the pelvic floor, the body's "core" is composed of the abdominal muscles and back and gluteal muscles. Exercises can help stabilize the entirety of the core, so that the low back does not need to exert as much effort for movement, lifting, bending, etc. "Core stabilization" can thereby decrease low-back pain.

Because physical therapy has minimal potential harms associated with it, it should be a key component in management of both acute and chronic pain. While physical therapy can be used on its own, it is often preferable to engage in it as part of a multidisciplinary approach to pain management (which may include psychological therapies).

For musculoskeletal pain, hot or cold packs, massage, and stretching (including traction) can be helpful.

Ferro Moura FK et al. Prescription of exercises for the treatment of chronic pain along the continuum of nociplastic pain: a systematic review with meta-analysis. Eur J Pain. 2021;25:51. [PMID: 32976664]

Fritz JM et al. Physical therapy referral from primary care for acute back pain with sciatica: a randomized controlled trial. Ann Intern Med. 2021;174:8. [PMID: 33017565]

Integrative Medicine Therapy

Integrative medicine therapies such as acupuncture, massage, cupping, tai chi/yoga, and music therapy may be helpful in treating pain. Studies have not shown strong evidence for integrative medicine for the treatment of chronic pain, but because acupuncture has very low risk, it may be considered in certain patients.

SELECTED INTERVENTIONAL MODALITIES FOR PAIN RELIEF

Pain management specialists are physicians who have completed a residency in anesthesiology, physical medicine and rehabilitation, neurology, internal medicine, emergency medicine, or psychiatry followed by a fellowship in pain management to learn medication management and interventional techniques for acute, chronic, and cancer pain. Interventional pain management modalities performed by pain management specialists involve *neuromodulation* of specific targets to alleviate pain. The procedures they perform include percutaneous needle injection of local anesthetics or corticosteroids, radiofrequency (thermal) lesioning, cryotherapy, chemical neurolysis, or surgical implantation of intrathecal medication delivery pump systems or neurostimulation devices. *While invasive procedures have inherent risks such as bleeding or infection, they can drastically reduce or even obviate the need for conventional pharmacologic therapies that may have side effects or be burdensome to the patient.*

For some patients, a nerve block, such as a celiac plexus block for pain from pancreatic cancer, can provide substantial relief. Intrathecal pumps may be most useful for patients with severe pain responsive to opioids but who experience intolerable side effects from systemic opioids (eg, sedation, urinary retention, constipation). In the palliative care setting, these pumps are appropriate when life expectancy is long enough to justify the discomfort and cost of surgical implantation.

Clinicians do not need to know all the details of interventional pain procedures but should consider referring their patients to pain management specialists if standard treatments are inadequate or associated with intolerable side effects. For example, a common question is whether prolonged opioid therapy with its inherent risks is better than an injection or an implanted device. Beyond knowing the benefits and risks, fiscal considerations may be key.

Table 5–10. Interventional sites and techniques for chronic pain by anatomic location. (Listed in alphabetical order within general location.)

Anatomic sites for neurostimulation	Dorsal column stimulation (spinal cord stimulation)	
	Dorsal root ganglion stimulation	
	Peripheral nerve or field stimulation	
Joints	Intra-articular injections	
	Joint denervation procedures	
Neuraxial blockage (block in the CNS)	Noncontinuous	Epidural (caudal, lumbar, thoracic, cervical; interlaminar vs transforaminal)
		Intrathecal
	Continuous neuraxial drug delivery	Epidural (tunneled catheter, port)
		Intrathecal (implanted intrathecal pump)
Paraneuraxial (planar blockade)	Paravertebral (intercostal)	
	Pectoralis and serratus anterior	
	Transversus abdominis plane/quadratus lumborum	
Peripheral nerve (perineural blockade)	Brachial plexus and branches	
	Lumbar plexus and branches	
Sympathetic ganglion	Celiac plexus	
	Cervical sympathetic blockade (stellate ganglion)	
	Ganglion impar	
	Gasserian ganglion	
	Lumbar sympathetic blockade	
	Sphenopalatine ganglion	
	Superior hypogastric plexus	

Table 5–10 and Table 5–11 list the procedures and the agents typically used in interventional pain modalities.

INTRATHECAL DRUG DELIVERY

A. Indications

Intrathecal drug delivery therapy is indicated for patients with both malignant and nonmalignant pain and has been shown to be effective, cost-effective, and safe. It is generally accepted that intrathecal opioids have a 100- to 300-fold efficacy compared with oral opioids; therefore, *the best candidates may be patients with good analgesic benefit from opioids but burdensome side effects*. Common indications include cancer pain, chronic low-back pain (in particular, post-laminectomy syndrome), complex regional pain syndrome, and other causes of nociceptive or neuropathic pain. In a randomized controlled trial comparing intrathecal therapy with comprehensive medication management in cancer pain, intrathecal therapy was shown to provide superior analgesia with fewer side effects and longer life expectancy. Due to the cost of implanting the device as well as the recovery time needed from surgical implantation, it is recommended that patients have a life expectancy of at least 2–3 months.

Table 5–11. Agents used[1] in neuromodulatory therapies. (Listed in alphabetic order within classes.)

Adjuvants	Clonidine
	Dexmedetomidine
	Others
Chemical neurolysis	Alcohol
	Phenol
Corticosteroids	Dexamethasone
	Methylprednisolone
	Triamcinolone
Neurostimulation	Various patterns, frequency, amplitude, pulse width
Opioids	Hydromorphone
	Fentanyl
	Morphine
Thermal neurolysis	Cryoanalgesia
	Radiofrequency ablation
Voltage-gated sodium channel blockade—local anesthetics	Bupivacaine
	Lidocaine
	Mepivacaine
	Ropivacaine

[1] Injected or applied.

List is not comprehensive but includes most commonly used agents.

B. Procedure

Intrathecal drug delivery systems consist of a pump with a drug reservoir, typically implanted in the abdominal wall, connected to a catheter that delivers medications into the intrathecal space. Initial percutaneous trialing is indicated for patients with noncancer or cancer pain; such percutaneous trialing may consist of either epidural or intrathecal delivery of bolus or continuous medication to determine efficacy and side effect profiles of planned therapeutic agent(s). Some patients with cancer may not undergo a trial to avoid delaying final implantation. Subsequent implantation of an intrathecal drug delivery system involves two incisions: one in the spine to accommodate the catheter and anchor, and another in the lower abdominal region to create a pocket to hold the pump. The catheter is tunneled through the lower abdominal and flank subcutaneous tissues to connect to the pump. Both trial and implantation are typically performed under sedation with local anesthetic infiltration; spinal anesthesia delivered from the pump itself can also be utilized for pump implantation. Some patients may require general anesthesia to tolerate the implantation procedure.

C. Medications Used

According to the Polyanalgesic Conference Consensus (PACC) guidelines for both malignant and nonmalignant pain, first-line intrathecal delivery medications include monotherapy with either morphine or ziconotide, a calcium channel inhibitor. However, the PACC guidelines also state that de facto practice includes combination therapy with opioids (eg, fentanyl, hydromorphone) and local anesthetic (eg, bupivacaine) and may include other medications (eg, baclofen or clonidine). Respiratory depression and sedation are two of the most concerning side effects of many intrathecal medications. Side effects of morphine and fentanyl include nausea, edema, constipation, urinary retention, and pruritus but at a much lower rate than these same medications administered systemically. While ziconotide is FDA-approved, its use is limited due to side effects including myositis and polyarthralgias as well as psychiatric and neurologic adverse effects (it is contraindicated in patients with preexisting psychosis).

D. Advantages and Disadvantages

The main advantage of intrathecal delivery therapy is targeted delivery of medication to the spinal cord with increased efficacy and diminished side effects compared with systemic analgesic medications. Intrathecal therapy has been found to be effective with decreased side effects and improved analgesia in 80% of patients with cancer. However, intrathecal therapy requires regular pump refills and may be complicated by rare adverse events including infections, catheter or pump malfunctions requiring surgical revision, or development of catheter tip granulomas, potentially leading to inadequate analgesia or neurologic deficits. Pump batteries may last from 5 years to 10 years depending on usage. Fatalities surrounding intrathecal therapy have been linked to respiratory depression when high doses and high cervical catheters are used or when combined with high systemic doses of medications; patients must be monitored for respiratory depression or sedation when initiating or increasing intrathecal therapeutic agents. Some intrathecal pumps need to be emptied prior to MRI; due to the magnetic forces of the MRI, the entirety of the drug reservoir could inadvertently open. Therefore, it is critical that the type of pump is known prior to placing the patient in an MRI machine. Additionally, anticoagulants and NSAIDs need to be stopped prior to pump implantation and need to be held briefly after the implantation as well; this temporary cessation imposes the risk of potentially causing blood clots.

E. Alternatives

For patients with limited life expectancy, continuous epidural drug delivery via an external pump or subcutaneous port may be more appropriate. Systemic medications delivered orally, intravenously, topically, or even by a subcutaneous infusion (as in palliative care settings) are alternatives to intrathecal therapy.

SPINAL STIMULATION

A. Indications

Spinal stimulation targets neuropathic pain in the trunk and limbs, such as from failed back surgery syndrome, complex regional pain syndrome, and radiculopathy, as well as neuropathic pain associated with cancer.

B. Procedure

Neurostimulation devices consist of an implantable pulse generator typically placed in the flank or abdomen just under the skin, and an array of electrical contacts on small cylindrical or paddle leads placed in the epidural space. *Neurostimulation devices transmit electrical pulses to the spinal cord or dorsal root ganglion to block pain transmission.* Paddle leads require neurosurgical implantation with laminotomy (and general anesthesia), while percutaneous wire leads may be implanted under sedation. Patients undergo a 3- to 7-day trial during which the leads are attached to an external battery source and undergo programming with different pulse waveforms to assess therapeutic efficacy prior to surgical implantation of permanent leads and implantable pulse generator.

C. Stimulation Parameters

Double-blind RCTs have shown that both functional status and pain scores can be significantly improved using spinal cord stimulation systems that adapt the output to the patient's individual neural response in a closed loop fashion, thereby providing long-term improvement in pain relief, sleep, mood, disability, and opioid reduction. For more focal neuropathic pain conditions such as postoperative inguinal nerve injuries or thoracic postherpetic neuralgias, stimulation of the dorsal root ganglion can provide focal analgesia.

D. Advantages and Disadvantages

Spinal cord stimulation is a reversible technology that may provide superior analgesic efficacy while eliminating the need for systemic medications. Literature suggests spinal cord stimulation is efficacious in 80–90% of well-selected patients, such as those with neuropathic low-back pain due to post-laminectomy syndrome. In fact, spinal cord stimulation has now advanced to a higher position in the treatment continuum; *it can be considered before using long-term moderate doses of systemic opioids*. On the other hand, because it is a surgical procedure, it may be associated with complications, such as infection, lead migration, device malfunction, or neurologic deficits. While MRIs were contraindicated with some older systems, most newer systems allow for limited MRI imaging. Batteries may require charging a few times a week but typically do not require replacement for 5–10 years. Similar to intrathecal pumps, anticoagulants and NSAIDs need to be stopped prior to implantation of spinal cord stimulation devices because of the potential risks (eg, bleeding). The implanting surgeon, prescribing physician, and patient need to discuss the benefits and risks before proceeding. In addition, a psychological evaluation is typically performed prior to initiating therapy to rule out any severe untreated psychological comorbidities and assess expectation of treatment and appropriateness of implantation.

E. Alternatives

In addition to medication management for pain, two neuromodulatory techniques may serve as alternatives to dorsal horn and dorsal root ganglion stimulation. **Peripheral nerve stimulation** targets peripheral nerves using a similar system of a lead connected to a pulse generator. It may be most appropriate when there is a very specific neurologic target. **Transcutaneous electrical nerve stimulators (TENS)** and systemic pharmacologic therapies are alternatives.

CELIAC PLEXUS BLOCK & NEUROLYSIS

A. Indications

A celiac plexus block refers to injection of a long-acting anesthetic (eg, bupivacaine) with or without a corticosteroid (eg, methylprednisolone); with corticosteroids, the block can provide relief for a few weeks to months. **Celiac plexus neurolysis** involves injection of a neurolytic agent (eg, alcohol or phenol); it may provide pain relief more consistently for 2–6 months. The most common indication is pancreatic cancer pain, but it can be used for pain from other malignancies (eg, stomach, liver, spleen, kidney, and GI tract) or from chronic pancreatitis. Multiple randomized controlled trials and meta-analyses have shown superiority of celiac plexus neurolysis to medication management for pancreatic cancer, but evidence of its efficacy for chronic pancreatitis is more mixed.

B. Procedure

The most common approach is a percutaneous posterior approach under fluoroscopy guidance, with bilateral needles targeted to the celiac plexus at the level of T12–L1. Alternatively, ultrasound, CT, or endoscopic guidance can be used. Minimal sedation is required for the percutaneous approaches, while heavy sedation or general anesthesia may be required for endoscopic guidance.

C. Medications Used

Chemical neurolysis with alcohol or phenol is used to extend the duration of the analgesia to ≥ 2 months compared to a block with local anesthetic (eg, bupivacaine) and corticosteroid (eg, methylprednisolone), which produces an analgesic duration of weeks to months. For chemical neurolysis, ethanol is used most often because it does not require compounding and importantly has a lower chance of permanent neurologic damage compared with phenol; however, it is more painful on injection.

D. Advantages and Disadvantages

The primary advantage is improved analgesia without need for systemic medications and their untoward effects. Neurolytic celiac plexus blockade is effective in 70–80% of patients. Common side effects of celiac plexus interventions include transient hypotension and transient diarrhea. Transient or permanent spinal cord damage is rare (0–0.2%) with local anesthetic, but inadvertent peripheral nerve injury is increased with the use of alcohol or phenol.

E. Alternatives

Standard pain management is with oral or transdermal systemic analgesic (eg, opioid) medication. Intrathecal therapy also is an alternative, especially for cancer pain.

EPIDURAL CORTICOSTEROID INJECTION

A. Indications

Epidural corticosteroid injections are indicated for patients with chronic neck pain, low-back pain, and radicular pain resulting from central or neuroforaminal stenosis in the cervical, thoracic, or lumbosacral region. Both central and neuroforaminal stenosis may be caused by degenerative disk disease, disk herniation, or facet arthropathy. Epidural corticosteroid injections are relatively safe and are appropriate after conservative measures, such as physical therapy and analgesic medications, have been tried and found unsuccessful.

B. Procedure

Fluoroscopy is typically used to assist with visualizing the bony landmarks; either an interlaminar or a transforaminal approach can be used. Interlaminar access is obtained by placing a needle between the lamina of adjacent vertebral levels, whereas transforaminal access is obtained by inserting a needle through the neuroforamen to access the epidural space. These needle insertion procedures can be performed with topical local anesthetic or with minimal sedation.

C. Medications Used

Typically, a particulate corticosteroid such as methylprednisolone is used alone or in combination with a local anesthetic. For the transforaminal approach, where inadvertent vascular access is more of a concern, a nonparticulate corticosteroid such as dexamethasone may be preferred.

D. Advantages and Disadvantages

Epidural corticosteroid injections are advantageous for patients who have not responded to conservative therapy, are not surgical candidates, or do not want surgery. The best evidence of the effectiveness of epidural corticosteroid injections is the short-term improvement of radiculopathy in both the lumbar and cervical regions. Disadvantages include possible post–dural puncture headache, transient weakness, and, rarely, permanent neurologic deficits. Patients receiving systemic anticoagulation may need to hold their anticoagulants before receiving corticosteroid injections, which could increase their risk of cardiovascular events; these cases should be discussed with the clinician managing the anticoagulation prior to performing any epidural corticosteroid injections.

E. Alternatives

Alternatives include conservative therapy, such as oral analgesic medication management, physical therapy, pain psychology, acupuncture, and surgery.

Verheijen EJA et al. Epidural steroid compared to placebo injection in sciatica: a systematic review and meta-analysis. Eur Spine J. 2021;30:3255. [PMID: 33974132]

When to Refer

Patients should be referred to pain management specialists if they have:

- Pain that does not respond to low-dose systemic opioids at typical doses or the opioids cause major adverse effects at typical doses.
- Pain that cannot be controlled expeditiously or safely by other clinicians.
- Neuropathic pain that does not respond to first-line treatments.
- Complex medication management that requires high dose of medications, especially long-acting opioids such as buprenorphine or methadone.
- Severe pain from malignancy, including primary disease (eg, pancreatic cancer) or metastatic disease (eg, bony metastases).

When to Admit

- Severe exacerbation of pain not responsive to previous stable oral opioids given around-the-clock plus breakthrough doses.
- Pain that is so severe that it cannot be controlled at home.
- Uncontrollable side effects from opioids, including nausea, vomiting, myoclonus, and altered mental status.
- Need for a surgical procedure, such as implantation of an intrathecal drug delivery pump or neurostimulation device.

Dermatologic Disorders

Nathan W. Rojek, MD
Scott Worswick, MD

Dermatologic diseases are diagnosed by the types of lesions they cause. Identify the morphology of the lesion(s) to establish a differential diagnosis (Table 6–1), and obtain the elements of the history, physical examination, and appropriate laboratory and histopathologic tests to confirm the diagnosis. Specific clinical situations, such as an immunocompromised or critically ill patients, lead to different diagnostic considerations.

PRINCIPLES OF DERMATOLOGIC THERAPY

Frequently Used Treatment Measures

A. Bathing

Soap should be used only in the axillae and groin and on the feet by persons with dry or inflamed skin. Soaking in water for 10–15 minutes before applying topical corticosteroids or emollient enhances their efficacy (Soak and Smear).

B. Topical Therapy

Nondermatologists should become familiar with a representative agent in each category for each indication (eg, topical corticosteroid, topical retinoid, etc).

1. Corticosteroids—Topical corticosteroid creams, lotions, ointments, gels, foams, and sprays are presented in Table 6–2. Topical corticosteroids are divided into classes based on potency. Agents within the same class are equivalent therapies; however, prices of topical corticosteroids vary dramatically. For a given agent, higher lipophilicity (greasiness) corresponds with increased potency such that for the same compound and strength an ointment formulation is more potent than a cream which is more potent than a lotion. The potency of a topical corticosteroid may be dramatically increased by occlusion (covering with a water-impermeable barrier) for at least 4 hours. Depending on the location of the skin condition, gloves, plastic wrap, moist pajamas covered by dry pajamas (wet wraps), or plastic occlusive suits can be used. Caution should be used in applying topical corticosteroids to areas of thin skin (face, genitals, skin folds). Topical corticosteroid use on the eyelids may result in glaucoma or cataracts. The clinician may estimate the amount of topical corticosteroid needed by using the “rule of nines” (as in burn evaluation; see Figure 42–2). Approximately 20–30 g is needed to cover the entire body surface of an adult. Systemic absorption does occur with topical corticosteroids, but complications of systemic corticosteroids are rare.

2. Emollients for dry skin (“moisturizers”)—Dry skin is a result of abnormal function of the epidermis. Emollients restore the epidermis by promoting keratinocyte differentiation and by producing innate antimicrobials; some restore skin barrier lipids, including ceramides. Ointments and creams, rather than lotions, are the best moisturizers. **Emollients are most effective when applied to wet skin.** Plain petrolatum is allergen-free and can be used if allergic contact dermatitis to topical products is suspected.

The scaly appearance of dry skin may be improved by emollients with concomitant use of keratolytics including urea, lactic acid, or glycolic acid–containing products provided no inflammation (erythema or pruritus) is present.

3. Drying agents for weepy dermatoses—If the skin is weepy from infection or inflammation, drying agents may be beneficial. The best drying agent is water applied as repeated compresses for 15–30 minutes, alone or with aluminum salts (Burow solution, Domeboro tablets).

4. Topical antipruritics—Lotions that contain 0.5% each of camphor and menthol (Sarna) or pramoxine hydrochloride 1% (with or without 0.5% menthol, eg, Prax, PrameGel, Aveeno Anti-Itch lotion) are effective antipruritic agents. Hydrocortisone, 1% or 2.5%, may be incorporated for its anti-inflammatory effect (Pramosone cream, lotion, or ointment). Doxepin cream 5% reduces pruritus but may cause drowsiness. Pramoxine and doxepin are most effective when applied with topical corticosteroids. Topical capsaicin and lidocaine can be effective in some forms of neuropathic itch.

C. Systemic Antipruritic Drugs

1. Antihistamines and antidepressants—H_1-blockers are the agents of choice for pruritus due to histamine, such as urticaria. Otherwise, they appear to benefit itchy patients only by their sedating effects. Hydroxyzine 25–50 mg

Table 6–1. Morphologic categorization of skin lesions and diseases.

Pigmented	Freckle, lentigo, seborrheic keratosis, nevus, blue nevus, halo nevus, melanoma
Scaly	Psoriasis, dermatitis (atopic, stasis, seborrheic, chronic allergic contact or irritant contact), xerosis (dry skin), lichen simplex chronicus, tinea pedis/cruris/corporis, tinea versicolor, secondary syphilis, pityriasis rosea, discoid lupus erythematosus, exfoliative dermatitis, drug eruption, actinic keratosis, Bowen disease
Vesicular	Herpes simplex, varicella, herpes zoster, pompholyx (vesicular dermatitis of palms and soles), vesicular tinea, autoeczematization, dermatitis herpetiformis, miliaria crystallina, scabies, photosensitivity, acute contact allergic dermatitis, drug eruption
Weepy or encrusted	Impetigo, acute contact allergic dermatitis, any vesicular dermatitis
Pustular	Acne vulgaris, acne rosacea, folliculitis, candidiasis, miliaria pustulosa, pustular psoriasis, any vesicular dermatitis, drug eruption
Figurate (“shaped”) erythema	Urticaria, erythema multiforme, erythema migrans, cellulitis, erysipelas, erysipeloid, arthropod bites, erythema annulare centrifigum, erythema marginatum, erythema chronicum migrans
Bullous	Impetigo, blistering dactylitis, pemphigus, pemphigoid, porphyria cutanea tarda, drug eruptions, erythema multiforme, toxic epidermal necrolysis
Papular	**Hyperkeratotic:** warts, corns, seborrheic keratoses **Purple-violet:** lichen planus, drug eruptions, Kaposi sarcoma, lymphoma cutis, Sweet syndrome **Flesh-colored, umbilicated:** molluscum contagiosum **Pearly:** basal cell carcinoma, intradermal nevi **Small, red, inflammatory:** acne, rosacea, miliaria rubra, candidiasis, scabies, folliculitis
Pruritus[1]	Xerosis, scabies, pediculosis, lichen planus, lichen simplex chronicus, bites, systemic causes, anogenital pruritus
Nodular, cystic	Erythema nodosum, furuncle, cystic acne, follicular (epidermal) inclusion cyst, metastatic tumor to skin
Photodermatitis	Drug eruption, polymorphic light eruption, lupus erythematosus
Morbilliform	Drug eruption, viral infection, secondary syphilis
Erosive	Any vesicular dermatitis, impetigo, aphthae, lichen planus, erythema multiforme, intertrigo
Ulcerated	Decubiti, herpes simplex, skin cancers, parasitic infections, syphilis (chancre), chancroid, vasculitis, stasis, arterial disease, pyoderma gangrenosum

[1] Not a morphologic class but included because it is one of the most common dermatologic presentations.

Table 6–2. Useful topical dermatologic therapeutic agents.[1]

Agent	Formulations, Strengths	Frequency of Application	Potency Class	Common Indications	Comments
Corticosteroids (Listed in Order of Increasing Potency)					
Hydrocortisone acetate	Cream 1% Ointment 1% Solution 1%	Twice daily	Low	Seborrheic dermatitis Pruritus ani Intertrigo	Not the same as valerate or hydrocortisone butyrate Not for poison oak OTC lotion (Aquanil HC), OTC solution (Scalpicin)
	Cream 2.5% Ointment 2.5%			As for 1% hydrocortisone	Perhaps better for pruritus ani Not clearly better than 1% More expensive Not OTC
Alclometasone dipropionate (Aclovate)	Cream 0.05% Ointment 0.05%	Twice daily	Low	As for hydrocortisone	More efficacious than hydrocortisone Perhaps causes less atrophy
Desonide	Cream 0.05% Ointment 0.05% Lotion 0.05%	Twice daily	Low	As for hydrocortisone For lesions on face or body folds resistant to hydrocortisone	More efficacious than hydrocortisone Can cause rosacea or atrophy Not fluorinated

(*continued*)

Table 6–2. Useful topical dermatologic therapeutic agents.[1] (continued)

Agent	Formulations, Strengths	Frequency of Application	Potency Class	Common Indications	Comments
Clocortolone (Cloderm)	Cream 0.1%	Three times daily	Medium	Contact dermatitis Atopic dermatitis	Does not cross-react with other corticosteroids chemically and can be used in patients allergic to other corticosteroids
Prednicarbate (Dermatop)	Emollient cream 0.1% Ointment 0.1%	Twice daily	Medium	As for triamcinolone	May cause less atrophy No generic formulations Preservative-free
Triamcinolone acetonide	Cream 0.1% Ointment 0.1% Lotion 0.1%	Twice daily	Medium	Eczema on extensor areas Used for psoriasis with tar Seborrheic dermatitis and psoriasis on scalp	Caution in body folds, face Economical in 0.5-lb and 1-lb sizes for treatment of large body surfaces Economical as solution for scalp
	Cream 0.025% Ointment 0.025%	Twice daily	Medium	As for 0.1% strength	Possibly less efficacy and few advantages over 0.1% formulation
Fluocinolone acetonide	Cream 0.025% Ointment 0.025%	Twice daily	Medium	As for triamcinolone	
	Solution 0.01%	Twice daily	Medium	As for triamcinolone	
Mometasone furoate (Elocon)	Cream 0.1% Ointment 0.1% Lotion 0.1%	Once daily	Medium	As for triamcinolone	Often used inappropriately on the face or on children Not fluorinated
Desoximetasone	Cream 0.05% Cream 0.25% Gel 0.05% Ointment 0.25%	Twice daily	High	As for triamcinolone	Comparable potency to fluocinonide Suggested for use when allergic contact dermatitis to topical corticosteroid is suspected; ointment useful when allergic contact dermatitis to propylene glycol is suspected
Diflorasone diacetate	Cream 0.05% Ointment 0.05%	Twice daily	High	Nummular dermatitis Allergic contact dermatitis Lichen simplex chronicus	
Fluocinonide (Lidex)	Cream 0.05% Gel 0.05% Ointment 0.05% Solution 0.05%	Twice daily	High	As for betamethasone Gel useful for poison oak	Economical generics Lidex cream can cause stinging on eczema Lidex emollient cream preferred
Betamethasone dipropionate (Diprolene)	Cream 0.05% Ointment 0.05% Lotion 0.05%	Twice daily	Ultra-high	For lesions resistant to high-potency corticosteroids Lichen planus Insect bites	Economical generics available
Clobetasol propionate (Temovate)	Cream 0.05% Ointment 0.05% Lotion 0.05%	Twice daily	Ultra-high	As for betamethasone dipropionate	Somewhat more potent than diflorasone Limited to 2 continuous weeks of use Limited to 50 g or less per week Cream may cause stinging; use "emollient cream" formulation Generic available
Halobetasol propionate (Ultravate)	Cream 0.05% Ointment 0.05%	Twice daily	Ultra-high	As for clobetasol	Same restrictions as clobetasol Cream does not cause stinging Compatible with calcipotriene (Dovonex)
Flurandrenolide (Cordran)	Tape: 3″ roll Lotion 0.05%	Every 12 hours	Ultra-high	Lichen simplex chronicus	Tape version protects the skin and prevents scratching

(*continued*)

Table 6–2. Useful topical dermatologic therapeutic agents.[1] (continued)

Agent	Formulations, Strengths	Frequency of Application	Potency Class	Common Indications	Comments
Nonsteroidal Anti-inflammatory Agents Useful for Dermatitis (Listed Alphabetically)					
Crisaborole (Eucrisa)	Ointment 2%	Twice daily	N/A	Atopic dermatitis	Steroid substitute not causing atrophy or striae May sting or burn on initial application
Pimecrolimus[2] (Elidel)	Cream 1%	Twice daily	N/A	Atopic dermatitis	Steroid substitute not causing atrophy or striae
Ruxolitinib (Opzelura)	Cream 1.5%	Twice daily	N/A	Atopic dermatitis	Steroid substitute not causing atrophy or striae Many potential systemic side effects including malignancy, infection and cardiovascular
Roflumilast (Zoryve)	Cream 0.15%	Once daily	N/A	Atopic dermatitis	Steroid substitute not causing atrophy or striae May cause diarrhea or headache
Tacrolimus[2] (Protopic)	Ointment 0.1% Ointment 0.03%	Twice daily	N/A	Atopic dermatitis	Steroid substitute not causing atrophy or striae Burns in ≥ 40% of patients with eczema May cause flushing with ingestion of alcohol
Antibiotics (for Acne) (Listed Alphabetically)					
Clindamycin phosphate	Solution 1% Gel 1% Lotion 1% Pledget 1%	Twice daily	N/A	Mild papular acne	Lotion is less drying than solution, gel, or pledgets for patients with sensitive skin Recommend use with benzoyl peroxide to avoid antibiotic resistance from monotherapy
Clindamycin/ Benzoyl peroxide (BenzaClin)	Gel	Twice daily	N/A	As for benzamycin	No generic More effective than either agent alone
Dapsone	Gel 5%	Once daily	N/A	Mild papulopustular acne	More expensive, well tolerated Recommend use with benzoyl peroxide to avoid antibiotic resistance from monotherapy
Erythromycin	Solution 2% Gel 2% Pledget 2%	Twice daily	N/A	As for clindamycin	Many different manufacturers Economical Recommend use with benzoyl peroxide to avoid antibiotic resistance from monotherapy
Erythromycin/ Benzoyl peroxide (Benzamycin)	Gel	Twice daily	N/A	As for clindamycin Can help treat comedonal acne	No generic More expensive More effective than other topical antibiotics Main jar requires refrigeration
Minocycline	Foam: 4%	Once daily	N/A	As for clindamycin	No generic More expensive May cause skin yellowing (temporary, washes off)
Antibiotics (for Impetigo)					
Mupirocin (Bactroban)	Ointment 2% Cream 2%	Three times daily	N/A	Impetigo, folliculitis	Because of cost, use limited to tiny areas of impetigo Used in the nose twice daily for 5 days to reduce staphylococcal carriage

(*continued*)

Table 6–2. Useful topical dermatologic therapeutic agents.[1] (continued)

Agent	Formulations, Strengths	Frequency of Application	Potency Class	Common Indications	Comments
Retapamulin (Altabax)	Ointment 1%	Twice daily	N/A	Impetigo	For *Staphylococcus aureus* or *Streptococcus pyogenes* infection Typically reserved for mupirocin-resistant infections
Ozenoxacin (Ozanex)	Cream 1%	Twice daily (5 days)	N/A	Impetigo	Topical fluoroquinolone Activity against MRSA
Antifungals: Imidazoles (Listed Alphabetically)					
Clotrimazole	Cream 1%: OTC Solution 1%	Twice daily	N/A	Dermatophyte and *Candida* infections	Available OTC Inexpensive generic cream available
Econazole (Spectazole)	Cream 1%	Once daily	N/A	As for clotrimazole	Somewhat more effective than clotrimazole and miconazole
Ketoconazole (Nizoral)	Cream 2% g	Once daily	N/A	As for clotrimazole	Somewhat more effective than clotrimazole and miconazole
Miconazole	Cream 2%: OTC	Twice daily	N/A	As for clotrimazole	As for clotrimazole
Oxiconazole (Oxistat)	Cream 1% Lotion 1%	Twice daily	N/A	As for clotrimazole	
Sertaconazole (Ertaczo)	Cream 2%	Twice daily	N/A	Refractory tinea pedis	By prescription More expensive
Sulconazole (Exelderm)	Cream 1% Solution 1%	Twice daily	N/A	As for clotrimazole	No generic Somewhat more effective than clotrimazole and miconazole
Other Antifungals (Listed Alphabetically)					
Butenafine (Mentax)	Cream 1%: OTC	Once daily	N/A	Dermatophytes	Fast response; high cure rate; expensive Available OTC
Ciclopirox (Loprox) (Penlac)	Cream 0.77% Lotion 0.77% Solution 8%	Twice daily	N/A	As for clotrimazole	No generic Somewhat more effective than clotrimazole and miconazole
Efinaconazole (Jublia)	Solution 10%	Once daily for 48 weeks	N/A	Onychomycosis	No generic; more effective than ciclopirox for nail disease
Naftifine (Naftin)	Cream 1% Gel 1%	Once daily	N/A	Dermatophytes	No generic Somewhat more effective than clotrimazole and miconazole
Tavaborole (Kerydin)	Solution 5%	Once daily for 48 weeks	N/A	Onychomycosis	No generic available
Terbinafine (Lamisil)	Cream 1%: OTC	Once daily	N/A	Dermatophytes	Fast clinical response OTC
Antipruritics (Listed Alphabetically)					
Camphor/menthol (Sarna)	Lotion 0.5%/0.5%	Two to three times daily	N/A	Mild eczema, xerosis, mild contact dermatitis	
Capsaicin (various)	Cream 0.025% Cream 0.075%	Three to four times daily	N/A	Topical antipruritic, best used for neuropathic itching	Burning/stinging with initial application that subsides with consistent ongoing use
Doxepin (Zonalon)	Cream 5%	Four times daily	N/A	Topical antipruritic, best used in combination with appropriate topical corticosteroid to enhance efficacy	Can cause sedation

(*continued*)

Table 6–2. Useful topical dermatologic therapeutic agents.[1] (continued)

Agent	Formulations, Strengths	Frequency of Application	Potency Class	Common Indications	Comments
Pramoxine hydrochloride (Prax)	Lotion 1% OTC	Four times daily	N/A	Dry skin, varicella, mild eczema, pruritus ani	OTC formulations (Prax, Aveeno Anti-Itch Cream or Lotion; Itch-X Gel) By prescription mixed with 1% or 2% hydrocortisone

[1] For a given agent, higher lipophilicity (greasiness) corresponds with increased potency; for example, triamcinolone 0.1% ointment is more potent than triamcinolone 0.1% cream, which in turn is more potent than triamcinolone 0.1% lotion.

[2] Topical tacrolimus and pimecrolimus should be used only when other topical treatments are ineffective. Treatment should be limited to an area and duration be as brief as possible. Use of these agents should be avoided in persons with known immunosuppression, HIV infection, bone marrow and organ transplantation, or lymphoma; those at high risk for lymphoma; and those with a history of lymphoma.

MRSA, methicillin-resistant *Staphylococcus aureus;* N/A, not applicable; OTC, over-the-counter.

orally at night is a typical dose. Sedating and nonsedating antihistamines are of limited value for the treatment of pruritus associated with inflammatory skin disease. Preferable agents include antidepressants (such as doxepin, mirtazapine, and paroxetine) and agents that act directly on the neurons that perceive or modulate pruritus (such as gabapentin, pregabalin, and duloxetine).

2. Systemic corticosteroids—See Chapter 30.

Rupert J et al. Pruritus: diagnosis and management. Am Fam Physician. 2022;105:55. [PMID: 35029946]

Sunscreens

Protection from UV light reduces the incidence of sunburn, actinic keratoses, melanoma, and some nonmelanoma skin cancers when initiated at any age and in any skin type. The best protection is shade, but protective clothing, avoidance of direct sun exposure during the peak hours of the day, and daily use of sunscreens are important.

A broad-spectrum (protection against UVA and UVB) sunscreen should be used daily with a sun protective factor (SPF) of at least 30. Clinicians should reinforce regular sunscreen use and reapplication every few hours or more depending on exercise level and exposure to water. Sunscreens with protection against UVA as well as UVB are helpful in managing photosensitivity disorders. Health implications of systemic absorption of chemical sunscreens are unknown.

Complications of Topical Dermatologic Therapy

Complications of topical therapy include allergy, irritation, and other side effects. Reactions may result from the active or inactive ingredients, including fragrances and preservatives.

A. Allergy

Of the topical antibiotics, neomycin and bacitracin have the greatest potential for sensitization. Diphenhydramine, benzocaine, vitamin E, aromatic oils, preservatives, fragrances, tea tree oil, and even topical corticosteroids can cause allergic contact dermatitis.

B. Irritation

Preparations of tretinoin, benzoyl peroxide, and other acne medications should be applied sparingly to the skin.

C. Other Side Effects

Topical corticosteroids may induce acne-like lesions on the face (steroid rosacea) and atrophic striae in body folds.

NEOPLASTIC LESIONS

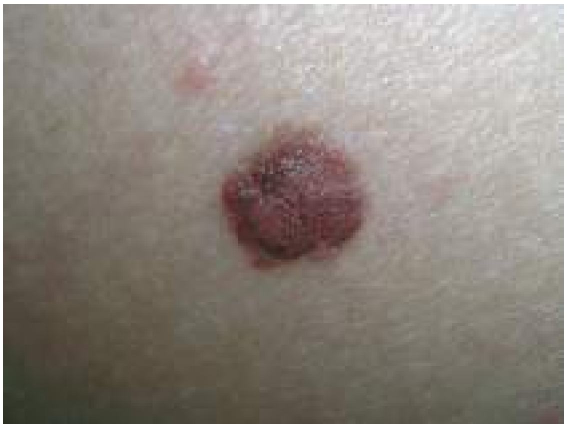
PIGMENTED NEOPLASMS

BENIGN PIGMENTED LESIONS

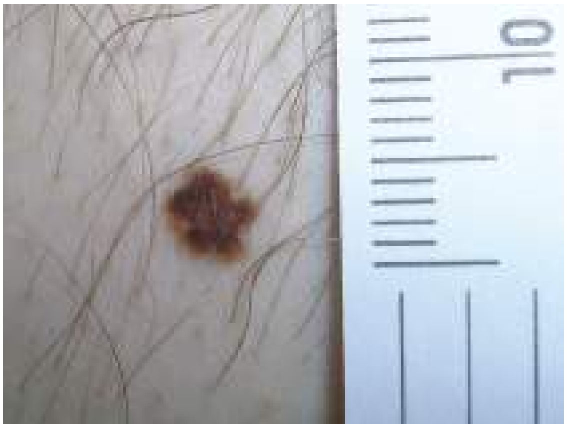
1. Melanocytic Nevi (Normal Moles)

In general, a benign mole is a small (< 6 mm) macule or papule with a well-defined border and homogeneous beige or pink to dark brown pigment. They represent benign melanocytic growths.

Moles have a typical natural history. Early in life, moles often appear as flat, small, brown lesions and are termed



▲ **Figure 6–1.** Benign, compound nevus on the back. (Reproduced, with permission, from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine*, 2nd ed. McGraw-Hill, 2013.)



▲ **Figure 6–2.** Atypical (dysplastic) nevus on the chest. Note irregular border and variegation in color. (Reproduced, with permission, from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine*, 2nd ed. McGraw-Hill, 2013.)

"junctional nevi" because the nevus cells are at the junction of the epidermis and dermis. Over time, these moles enlarge and often become raised, reflecting the appearance of a dermal component, giving rise to "compound nevi" (Figure 6–1). Moles may darken and grow during pregnancy. As White patients enter their eighth decade, most moles have lost their junctional component and dark pigmentation as a result of normal senescence. At every stage of life, normal moles should be well demarcated, symmetric, and uniform in contour and color. Regular mole screening is not an evidence-based recommendation for all adults, although rates of screening continue to rise.

Yeh I. Melanocytic naevi, melanocytomas and emerging concepts. Pathology. 2023;55:178. [PMID: 36642570]

2. Atypical Nevi

The term "atypical nevus" is synonymous with the older term "dysplastic nevus." Dermoscopy by a trained clinician may be a useful tool in the evaluation of atypical nevi. Clinically, these moles are large (6 mm or more in diameter), with an ill-defined, irregular border and irregularly distributed pigmentation (Figure 6–2). An estimated 5–10% of the White population in the United States has one or more atypical nevi, for which recreational sun exposure is a primary risk. There is an increased risk of melanoma in patients with 50 or more nevi with one or more atypical moles and one mole 8 mm or larger and patients with any number of definitely atypical moles. These patients should be educated in how to recognize changes in moles and be monitored every 6–12 months by a clinician. Kindreds with familial melanoma (numerous atypical nevi and a family history of two first-degree relatives with melanoma) require closer attention since their risk of developing single or multiple melanomas approaches 50% by age 50. Moles should be removed only if they are suspected to be melanomas.

Skudalski L et al. Melanoma: how and when to consider clinical diagnostic technologies. J Am Acad Dermatol. 2022;86:503. [PMID: 34915058]

3. Blue Nevi

Blue nevi are small, slightly elevated, blue-black lesions (Figure 6–3) that favor the dorsal hands. They are common in persons of Asian descent and may be single or multiple. If the lesion has remained unchanged for years, it may be considered benign, since malignant blue nevi are rare. Blue-black papules and nodules that are new or growing must be evaluated to rule out nodular melanoma.

4. Freckles & Lentigines

Freckles (ephelides) and lentigines are flat brown macules, typically between 3 mm and 5 mm in diameter. Freckles first appear in young children, darken with UV exposure, and fade with cessation of sun exposure. They are determined by genetic factors. In adults, lentigines gradually appear in sun-exposed areas, particularly the face, dorsal hands, upper back, and upper chest, starting in the fourth to fifth decade of life, and are associated with photoaging as well as estrogen and progesterone use. They should be evaluated like all pigmented lesions: if the pigmentation is homogeneous and they are symmetric and flat, they are most likely benign. They can be treated with topical

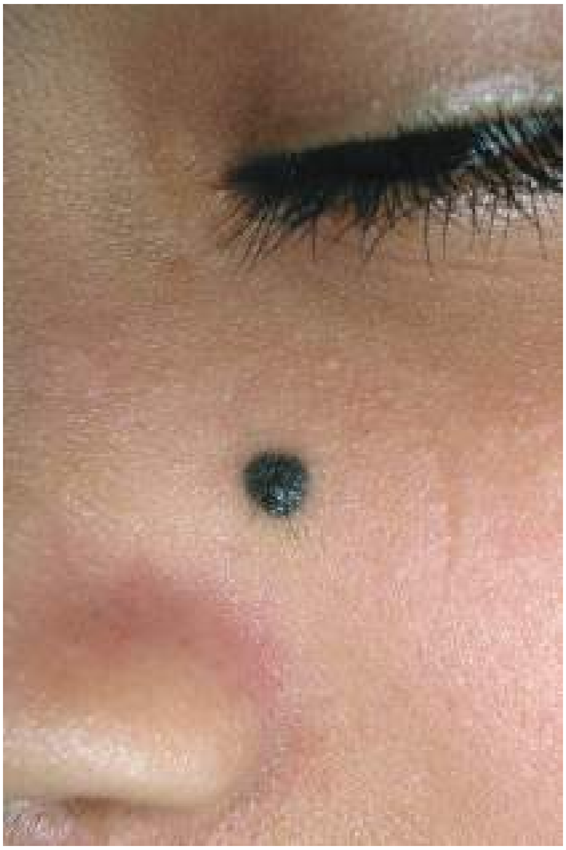

Figure 6–3. Blue nevus on the left cheek, a darkly pigmented blue-black macule with some resemblance to a melanoma due to its dark pigmentation. (Reproduced, with permission, from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

retinoids such as 0.1% tretinoin or 0.1% adapalene, hydroquinone, laser/light therapy, or cryotherapy.

5. Seborrheic Keratoses

Seborrheic keratoses are benign papules and plaques, beige to brown or even black, 3–20 mm in diameter, with a velvety or warty surface. They appear to be stuck or pasted onto the skin (Figure 6–4). They are extremely common—especially in older adults—and may be mistaken for melanomas or other types of cutaneous neoplasms. No treatment is needed. They may be frozen with liquid nitrogen or curetted if itchy or inflamed but usually recur after treatment.

MALIGNANT PIGMENTED LESIONS

1. Malignant Melanoma

ESSENTIALS OF DIAGNOSIS

- May be flat or raised with irregular borders.
- Examination may show varying colors, including brown, red, white, black, and blue.
- Should be suspected in any pigmented skin lesion with recent change in appearance.
- Less than 30% develop from existing moles.

General Considerations

Malignant melanoma, the fourth most common of all cancers in the United States, is the leading cause of death due to skin disease and has doubled in incidence over the past 30 years. In 2023 approximately 97,610 new invasive melanomas were diagnosed in the United States, and melanoma caused an estimated 7990 deaths (two-thirds in men). The lifetime risk of melanoma is 2% in White individuals and 0.1–0.5% in persons with skin of color. One in four cases occurs before age 40. Although the overall number of melanomas diagnosed each year continues to rise, there has simultaneously been a decrease in mortality (likely due to both earlier detection and availability of immunotherapy).

Melanoma thickness is the single most important prognostic factor. Ten-year survival rates are 95% if thickness is < 1 mm; 80% for 1–2 mm; and 55% for 2–4 mm. The 5-year survival rate is 62% if there is lymph node involvement and 16% if there are distant metastases.

Clinical Findings

Primary malignant melanomas may be classified into various clinicohistopathologic types, including superficial spreading melanoma (two-thirds of all melanomas arising on intermittently sun-exposed skin); lentigo melanoma (arising on chronically sun-exposed skin of older individuals); nodular melanoma; acral-lentiginous melanomas (arising on palms, soles, and nail beds); ocular melanoma; and melanomas on mucous membranes. Different types of melanoma appear to have distinct oncogenic mutations, which may be important in the treatment of patients with advanced disease. Clinical features of pigmented lesions suspicious for melanoma are an irregular, notched border where the pigment appears to be spreading into the normal surrounding skin and irregular surface topography (ie, partly raised and partly flat) (Figure 6–5). Color variegation is present and is an important indication for referral. A useful mnemonic is the ABCDE rule: Asymmetry, Border irregularity, Color variegation, Diameter > 6 mm, and Evolution. Less than 30% of melanomas develop from existing moles. **The history of a changing mole (evolution, including bleeding and ulceration) is the single most important historical reason for close evaluation and possible referral.** A mole that appears distinct from the patient's other moles deserves special scrutiny—the "ugly duckling sign."

While superficial spreading melanoma is largely a disease of White individuals, persons with darker skin pigmentation are at risk for this and other types of melanoma, particularly acral lentiginous melanomas, for which UV exposure may not be a significant association. These occur as dark, irregularly shaped lesions on the palms and soles and as new, often broad and solitary, darkly pigmented, longitudinal streaks in the nails, typically with involvement of the proximal nail fold. Acral lentiginous melanoma may be a difficult or delayed diagnosis because benign pigmented lesions of the hands, feet, and nails occur commonly in more darkly pigmented persons, and clinicians may hesitate to biopsy these sites. Clinicians should give special attention to new or changing lesions in these areas.

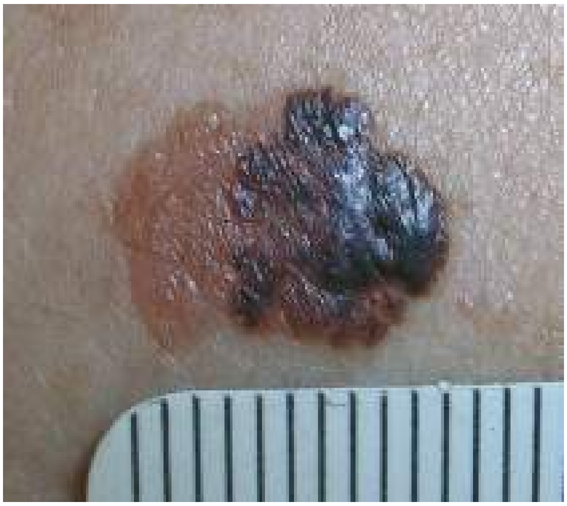

Figure 6–5. Malignant melanoma. Note the classic "ABCDE" features: asymmetry, irregular border, multiple colors, diameter > 6 mm, and evolution or change. (Reproduced, with permission, from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine*, 2nd ed. McGraw-Hill, 2013.)

Treatment

Treatment starts with biopsy or excision of the melanoma to confirm the diagnosis and the tumor depth. After histologic diagnosis, re-excision is recommended with margins dictated by the thickness of the tumor. Recommended surgical margins are 0.5–1 cm for melanoma in situ, 1 cm for lesions < 1 mm in thickness, and 1–2 cm for lesions > 1 mm in thickness.

Sentinel lymph node biopsy using preoperative lymphoscintigraphy and intraoperative lymphatic mapping is effective for staging melanoma patients with intermediate risk (depth > 8–10 mm but without clinical adenopathy or metastasis or high-risk histologic features such as ulceration). This procedure may not confer a survival advantage.

Patients with melanomas with > 1 mm depth or spread to lymph nodes or other sites should be referred to expert centers for serial monitoring and appropriate treatment. Identifying the oncogenic mutations in patients with advanced melanoma may dictate targeted therapy, most commonly to specific BRAF mutations. Additionally, immunotherapy treatments directed toward immune costimulatory molecules such as PD-1 can activate systemic immune-directed destruction of metastatic melanoma.

NONPIGMENTED NEOPLASMS

BENIGN LESIONS

1. Epidermal Inclusion Cyst

ESSENTIALS OF DIAGNOSIS

- Firm dermal papule or nodule.
- Overlying black comedone or "punctum."
- Expressible foul-smelling cheesy material.
- May become red and drain, mimicking an abscess.

General Considerations

Epidermal inclusion cysts (EICs) are common, benign growths of the upper portion of the hair follicle.

EICs favor the face and trunk and may complicate nodulocystic acne vulgaris. Individual lesions range in size from 0.3 cm to several centimeters. An overlying pore or punctum is characteristic. Dermoscopy can aid in observing a tiny punctum when not visible to the naked eye. Lateral pressure may lead to extrusion of a foul-smelling, cheesy material.

Differential Diagnosis

EICs are distinguished from lipomas by being more superficial (in the dermis, not the subcutaneous fat) and by their overlying punctum.

Complications

EICs may rupture, creating an acute inflammatory nodule very similar to an abscess. Cultures of the expressed material will be sterile.

Treatment

Treatment is not required if asymptomatic. Small (1–3 cm) lesions can be treated with a punch incision and removal of cystic contents. Inflamed lesions may be treated with incision and drainage or intralesional triamcinolone acetonide 5–10 mg/mL. For large or symptomatic cysts, surgical excision is curative.

Alexa AI et al. Therapeutic challenges in epidermal inclusion cysts with periocular localization: case reports. J Med Life. 2023;16:1575. [PMID: 38313165]

MALIGNANT & PREMALIGNANT LESIONS

1. Actinic Keratoses

Actinic keratoses are small (0.2–0.6 cm) papules—flesh-colored, pink, or slightly hyperpigmented—that feel like sandpaper and can be tender to palpation. They occur on sun-exposed parts of the body mostly in persons of fair complexion. Actinic keratoses are considered premalignant; 1:1000 lesions per year progress to squamous cell carcinoma.

Application of liquid nitrogen provides rapid eradication of lesions, which crust and disappear after 10–14 days. "Field treatment" with a topical agent can be considered in patients with multiple lesions in one region (eg, forehead, dorsal hands, etc). Fluorouracil cream is the most effective topical agent used for field treatment; imiquimod, ingenol mebutate, and photodynamic therapy are also effective. Any lesions that persist or recur should be evaluated for possible biopsy.

Arcuri D et al. Pharmacological agents used in the prevention and treatment of actinic keratosis: a review. Int J Mol Sci. 2023;24:4989. [PMID:36902419]

Mohney L et al. Use of topical calcipotriol plus 5-fluorouracil in the treatment of actinic keratosis: a systematic review. J Drugs Dermatol. 2022;2:60. [PMID: 35005863]

Worley B et al. Treatment of actinic keratosis: a systematic review. Arch Dermatol Res. 2023;31:1099. [PMID: 36454335]

2. Squamous Cell Carcinoma

ESSENTIALS OF DIAGNOSIS

- Nonhealing ulcer or warty nodule.
- Skin damage due to long-term sun exposure.
- Common in fair-skinned individuals and in organ transplant recipients.

Squamous cell carcinoma usually occurs subsequent to prolonged sun exposure on exposed parts in fair-skinned individuals who sunburn easily. It may arise from an actinic keratosis. The lesions appear as small red, conical, hard nodules that occasionally ulcerate (Figure 6–6). In actinically-induced squamous cell cancers, rates of metastasis are estimated to be 3–7%. Squamous cell carcinomas of the mucosal surfaces, ear, scalp, temple, and genitalia

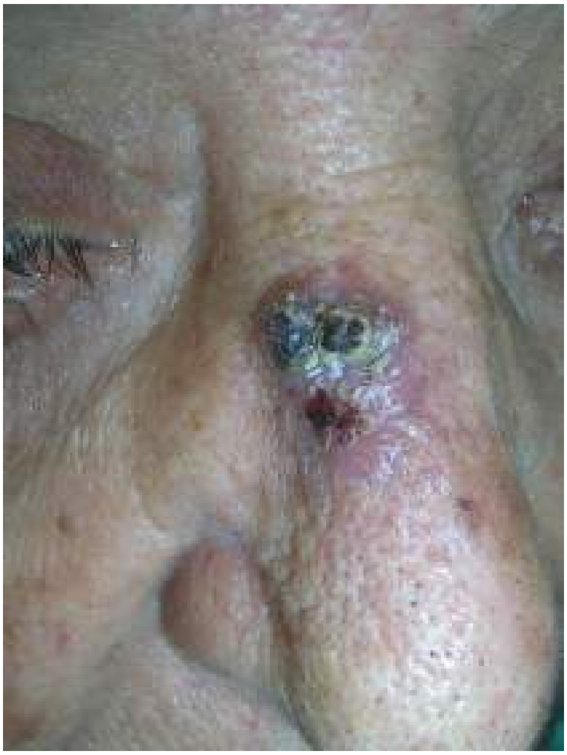

Figure 6–6. Squamous cell carcinoma: an irregular-shaped pink plaque with overlying hemorrhagic crust in a chronically sun-exposed area. (Reproduced, with permission, from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine*, 2nd ed. McGraw-Hill, 2013.)

have much higher rates of recurrence or metastasis and require special management. Patients with multiple squamous cell carcinomas (especially > 10) have higher rates of local recurrence and nodal metastases. Nicotinamide, 500 mg orally twice daily, can decrease the rate of development of squamous cell carcinomas by 30% in high-risk groups.

Squamous cell carcinoma in situ can be treated with imiquimod or 5-fluorouracil (in similar dosing as for superficial basal cell carcinoma) or curettage and electrodessication. The preferred treatment for invasive squamous cell carcinoma is excision or Mohs micrographic surgery. Mohs micrographic surgery is recommended for higher-risk sites (lips, temples, ears, nose, genitalia), recurrent tumors, aggressive histologic subtypes (perineural or perivascular invasion), large lesions (> 1.0 cm on face, > 2.0 cm on trunk or extremities), immunosuppressed patients, lesions developing within a scar, and tumors arising in the setting of genetic diseases. Follow-up for squamous cell carcinoma should be performed at least yearly and include careful examination of lymph nodes. For patients with metastatic disease, advanced therapeutic options now exist including PD-1 blockade and use of cetuximab.

Multiple squamous cell carcinomas are common on the sun-exposed skin of organ transplant patients and typically begin to appear after 5 years of immunosuppression. Regular dermatologic evaluation in at-risk organ transplant recipients is recommended. Skin cancers in organ transplant recipients may be aggressive, and careful management is required. Other forms of immunosuppression, such as chronic lymphocytic leukemia, HIV/AIDS, and chronic iatrogenic immunosuppression, may also increase skin cancer risk and be associated with more aggressive skin cancer behavior.

Marin-Acevedo JA et al. Cetuximab for immunotherapy-refractory/ineligible cutaneous squamous cell carcinoma. Cancers. 2023;15:3180. [PMID: 3737090]

3. Bowen Disease & Paget Disease

Bowen disease (intraepidermal squamous cell carcinoma) can develop on sun-exposed and non–sun-exposed skin. The lesion is usually a small (0.5–3 cm), well-demarcated, slightly raised, pink to red, scaly plaque and may resemble psoriasis or a large actinic keratosis. Lesions may progress to invasive squamous cell carcinoma. Excision or other definitive treatment such as topical treatment (fluorouracil or imiquimod) or photodynamic therapy is indicated.

Extramammary Paget disease, a manifestation of intraepidermal carcinoma or underlying genitourinary or GI cancer, resembles chronic eczema and usually involves apocrine areas such as the genitalia. Mammary Paget disease of the nipple is a unilateral, or rarely bilateral, red scaling plaque that may ooze and is associated with an underlying intraductal mammary carcinoma (see Figure 19–3). While these lesions appear as red patches and plaques in fair-skinned persons, hyperpigmentation may be prominent in darker-skinned individuals.

Pérez JC et al. Extramammary Paget disease: a therapeutic challenge, for a rare entity. Curr Oncol Rep. 2023;25:1081. [PMID: 37421583]

4. Basal Cell Carcinoma

ESSENTIALS OF DIAGNOSIS

- Pearly papule, erythematous patch > 6 mm, or nonhealing ulcer.
- Usually in sun-exposed areas (face, trunk, lower legs).
- Common in fair-skinned persons with a history of sun exposure (often intense, intermittent).

General Considerations

Basal cell carcinomas are the most common form of cancer. They occur on sun-exposed skin in otherwise normal, fair-skinned individuals; UV light is the cause. Basal cell carcinomas can be divided into clinical and histologic subtypes, which determine both clinical behavior and treatment. The clinical subtypes include superficial, nodular, pigmented, and morpheaform. The histologic subtypes include superficial, nodular, micronodular, and infiltrative. Because a second basal cell carcinoma develops in up to half of patients, skin examination is required at least yearly to detect new or recurrent lesions. Nicotinamide, 500 mg orally twice daily, can decrease the rate of development of basal cell carcinomas by 20% in high-risk groups.

Clinical Findings

The most common presentation is a papule or nodule with a central erosion. Occasionally the nodules have stippled pigment (pigmented basal cell carcinoma). Basal cell carcinomas grow slowly, attaining a size of 1–2 cm or more in diameter, usually only after years of growth. There is a "pearly" appearance, with telangiectatic vessels easily visible (Figure 6–7). It is the pearly or translucent quality of these lesions that is most diagnostic, a feature best appreciated if the skin is stretched. On the back and chest, basal cell carcinomas appear as reddish, somewhat shiny, scaly thin papules or plaques. Morpheaform basal cell carcinomas are scar-like in appearance. Basal cell carcinomas are more common and more likely to recur in immunosuppressed patients, including those with non-Hodgkin lymphoma and those who have undergone solid organ or allogeneic hematopoietic stem cell transplantation.

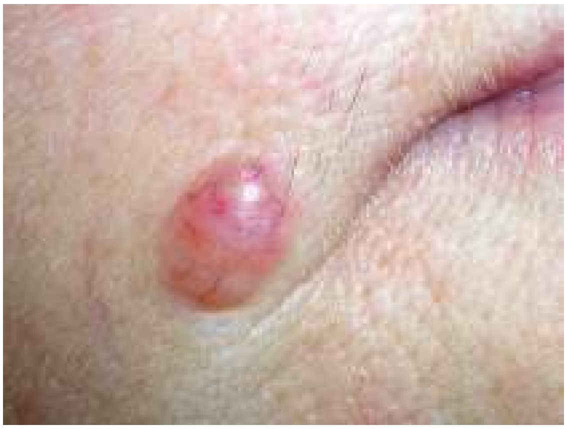

Figure 6–7. Pearly nodular basal cell carcinoma on the face of a 52-year-old woman present for 5 years. (Reproduced, with permission, from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine*, 2nd ed. McGraw-Hill, 2013.)

Treatment

Lesions suspected to be basal cell carcinomas should be biopsied by shave or punch biopsy. Therapy is then aimed at eradication with minimal cosmetic deformity. The histopathologic classification of basal cell carcinomas determines therapy. Imiquimod (applied topically 5 nights per week for 6–10 weeks depending on patient reaction) and 5-fluorouracil (applied topically twice daily for up to 12 weeks) may be appropriate for select patients with superficial basal cell carcinomas, but the treated area must be observed for evidence of complete cure. Superficial or nodular type lesions can be treated with curettage and electrodesiccation, excision, or Mohs micrographic surgery, while those that are classified as morpheaform, micronodular or infiltrative should be treated with excision or Mohs micrographic surgery depending on the size and location of the lesion. Surgical excision has a recurrence rate of 5% or less.

Mohs micrographic surgery—removal of the tumor followed by immediate frozen section histopathologic examination of margins with subsequent re-excision of tumor-positive areas and final closure of the defect—gives the highest cure rates (98%) and results in less tissue loss than a classic excision. It is an appropriate therapy for tumors of the eyelids, nasolabial folds, canthi, external ear, and temple; for recurrent lesions; where tissue sparing is needed for cosmesis; and for those with morpheaform, infiltrative, or micronodular histopathology in certain locations.

Photodynamic therapy and topical application of a photosensitizing agent, followed by irradiation by a light source (typically blue or red), may be appropriate for some superficial and small nodular basal cell carcinomas.

Radiotherapy is effective and sometimes appropriate for older individuals (over age 65), but recurrent tumors after radiation therapy are more difficult to treat and may be more aggressive. Radiation therapy is the most expensive method to treat basal cell carcinoma and should be used only if other treatment options are not appropriate.

Hedgehog pathway inhibitors (vismodegib, sonidegib) are reserved for the treatment of advanced or metastatic basal cell carcinoma or in patients with extensive tumor burden (eg, basal cell nevus syndrome).

5. Kaposi Sarcoma

General Considerations

Human herpes virus 8 (HHV-8), or Kaposi sarcoma–associated herpes virus, is the cause of all forms of Kaposi sarcoma.

Red or purple plaques or nodules on cutaneous or mucosal surfaces are characteristic. Marked edema may occur with few or no skin lesions. Kaposi sarcoma commonly involves the GI tract. In asymptomatic patients, these lesions are not sought or treated. Pulmonary Kaposi sarcoma can present with shortness of breath, cough, hemoptysis, or chest pain; it may be asymptomatic, appearing only on CXR. Bronchoscopy may be indicated.

Treatment

For Kaposi sarcoma in older adults, palliative local therapy with intralesional chemotherapy (vincristine, vinblastine, or bleomycin) or radiation is usually all that is required. In the setting of iatrogenic immunosuppression, the treatment of Kaposi sarcoma is primarily reduction of doses of immunosuppressive medications. In AIDS-associated Kaposi sarcoma, the patient should first be given ART. Other therapeutic options in these patients include cryotherapy or intralesional vinblastine (0.1–0.5 mg/mL); radiation therapy for accessible and space-occupying lesions; and laser surgery for certain intraoral and pharyngeal lesions. Systemic therapy is indicated in patients with skin disease that is cosmetically unacceptable or those with advanced cutaneous, oral visceral, or nodal disease. ART plus chemotherapy appears to be more effective than ART alone (see Tables 44–5 and 44–6). First-line systemic therapies include liposomal doxorubicin and paclitaxel.

6. Cutaneous T-Cell Lymphoma (Mycosis Fungoides)

ESSENTIALS OF DIAGNOSIS

- Localized or generalized erythematous patches that progress to scaly plaques and nodules.
- Sometimes associated with pruritus, lymphadenopathy.
- Distinctive histology.

General Considerations

Mycosis fungoides is a cutaneous T-cell lymphoma that begins on the skin and may remain there for years or decades. It may progress to systemic disease, including Sézary syndrome (erythroderma with circulating malignant T cells).

Clinical Findings

A. Symptoms and Signs

Localized or generalized erythematous patches or scaly plaques are present usually on the trunk. Plaques are frequently over 5 cm in diameter. Pruritus is common and can be severe. The lesions often begin as nondescript patches and may be present more than a decade before the diagnosis is confirmed. Follicular involvement with hair loss is characteristic, and its presence should raise the suspicion of mycosis fungoides for any pruritic eruption. In more advanced cases, tumors appear. Local or diffuse lymphadenopathy may be due to benign expansion (dermatopathic lymphadenopathy) or involvement with mycosis fungoides.

B. Laboratory Findings

Diagnosis is based on skin biopsy. Numerous biopsies may be required before the diagnosis is confirmed. In more advanced disease, circulating malignant T cells (Sézary cells) can be detected in the blood. Eosinophilia may be present.

Differential Diagnosis

Mycosis fungoides may be confused with psoriasis, drug eruption, photoallergy, eczematous dermatitis, syphilis, or tinea corporis but is distinguished by histologic examination.

Treatment

The treatment of mycosis fungoides is complex. Early and aggressive treatment has not been proven to cure or prevent disease progression. Skin-directed therapies, including topical corticosteroids, topical mechlorethamine, bexarotene gel, and UV phototherapy, are used initially. If the disease progresses, psoralen and UVA (PUVA) plus retinoids, PUVA plus interferon, methotrexate, extracorporeal photopheresis, bexarotene, histone deacetylase inhibitors (romidepsin or vorinostat), targeted immunomodulators (brentuximab, mogamulizumab), and total skin electron beam treatment are used.

Prognosis

Mycosis fungoides is usually slowly progressive (over decades). Prognosis is better with patch or plaque stage disease and worse with erythroderma, tumors, and lymphadenopathy. Survival is not reduced in patients with limited patch disease. Overly aggressive treatment may lead to complications and premature demise.

CUTANEOUS INFECTIONS, INFESTATIONS, & BITES

FUNGAL INFECTIONS

The diagnosis of fungal infections of the skin is based on the location and characteristics of the lesions and on the following laboratory examinations: (1) Direct demonstration of fungi in 10% potassium hydroxide (KOH) evaluation of suspected lesions. **"If it's scaly, scrape it" is a time-honored maxim** (Figure 6–8). (2) Cultures of

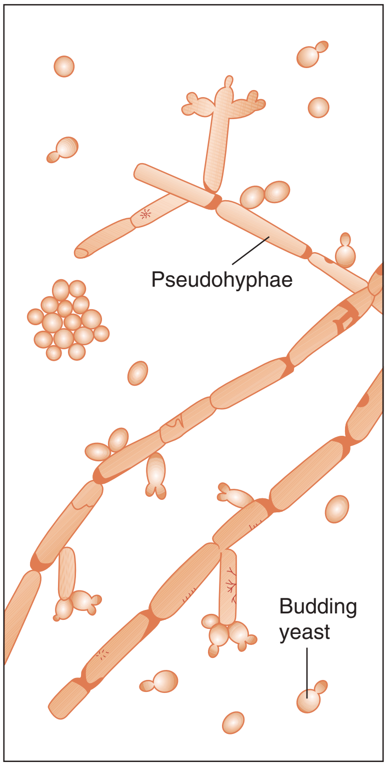

Figure 6–8. KOH preparation of fungus demonstrating pseudohyphae and budding yeast forms. (Reproduced, with permission, from Nicoll D et al. *Guide to Diagnostic Tests*, 7th ed. McGraw-Hill, 2017.)

organisms from skin scrapings. (3) Histologic sections of biopsies stained with periodic acid-Schiff technique may be diagnostic if scrapings and cultures are falsely negative.

Principles of Treatment

In general, fungal skin infections are treated topically (see Table 6–2). Oral agents (itraconazole, fluconazole, and terbinafine) may be useful for infections with extensive skin involvement or involvement of the nails or hair follicles, with special attention to their side effects and complications, including hepatic toxicity.

General Measures & Prevention

Since moist skin favors the growth of fungi, dry the skin carefully after perspiring heavily or after bathing. The use of a hair dryer on a low setting may be helpful. Antifungal or drying powders may be useful with the exception of powders containing corn starch (which may exacerbate fungal infections) and talc powder (which has been shown to be a risk factor for ovarian carcinoma in women). The use of topical corticosteroids for other diseases may be complicated by intercurrent tinea or candidal infection, and topical antifungals are often used in intertriginous areas with corticosteroids to prevent this.

TINEA CORPORIS OR TINEA CIRCINATA

ESSENTIALS OF DIAGNOSIS

- Ring-shaped lesions with an advancing scaly border and central clearing, or scaly patches with a distinct border.
- Microscopic examination of scrapings or culture confirms the diagnosis.

General Considerations

The lesions are often on exposed areas of the body such as the face and arms. A history of exposure to an infected pet (who may have scaly rash or patches of alopecia) may occasionally be obtained, usually indicating *Microsporum* infection. *Trichophyton rubrum* is the most common pathogen, usually representing extension onto the trunk or extremities of tinea cruris, pedis, or manuum.

Clinical Findings

A. Symptoms and Signs

Itching may be present. In classic lesions, rings of erythema have an advancing scaly border and central clearing.

B. Laboratory Findings

The diagnosis should be confirmed by KOH preparation or culture.

Differential Diagnosis

Positive fungal studies distinguish tinea corporis from other skin lesions with annular configuration, such as annular lesions of psoriasis, lupus erythematosus, syphilis, granuloma annulare, or pityriasis rosea. Psoriasis typically involves the elbows, knees, scalp, and nails. Secondary syphilis is often manifested by characteristic palmar, plantar, and mucous membrane lesions. Tinea corporis rarely has the large number of symmetric lesions seen in pityriasis rosea. Granuloma annulare lacks scale.

Complications

Complications include extension of the disease down the hair follicles (which presents as papules and pustules and requires systemic antifungals to cure) and pyoderma.

Prevention

Treat infected household pets (*Microsporum* infections). To prevent recurrences, the use of foot powder and keeping feet dry by wearing sandals or changing socks can be useful.

Treatment

A. Local Measures

Tinea corporis responds to most topical antifungals, including terbinafine, butenafine, econazole, miconazole, ciclopirox, and clotrimazole, many of which are available over the counter in the United States (see Table 6–2). Terbinafine and butenafine require shorter courses and lead to the most rapid response. **Treatment should be continued for 1–2 weeks after clinical clearing**. Betamethasone dipropionate with clotrimazole (Lotrisone) is not recommended. Long-term improper use may result in side effects from the high-potency corticosteroid component, especially in body folds.

B. Systemic Measures

Itraconazole as a single weeklong pulse of 200 mg orally daily is effective in tinea corporis. Terbinafine, 250 mg orally daily for 1 month, is an alternative.

Prognosis

Tinea corporis usually responds promptly to topical therapy or to an oral agent within 4 weeks, although a variant of *Trichophyton indotineae,* which has been increasingly reported in travelers to southeast Asia, is often resistant to standard therapy.

Chanyachailert P et al. Cutaneous fungal infections caused by dermatophytes and non-dermatophytes: an updated comprehensive review of epidemiology, clinical presentations, and diagnostic testing. J Fungi (Basel). 2023;9:669. [PMID: 37367605]

Khurana A et al. Therapeutic updates on the management of tinea corporis or cruris in the era of *Trichophyton indotineae*: separating evidence from hype—a narrative review. Indian J Dermatol. 2023;68:525. [PMID: 38099117]

Saed GM. Is there a link between talcum powder, oxidative stress, and ovarian cancer risk? Expert Rev Anticancer Ther. 2024;24:485. [PMID: 38712572]

TINEA CRURIS (Jock Itch)

ESSENTIALS OF DIAGNOSIS

- Marked itching in intertriginous areas, usually sparing the scrotum.
- Peripherally spreading, sharply demarcated, centrally clearing erythematous lesions.
- May have associated tinea infection of feet or toenails.
- Laboratory examination with microscope or culture confirms diagnosis.

General Considerations

Tinea cruris lesions are confined to the groin and gluteal cleft. Intractable pruritus ani may occasionally be caused by a tinea infection.

Clinical Findings

A. Symptoms and Signs

Itching may be severe, or the rash may be asymptomatic. The lesions have sharp margins, cleared centers, and active, spreading scaly peripheries. Follicular pustules are sometimes encountered. The area may be hyperpigmented on resolution.

B. Laboratory Findings

Hyphae can be demonstrated microscopically in KOH preparations or skin biopsy. The organism may be cultured.

Differential Diagnosis

Tinea cruris must be distinguished from other lesions involving the intertriginous areas, such as candidiasis, seborrheic dermatitis, intertrigo, psoriasis of body folds (“inverse psoriasis”), and erythrasma (corynebacterial infection of intertriginous areas). Candidiasis is generally bright red and marked by satellite papules and pustules outside of the main border of the lesion. *Candida* typically involves the scrotum. Seborrheic dermatitis also often involves the face, sternum, axillae, and genitalia (but not the crural folds). Intertrigo tends to be less red, less scaly, and present in individuals with obesity in moist body folds with less extension onto the thigh. “Inverse psoriasis” is characterized by distinct plaques. Other areas of typical psoriatic involvement should be checked, and the KOH examination will be negative. Erythrasma is best diagnosed with Wood (UV) light—a brilliant coral-red fluorescence is seen.

Treatment

A. General Measures

Drying powder (eg, miconazole nitrate [Zeasorb-AF]) can be dusted into the involved area in patients with excessive perspiration or occlusion of skin due to obesity as a preventive measure but is less helpful for treatment.

B. Local Measures

Any of the topical antifungal preparations listed in Table 6–2 may be used. Terbinafine cream is curative in over 80% of cases after once-daily use for 7 days.

C. Systemic Measures

One week of either itraconazole, 200 mg orally daily, or terbinafine, 250 mg orally daily, can be effective.

Prognosis

Tinea cruris usually responds promptly to topical or systemic treatment but often recurs.

Lal N et al. Efficacy and safety of 250 mg versus 500 mg oral terbinafine in the treatment of tinea corporis and cruris: a randomized, assessor-blinded comparative study. Indian J Dermatol Venereol Leprol. 2023;89:665. [PMID: 36688883]

TINEA MANUUM & TINEA PEDIS (Tinea of Palms & Soles)

ESSENTIALS OF DIAGNOSIS

- Most often presents with asymptomatic scaling.
- May progress to fissuring or maceration in toe web spaces.
- May be a portal of entry for bacteria causing lower extremity cellulitis.
- Itching, burning, and stinging of interdigital web; scaling palms and soles; vesicles on soles in inflammatory cases.
- KOH preparation or fungal culture of skin scapings is usually positive.

General Considerations

Tinea of the hands and feet (athlete’s foot) is a common acute or chronic dermatosis. Most infections are caused by *Trichophyton* species.

Clinical Findings

A. Symptoms and Signs

The presenting symptom may be itching, burning, or stinging. Pain may indicate secondary infection with complicating cellulitis. Interdigital tinea pedis is the most common predisposing cause of lower extremity cellulitis in healthy individuals. Regular examination of the feet of patients with diabetes for evidence of scaling and fissuring and treatment of any identified tinea pedis may prevent complications. Tinea pedis has several presentations that vary with the location. On the sole and heel, tinea may appear as chronic noninflammatory scaling, occasionally with

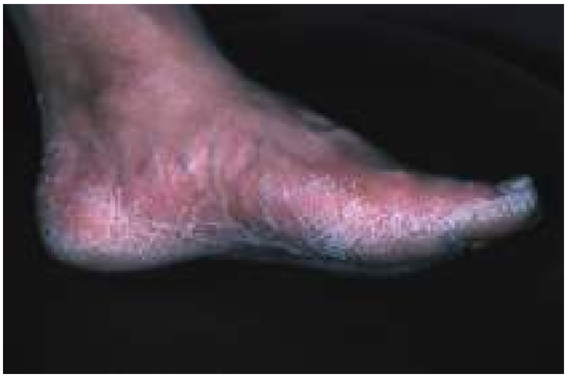

Figure 6–9. Tinea pedis in the moccasin distribution. (Reproduced, with permission, from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine*, 2nd ed. McGraw-Hill, 2013.)

thickening and fissuring. This may extend over the sides of the feet in a "moccasin" distribution (Figure 6–9). The KOH preparation is usually positive. Tinea pedis often appears as a scaling or fissuring of the toe webs, often with maceration (Figure 6–10). As the web spaces become more macerated, the KOH preparation and fungal culture are less often positive because bacterial species begin to dominate. Finally, there may also be vesicles, bullae, or generalized exfoliation of the skin of the soles, or nail involvement in the form of discoloration, friability, and thickening of the nail plate.

B. Laboratory Findings

KOH and culture do not always demonstrate pathogenic fungi from macerated areas.

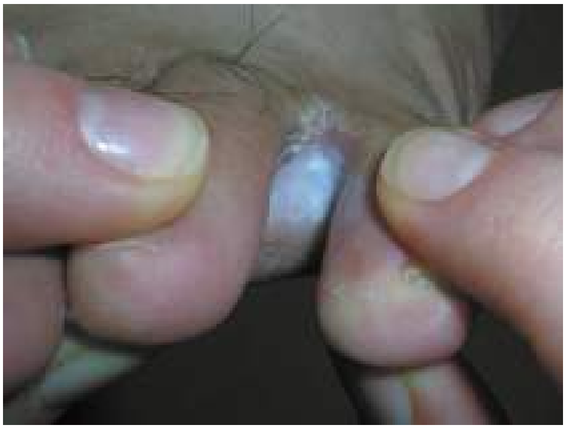

Figure 6–10. Tinea pedis in the interdigital space between fourth and fifth digits. The differential diagnosis includes a bacterial primary or secondary infection with gram-negative organisms. (Reproduced, with permission, from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley HS. *The Color Atlas and Synopsis of Family Medicine*, 3rd ed. McGraw-Hill, 2019.)

Differential Diagnosis

Other skin conditions involving the same areas are interdigital erythrasma (which will be positive with Wood light), psoriasis (which may cause scaling on the palms or soles and nail changes), and contact dermatitis (often involving the dorsal surfaces). Vesicular lesions should be differentiated from pompholyx (dyshidrosis) and scabies by proper scraping of the roofs of individual vesicles. Rarely, gram-negative organisms may cause toe web infections, manifesting as an acute erosive flare of interdigital disease. *Candida* may also cause erosive interdigital disease.

Prevention

The essential factor in prevention is personal hygiene. Wear open-toed sandals if possible. Use of sandals in community showers and bathing places is often recommended, though the effectiveness of this practice has not been studied. Careful drying between the toes after showering is essential. A hair dryer used on cooler setting may be helpful. Socks should be changed frequently, and absorbent nonsynthetic socks are preferred. Apply dusting and drying powders as necessary. The use of powders containing antifungal agents (eg, Zeasorb-AF) or long-term use of antifungal creams may prevent recurrences of tinea pedis.

Treatment

A. Local Measures

1. Macerated stage—Treat with aluminum subacetate solution soaks for 20 minutes twice daily. Broad-spectrum antifungal creams and solutions (containing imidazoles or ciclopirox) (Table 6–2) will help combat diphtheroids and other gram-positive organisms present at this stage and alone may be adequate therapy. If topical imidazoles fail, 1 week of once-daily topical allylamine treatment (terbinafine or butenafine) will often result in clearing.

2. Dry and scaly stage—Use any of the antifungal agents listed in Table 6–2. The addition of urea 10–20% lotion or cream may increase the efficacy of topical treatments in thick ("moccasin") tinea of the soles.

B. Systemic Measures

Itraconazole, 200 mg orally daily for 2 weeks or 400 mg daily for 1 week, or terbinafine, 250 mg orally daily for 2–4 weeks, may be used in refractory cases. If the infection is cleared by systemic therapy, the patient should be encouraged to begin maintenance with topical therapy, since recurrence is common.

Prognosis

For many individuals, tinea pedis is a chronic affliction, temporarily cleared by therapy only to recur. Treatment of tinea pedis or manuum without systemic treatment of affected nails may result in recurrent skin disease.

Issa NT et al. Individual article: updated review of topical pharmaceuticals and complementary and alternative medications for the treatment of onychomycosis in both general and special populations in the United States. J Drugs Dermatol. 2023;22:SF378719 [PMID: 37683068]

Leung AK et al. Tinea pedis: an updated review. Drugs Context. 2023;12:2023-5-1. [PMID: 37415917]

TINEA VERSICOLOR (Pityriasis Versicolor)

ESSENTIALS OF DIAGNOSIS

- Velvety, tan, pink, or white macules, or white macules that do not tan with sun exposure.
- Fine scales that are not visible but are seen by scraping the lesion.
- Central upper trunk the most frequent site.
- Yeast and short hyphae observed on microscopic examination of scales.

General Considerations

Tinea versicolor is a mild, superficial *Malassezia* infection of the skin (usually of the upper trunk). This yeast is a colonizer of all humans, which accounts for the high recurrence rate after treatment. The eruption is often called to patients' attention by the fact that the involved areas will not tan, and the resulting hypopigmentation may be mistaken for vitiligo. A hyperpigmented form is not uncommon.

Clinical Findings

A. Symptoms and Signs

Lesions are asymptomatic, but a few patients note itching. The lesions are velvety, tan, pink, or white macules or thin papules that vary from 4 mm to 5 mm in diameter to large confluent areas. The lesions initially do not look scaly, but scales may be readily obtained by scraping the area. Lesions may appear on the trunk, upper arms, neck, and groin.

B. Laboratory Findings

Large, blunt hyphae and thick-walled budding spores ("spaghetti and meatballs") are seen on KOH. Fungal culture is not useful.

Differential Diagnosis

Vitiligo usually presents with larger periorificial and acral lesions and is also characterized by depigmentation rather than hypopigmentation (as is seen in tinea versicolor). Vitiligo does not scale. Pink and red-brown lesions on the chest are differentiated from seborrheic dermatitis of the same areas by the KOH preparation, though seborrheic dermatitis and tinea versicolor often co-exist in the same patient.

Treatment & Prognosis

A. Initial Treatment

A regimen of two doses of oral fluconazole, 300 mg, 14 days apart, is first-line treatment; the risk of hepatitis is minimal. Additional doses may be required in severe cases or humid climates. Clinicians must stress to the patient that following treatment, the alterations in pigmentation may take months to resolve.

Topical treatments include selenium sulfide lotion, which may be applied from neck to waist daily and left on for 5–15 minutes for 7 days; this treatment is then repeated weekly for a month. Ketoconazole shampoo, 1% or 2%, lathered on the chest and back and left on for 5 minutes may also be used weekly for treatment.

B. Maintenance Therapy

Topical treatments as described above can be used for maintenance therapy. Imidazole creams, solutions, and lotions (eg, clotrimazole or miconazole) are quite effective for localized areas but are too expensive for use over large areas, such as the chest and back. Without maintenance therapy, recurrences will occur in over 80% of "cured" cases.

MUCOCUTANEOUS CANDIDIASIS

ESSENTIALS OF DIAGNOSIS

- Severe pruritus of vulva, anus, or body folds.
- Superficial denuded, beefy-red areas with or without satellite vesicopustules.
- Whitish curd-like concretions on the oral and vaginal mucous membranes.
- Yeast and pseudohyphae on microscopic examination of scales or curd.

General Considerations

Mucocutaneous candidiasis is a superficial fungal infection that may involve almost any cutaneous or mucous surface. It is most likely to occur in patients with diabetes, in persons with obesity, in the setting of immunosuppression, and during pregnancy. Systemic antibiotics, oral corticosteroids, hormone replacement therapy, and oral contraceptive agents may be contributory. Oral and interdigital candidiasis may be the first sign of HIV infection (see Chapter 36). Denture use predisposes to infection.

Clinical Findings

A. Symptoms and Signs

Itching may be intense. Burning is reported, particularly around the vulva and anus. The lesions consist of superficially denuded, beefy-red areas in the depths of the body folds, such as in the groin and the intergluteal cleft, beneath the breasts, at the angles of the mouth, in the webspaces of digits, and in the umbilicus. The peripheries of these denuded lesions are superficially undermined, and there may be satellite vesicopustules. Whitish, curd-like concretions may be present on mucosal lesions (Figure 6–11). Paronychia may occur.

B. Laboratory Findings

Clusters of budding yeast and pseudohyphae can be seen under high power (400×) when skin scales or curd-like lesions are mounted in 10% KOH. Culture can confirm the diagnosis.

Differential Diagnosis

Intertrigo, seborrheic dermatitis, tinea cruris, "inverse psoriasis," and erythrasma involving the same areas may mimic mucocutaneous candidiasis.

Complications

Systemic invasive candidiasis with candidemia may occur in patients who are immunosuppressed or receiving broad-spectrum antibiotic or intravenous hypertonic glucose solutions (eg, hyperalimentation) (Chapter 41). There may or may not be clinically evident mucocutaneous candidiasis.

Treatment

A. General Measures

Affected parts should be kept dry and exposed to air as much as possible. Water immersion should be minimized, and gloves should be worn for those with infected nails or digital skin. If possible, discontinue systemic antibiotics.

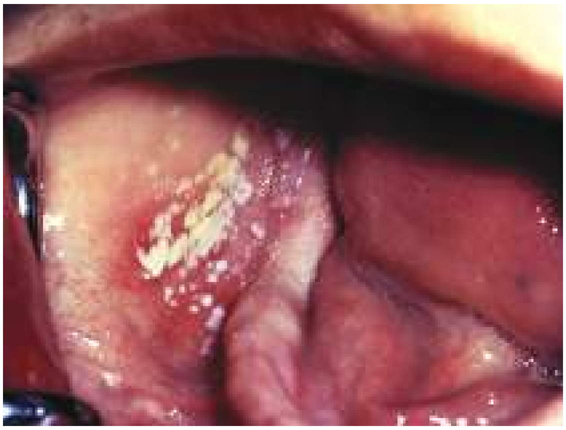

Figure 6–11. Oral mucosal candidiasis. (From Sol Silverman, Jr., DDS/Centers for Disease Control and Prevention.)

B. Local Measures

1. Nails and paronychia—Apply clotrimazole solution 1% twice daily. Thymol 4% in ethanol applied once daily is an alternative.

2. Skin—Apply nystatin ointment or clotrimazole cream 1% plus hydrocortisone cream 1–2.5%, twice daily. Gentian violet 0.5% solution is economical and highly effective in treating mucocutaneous candidiasis, but the purple discoloration may represent a cosmetic issue. Severe or widespread cutaneous disease responds to fluconazole, 100–200 mg orally daily, for 1 week.

3. Vulvar and anal mucous membranes—For vaginal candidiasis, single-dose fluconazole, 150 mg orally, is effective. Intravaginal clotrimazole, miconazole, terconazole, or nystatin may also be used. Long-term suppressive therapy may be required for recurrent or "intractable" cases. Non-albicans candidal species may be identified by culture in some refractory cases and may respond to oral itraconazole, 200 mg twice daily for 2–4 weeks.

4. Balanitis—This is most frequent in uncircumcised men and is usually caused by *Candida*. Topical nystatin ointment is the initial treatment if the lesions are mildly erythematous or superficially erosive. Soaking with dilute 5% aluminum acetate for 15 minutes twice daily may quickly relieve burning or itching. Chronicity and relapses, especially after sexual contact, suggest reinfection from a sexual partner who should be treated. Severe purulent balanitis is usually due to bacteria. If it is so severe that phimosis occurs, oral antibiotics—some with activity against anaerobes—are required; if rapid improvement does not occur, urologic consultation is indicated.

5. Mastitis—Lancinating breast pain and nipple dermatitis in breast-feeding women may be a manifestation of *Candida* colonization/infection of the breast ducts. Topical nystatin cream and clotrimazole 0.1% cream are safe during lactation. Topical gentian violet 0.5% daily for 7 days is also useful. Oral fluconazole, 200 mg daily for 2 weeks, is effective and safe during lactation.

Prognosis

Cases of cutaneous candidiasis range from the easily cured to the intractable and prolonged.

Hellier SD et al. Beyond fluconazole: a review of vulvovaginal candidiasis diagnosis and treatment. Nurse Pract. 2023;48:33. [PMID: 37643144]

Lu H et al. Candidiasis: from cutaneous to systemic, new perspectives of potential targets and therapeutic strategies. Adv Drug Deliv Rev. 2023;199:114960. [PMID: 37307922]

Shahabudin S et al. Candida albicans skin infection in diabetic patients: an updated review of pathogenesis and management. 2024;67:e13753. [PMID: 38877612]

INTERTRIGO

Intertrigo is caused by the macerating effect of heat, moisture, and friction. It is especially likely to occur in persons with obesity and in humid climates. The symptoms are itching, stinging, and burning. The body folds develop fissures, erythema, maceration, and superficial denudation. Candidiasis may complicate intertrigo, as can bacterial infections. "Inverse psoriasis," seborrheic dermatitis, tinea cruris, and erythrasma must be ruled out.

Maintaining hygiene and keeping the area dry are helpful. Compresses may be useful acutely. Hydrocortisone 1% cream plus an imidazole or clotrimazole 1% cream is effective. Recurrences are common.

Romanelli M et al. The diagnosis, management and prevention of intertrigo in adults: a review. J Wound Care. 2023;32:411. [PMID: 37405940]

VIRAL INFECTIONS

HERPES SIMPLEX (Cold or Fever Sore; Genital Herpes)

ESSENTIALS OF DIAGNOSIS

- Recurrent small, grouped vesicles (especially orolabial and genital) on an erythematous base.
- May follow minor infections, trauma, stress, or sun exposure.
- Regional tender lymphadenopathy may occur.
- Direct fluorescent antibody or PCR tests are positive.

General Considerations

Over 85% of adults have serologic evidence of herpes simplex type 1 (HSV-1) infections, most often acquired asymptomatically in childhood. Occasionally, primary infections may be manifested as severe gingivostomatitis. Thereafter, the patient may have recurrent self-limited attacks, provoked by sun exposure, orofacial surgery, fever, viral infection, or immunosuppression.

About 25% of the US population has serologic evidence of infection with herpes simplex type 2 (HSV-2). HSV-2 causes lesions whose morphology and natural history are similar to those caused by HSV-1 but are typically located on the genitalia or buttocks. The infection is often acquired by sexual contact. In monogamous heterosexual couples where one partner has HSV-2 infection, seroconversion of the noninfected partner occurs in 10% over a 1-year period. Up to 70% of such infections appeared to be transmitted during periods of asymptomatic shedding. Genital herpes may also be due to HSV-1.

Clinical Findings

A. Symptoms and Signs

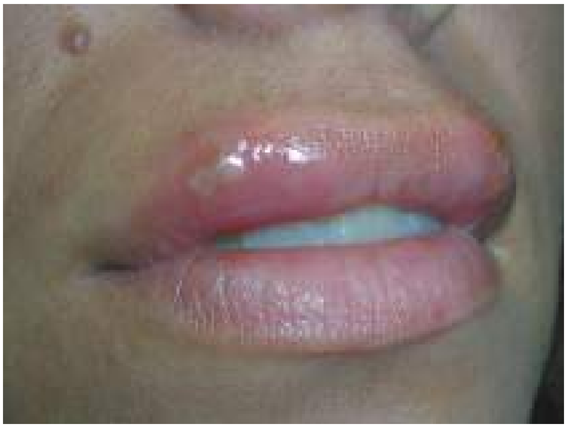

Figure 6–12. Orolabial herpes simplex showing deroofed blisters (ulcer). (Reproduced, with permission, from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine*, 2nd ed. McGraw-Hill, 2013.)

The principal symptoms are burning and stinging. Neuralgia may precede or accompany attacks. The lesions consist of small, grouped vesicles on an erythematous base that can occur anywhere but that most often occur on the vermilion border of the lips (Figure 6–12), the oral cavity, penile shaft, the labia, the perianal skin, and the buttocks. Any erosion or fissure in the anogenital region can be due to herpes simplex. Regional lymph nodes may be swollen and tender. The lesions usually crust and heal in 1 week. Immunosuppressed patients may have unusual variants, including verrucous or nodular herpes lesions at typical sites of involvement. Lesions of herpes simplex must be distinguished from chancroid, syphilis, lymphogranuloma venereum, pyoderma gangrenosum, Behcet syndrome, or trauma.

B. Laboratory Findings

Direct fluorescent antibody slide tests offer rapid, sensitive diagnosis. Viral culture or PCR may also be helpful. Herpes serology is not used in the diagnosis of an acute genital ulcer. Specific HSV-2 serology can determine who is HSV-infected and potentially infectious, but routine HSV-2 screening is not recommended by the USPSTF.

Complications

Complications include pyoderma, eczema herpeticum, herpetic whitlow, herpes gladiatorum (epidemic herpes transmitted by contact), proctitis, esophagitis, neonatal infection, keratitis, and encephalitis.

Treatment

A. Systemic Therapy

Three commonly used systemic agents are available for the treatment of acute herpes infections: acyclovir, valacyclovir, and famciclovir. All three agents are very effective, and when used properly, virtually nontoxic. Only acyclovir is available for intravenous administration.

1. For first clinical episode—Recommended treatment for the first clinical episodes of herpes simplex includes acyclovir, 400 mg orally five times daily (or 800 mg three times daily); valacyclovir, 1000 mg orally twice daily; or famciclovir, 250 mg orally three times daily; treatment is for 7–10 days, depending on the severity of the outbreak.

2. For mild recurrences—Most cases do not require therapy. Pharmacotherapy of recurrent HSV is of limited benefit, reducing the average outbreak by only 12–24 hours. **To be effective, the treatment must be initiated by the patient at the first sign of recurrence**. If treatment is desired, recurrent genital herpes outbreaks may be treated with 3 days of valacyclovir, 500 mg orally twice daily, 5 days of acyclovir, 200 mg orally five times a day, or 5 days of famciclovir, 125 mg orally twice daily. Valacyclovir, 2 g twice daily for 1 day, and famciclovir, 1 g once or twice in 1 day, are equally effective short-course alternatives and can abort impending recurrences of both orolabial and genital herpes. The addition of a potent topical corticosteroid three times daily reduces the duration, size, and pain of orolabial herpes treated with an oral antiviral agent.

3. For frequent or severe recurrences—Suppressive treatment reduces recurrences by 85%, viral shedding by > 90%, and the risk of transmission by 50%. The recommended suppressive doses, taken continuously, are acyclovir, 400 mg orally twice daily; valacyclovir, 500 mg orally once daily; or famciclovir, 125–250 mg orally twice daily. Pritelivir, 100 mg orally once daily, may have superior reduction of viral shedding in HSV-2 compared to valacyclovir, 500 mg orally once daily. Long-term suppression appears safe, and after 5–7 years a substantial proportion of patients can discontinue treatment.

Sunscreens are useful adjuncts in preventing sun-induced orolabial recurrences. A preventive antiviral medication should be started beginning 24 hours prior to UV light exposure, dental surgery, or orolabial cosmetic surgery. The use of latex condoms and patient education have proved effective in reducing genital herpes transmission in some but not all studies. No single or combination intervention absolutely prevents transmission.

B. Local Measures

Topical therapy has limited efficacy and is generally not recommended because evidence shows that it minimally reduces skin healing time.

▶ Prognosis

Aside from the complications described above, recurrent attacks last several days, and patients recover without sequelae.

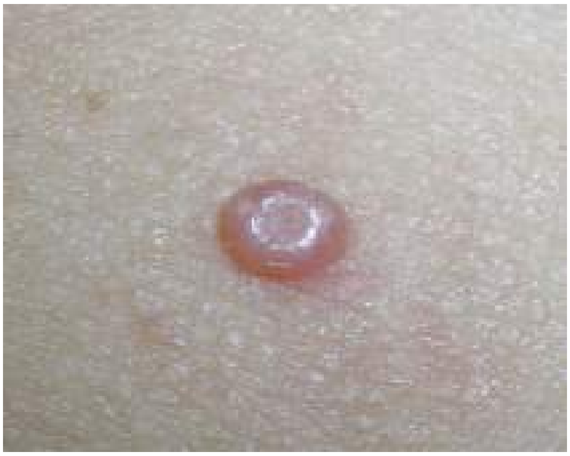
HERPES ZOSTER (SHINGLES)

See Chapter 37.

MOLLUSCUM CONTAGIOSUM



▲ **Figure 6–13.** Umbilicated—molluscum. (Reproduced, with permission, from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine*, 3rd ed. McGraw-Hill, 2019.)

Molluscum contagiosum, caused by a poxvirus, presents as single or multiple dome-shaped, waxy papules 2–5 mm in diameter that are umbilicated (Figure 6–13). Lesions at first are firm, solid, and flesh-colored but upon reaching maturity become soft, whitish, or pearly gray and may suppurate. The principal sites of involvement are the face, lower abdomen, and genitals.

The lesions are autoinoculable and spread by wet skin-to-skin contact. In sexually active individuals, they may be confined to the penis, pubis, perianal area, and inner thighs and are considered an STI.

Molluscum contagiosum is common in patients with AIDS, usually with a helper T-cell count < 100/mcL (0.1×10^9/L). Extensive lesions tend to develop over the face and neck as well as in the genital area.

The diagnosis is easily established in most instances because of the distinctive central umbilication of the dome-shaped lesion. Estimated time to remission is 13 months. The best treatment is by curettage or applications of liquid nitrogen as for warts—but more briefly. When lesions are frozen, the central umbilication often becomes more apparent. Light electrosurgery with a fine needle is also effective. Cantharidin (applied in the office and then washed off by the patient 4 hours later) is a safe and effective option. Another treatment option is 10% or 15% potassium hydroxide solution applied twice daily until lesions clear. Salicylic acid, podophyllotoxin, tretinoin, imiquimod, berdazimer 10.3% gel, and intralesional immunotherapy are additional treatment options. Physical destruction with pulsed dye laser or via extraction of molluscum bodies with a comedone extractor or curette is also effective. Lesions are difficult to eradicate in patients with AIDS unless immunity improves; however, with antiretroviral treatment, molluscum usually spontaneously clears.

WARTS

ESSENTIALS OF DIAGNOSIS

- Verrucous papules anywhere on the skin or mucous membranes, usually not > 1 cm in diameter.
- Prolonged incubation period (average 2–18 months).
- Spontaneous "cures" of common warts in 50% at 2 years.
- "Recurrences" (new lesions) are frequent.

General Considerations

Warts (common, plantar, and genital [condylomata acuminata]) are caused by HPV. Typing of HPV lesions is not a part of standard medical evaluation except in the case of anogenital dysplasia.

Clinical Findings

There are usually no symptoms. Tenderness on pressure occurs with plantar warts; itching occurs with anogenital warts (Figure 6–14). Flat warts are most evident under oblique illumination. Periungual warts may be dry, fissured, and hyperkeratotic and may resemble hangnails. Plantar warts resemble plantar corns or calluses.

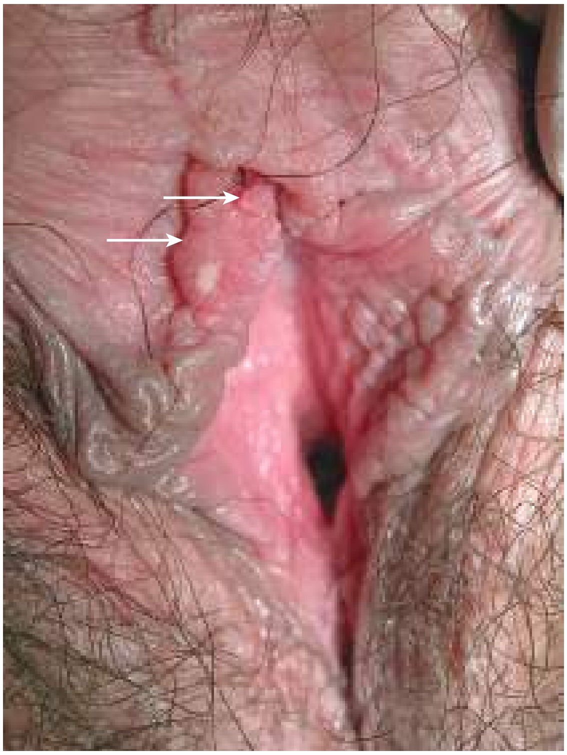

Figure 6–14. Condylomata acuminata around the clitoris, labia minor, and opening of the vagina. (Reproduced, with permission, from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine*, 2nd ed. McGraw-Hill, 2013.)

Differential Diagnosis

Some warty-looking lesions are actually seborrheic keratosis, hypertrophic actinic keratoses or squamous cell carcinomas. Condylomata lata of secondary syphilis can resemble large warts. Molluscum contagiosum lesions are pearly with a central dell. In AIDS, wart-like lesions may be caused by herpes or varicella zoster virus.

Prevention

Administration of a vaccine against certain anogenital HPV types (including 6, 11, 16, 18, 31, 33, 45, 52, and 58) can prevent infection with these wart types and reduce anogenital, oropharyngeal, and cervical cancer. It is recommended for teenagers and young adults, men who have sex with men, and immunocompromised patients (see Chapters 1 and 21). There may be a role for adjuvant vaccination in HPV-infected patients.

Treatment

Treatment is aimed at inducing "wart-free" intervals for as long as possible without scarring since no treatment can guarantee a remission or prevent recurrences. In immunocompromised patients, the goal is to control the size and number of lesions present. Certain types (HPV 1) are more responsive to treatment than others (eg, HPV 2, HPV 27).

A. Treatment of Nongenital Warts

For common warts of the hands, patients are usually offered liquid nitrogen or keratolytic agents. The former may work in fewer treatments but requires office visits and is painful.

1. Liquid nitrogen—Liquid nitrogen cryotherapy is applied to achieve a thaw time of 30–45 seconds. Two freeze-thaw cycles are given every 2–4 weeks for several visits. Scarring will occur if it is used incorrectly. Liquid nitrogen may cause permanent depigmentation, especially in more darkly pigmented individuals.

2. Keratolytic agents and occlusion—Salicylic acid products may be used against common warts or plantar warts. They are applied, then occluded. Plantar warts may be treated by applying a 40% salicylic acid plaster after paring. The plaster may be left on for 5–6 days, then removed, the lesion pared down, and another plaster applied. Although it may take weeks or months to eradicate the wart, the method is safe and effective with almost no side effects. Chronic occlusion alone with water-impermeable tape (duct tape, adhesive tape) can work as well as cryotherapy.

3. Operative removal—Plantar warts may be removed by blunt dissection.

4. Laser therapy—The CO_2 laser can be effective for treating recurrent warts, periungual warts, plantar warts, and genital warts. It leaves open wounds that must fill in with granulation tissue over 4–6 weeks and is best reserved for warts resistant to all other modalities. Lasers with emissions of 585, 595, or 532 nm may also be used every 3–4 weeks to ablate common, plantar, facial, and anogenital warts.

5. Immunotherapy—Squaric acid dibutyl ester may be applied 1–5 times weekly in a concentration of 0.2–2% directly to the warts to induce a mild contact dermatitis. Between 60% and 80% of warts clear over 10–20 weeks. Injection of *Candida* antigen starting at 1:50 dilution and repeated every 3–4 weeks may be similarly effective in stimulating immunologic regression of common and plantar warts.

6. Other agents—Bleomycin (1 unit/mL), injected into common and plantar warts, has been shown to have a high cure rate. It should be used with caution on digital warts because of the potential complications of Raynaud phenomenon, nail loss, and terminal digital necrosis. 5-Fluorouracil 5% cream applied once or twice daily, usually with occlusion, has similar efficacy to other treatment methods. Topical or intralesional cidofovir may be effective in treating recalcitrant lesions, especially in immunocompromised patients.

7. Physical modalities—Soaking warts in hot (42.2°C) water for 10–30 minutes daily for 6 weeks or application of heating pads for a few minutes each day may result in involution in some cases.

B. Treatment of Genital Warts

1. Liquid nitrogen—Cryotherapy is the first-line surgical treatment for genital warts. Liquid nitrogen cryotherapy is applied to achieve a thaw time of 30–45 seconds. Two freeze-thaw cycles are given every 2–4 weeks for several visits. Scarring will occur if it is used incorrectly.

2. Podophyllum resin—For genital warts, the purified active component of the podophyllum resin, podofilox, is applied by the patient twice daily 3 consecutive days a week for cycles of 4–6 weeks. It is less irritating and more effective than “clinician-applied” podophyllum resin. After a single 4-week cycle, 45% of patients are wart-free but 60% relapse at 6 weeks. Thus, multiple cycles of treatment are often necessary. Patients unable to obtain the take-home podofilox may be treated in the clinician’s office by painting each wart carefully (protecting normal skin) every 2–3 weeks with 25% podophyllum resin (podophyllin) in compound tincture of benzoin.

3. Imiquimod—A 5% cream of this local interferon inducer has moderate activity in clearing external genital warts. Treatment is once daily on 3 alternate days per week. Response may be slow.

4. Sinecatechins—Derived from green tea extract, sinecatechins (10% or 15%) is FDA-approved for the treatment of anogenital warts. Application three times daily for 16 weeks achieves clearance rates from 40% to 81%, with the 15% formulation resulting in higher efficacy.

5. Operative removal—For pedunculated or large genital warts, snip biopsy (scissors) removal is more effective than cryotherapy.

6. Laser therapy—See Treatment of Nongenital Warts, above. For genital warts, it has not been shown that laser therapy is more effective than electrosurgical removal. Both carry some risk of aerosolization of HPV with inoculation into the airway of the patient or provider. Photodynamic therapy can be considered in refractory genital warts.

Prognosis

There is a striking tendency to develop new lesions. Warts may disappear spontaneously or may be unresponsive to treatment. Combining therapies (eg, liquid nitrogen plus immunotherapy) may improve therapeutic response.

BACTERIAL INFECTIONS

IMPETIGO

ESSENTIALS OF DIAGNOSIS

- Superficial blisters filled with purulent material that rupture easily.
- Crusted superficial erosions.
- Positive Gram stain and bacterial culture.

General Considerations

Impetigo is a contagious and autoinoculable infection of the skin (epidermis) caused by staphylococci or streptococci.

Clinical Findings

A. Symptoms and Signs

The lesions consist of macules, vesicles, bullae, pustules, and honey-colored crusts that when removed leave denuded red areas (Figure 6–15). The face and other exposed parts are most often involved. Ecthyma is a deeper form of impetigo caused by staphylococci or streptococci, with ulceration and scarring that occurs frequently on the extremities.

B. Laboratory Findings

Gram stain and culture confirm the diagnosis. In temperate climates, most cases are associated with *S aureus* infection. *Streptococcus* species are more common in tropical infections.

Differential Diagnosis

The main differential diagnoses of honey-colored crusting are acute allergic contact dermatitis and herpes simplex. Contact dermatitis may be suggested by the history or by

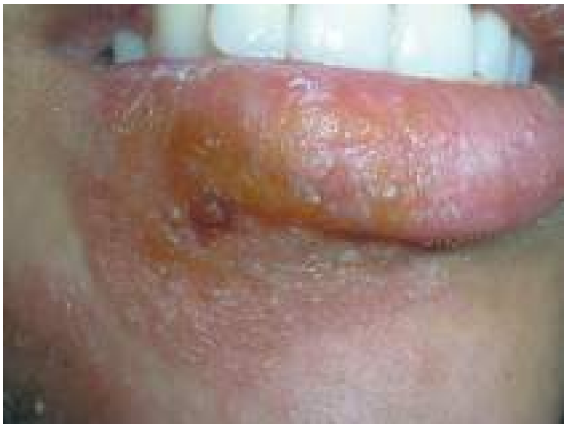

Figure 6–15. Typical honey-crusted plaque on the lip of an adult with impetigo. (Reproduced, with permission, from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley HS. *The Color Atlas and Synopsis of Family Medicine*, 3rd ed. McGraw-Hill, 2019.)

linear distribution of the lesions, and culture should be negative for staphylococci and streptococci. Herpes simplex infection usually presents with grouped vesicles or discrete erosions and may be associated with a history of recurrences. Viral cultures are positive.

Treatment

Soaks and scrubbing can be beneficial, especially in unroofing lakes of pus under thick crusts. Topical agents, such as mupirocin, ozenoxacin, and retapamulin, are first-line treatment options for infections limited to small areas. In widespread cases, or in immunosuppressed individuals, systemic antibiotics are indicated. Cephalexin, 250 mg orally four times daily, is usually effective. Community-associated methicillin-resistant *S aureus* (CA-MRSA) may cause impetigo, for which initial treatment may include doxycycline (100 mg orally twice daily) or trimethoprim-sulfamethoxazole (TMP-SMZ, double-strength tablet orally twice daily). Recurrent impetigo is associated with nasal carriage of *S aureus* and can be treated with rifampin, 300 mg orally twice daily for 5 days, or with intranasal mupirocin ointment twice daily for 14 days.

Zha M et al. Common skin conditions in children and adolescents: bacterial infections. FP Essent. 2024;541:14. [PMID: 38896828]

FOLLICULITIS (Including Sycosis)

ESSENTIALS OF DIAGNOSIS

- Itching and burning in hairy areas.
- Pustule surrounding and including the hair follicle.

General Considerations

Folliculitis has multiple causes. It is frequently caused by staphylococcal infection and less commonly by streptococcal or candida infections. When the lesion is deep-seated, chronic, and recalcitrant on the head and neck, it is called **sycosis.**

During antibiotic treatment of acne, gram-negative folliculitis may present as a flare of acne pustules or nodules. *Klebsiella, Enterobacter, Escherichia coli*, and *Proteus* have been isolated from these lesions.

Hot tub folliculitis (*Pseudomonas* folliculitis), caused by *Pseudomonas aeruginosa*, is characterized by pruritic or tender follicular, pustular lesions occurring within 1–4 days after bathing in a contaminated hot tub, whirlpool, or swimming pool. Flu-like symptoms may be present. Rarely, systemic infections may result.

Nonbacterial folliculitis may also be caused by friction and oils. Occlusion, perspiration, and chronic rubbing (eg, from tight-fitting clothing or heavy fabrics on the buttocks and thighs) can worsen this type of folliculitis.

Steroid acne may be seen during topical or systemic corticosteroid therapy and presents as eruptive monomorphous papules and papulopustules on the face and trunk. It responds to topical benzoyl peroxide.

Eosinophilic folliculitis is a sterile folliculitis that presents with urticarial papules with prominent eosinophilic infiltration. It is most common in immunosuppressed patients, especially those with AIDS. It may appear first with institution of antiretroviral therapy (ART) and be mistaken for a drug eruption.

Pseudofolliculitis is caused by ingrowing of tightly curled hairs in the beard area. In this entity, the papules and pustules are located at the side of and not in follicles. It may be treated by growing a beard, by using chemical depilatories, or by shaving with a foil-guard razor. Laser hair removal is dramatically beneficial in patients with pseudofolliculitis.

Pityrosporum folliculitis (caused by *Malassezia*) presents as 1- to 2-mm pruritic pink papulopustules on the upper trunk, hairline, and arms. It is often pruritic and tends to develop during periods of excessive sweating. It can also occur in immunosuppressed patients.

Demodex folliculitis is caused by the mite *Demodex folliculorum*. It presents as 1–2 mm papules and pustules on an erythematous base, often on the background of rosacea-like changes, in patients who have not responded to conventional treatment for rosacea. It is more common in immunosuppressed patients. KOH from the pustules will demonstrate *Demodex folliculorum* mites.

Clinical Findings

The symptoms range from slight burning and tenderness to intense itching. The lesions consist of papules or pustules centered around hair follicles (Figure 6–16).

Differential Diagnosis

It is important to differentiate bacterial from nonbacterial folliculitis. The history is important for pinpointing the causes of nonbacterial folliculitis, and a Gram stain and

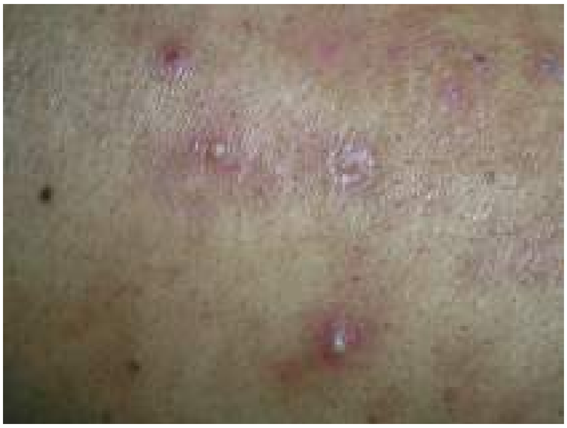

Figure 6–16. **Bacterial folliculitis. Hair emanating from the center of the pustule is the clinical hallmark of folliculitis.** (Reproduced, with permission, from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine*, 2nd ed. McGraw-Hill, 2013.)

culture are indispensable. One must differentiate bacterial folliculitis from acne vulgaris, pustular miliaria (heat rash), and other infections of the skin, such as impetigo or *Pityrosporum* folliculitis. Eosinophilic folliculitis in AIDS often requires biopsy for diagnosis.

Complications

Abscess formation is the major complication of bacterial folliculitis.

Prevention

Correct any predisposing local causes, such as oils or friction. Be sure that the water in hot tubs and spas is treated properly. If staphylococcal folliculitis is persistent, treatment of nasal or perineal carriage with rifampin, 600 mg daily for 5 days, or with topical mupirocin ointment 2% twice daily for 5 days, may help. Prolonged oral clindamycin, 150–300 mg/day for 4–6 weeks, or oral TMP-SMZ given 1 week per month for 6 months can be effective in preventing recurrent staphylococcal folliculitis and furunculosis. Bleach baths (¼–½ cup per 20 liters of bathwater for 15 minutes three to five times weekly) may reduce cutaneous staphylococcal carriage and not contribute to antibiotic resistance. Control of blood glucose in diabetes may reduce infections.

Treatment

A. Local Measures

Anhydrous ethyl alcohol containing 6.25% aluminum chloride, applied three to seven times weekly to lesions, may be helpful, especially for chronic frictional folliculitis of the buttocks. Topical antibiotics are generally ineffective if bacteria have invaded the hair follicle but may be prophylactic if used as an aftershave in patients with recurrent folliculitis after shaving.

B. Specific Measures

Pseudomonas folliculitis clears spontaneously in non-neutropenic patients if the lesions are superficial. It may be treated with ciprofloxacin, 500 mg orally twice daily for 5 days.

Systemic antibiotics are recommended for bacterial folliculitis due to other organisms. Extended periods of treatment (4–8 weeks or more) with antistaphylococcal antibiotics are required if infection involves the scalp or densely hairy areas, such as the axilla, beard, or groin (see Table 35–5).

Gram-negative folliculitis in acne patients may be treated with isotretinoin in compliance with all precautions discussed above.

Eosinophilic folliculitis may be treated initially by the combination of potent topical corticosteroids and oral antihistamines. In more severe cases, treatment is with one of the following: topical permethrin (application for 12 hours every other night for 6 weeks); itraconazole, 200–400 mg orally daily; indomethacin, 50–75 mg orally daily; cetirizine, 20–40 mg orally daily; UVB or PUVA phototherapy; or isotretinoin, 0.5 mg/kg/day orally for up to 5 months. A remission may be induced by some of these therapies, but long-term treatment may be required. In patients with HIV, initiation of ART can also help.

Pityrosporum folliculitis is treated with topical sulfacetamide lotion twice a day, alone or in combination with oral itraconazole or fluconazole.

Demodex folliculitis can be treated until cleared with topical 5% permethrin applied every other night; oral ivermectin, 200 mcg/kg once weekly; oral metronidazole, 500 mg once daily or 250 mg three times daily; or topical ivermectin or metronidazole.

Prognosis

Bacterial folliculitis usually resolves with appropriate treatment, but can be stubborn and persistent, requiring prolonged or intermittent courses of antibiotics.

Green M et al. Clinical characteristics and treatment outcomes of Pityrosporum folliculitis in immunocompetent patients. Arch Dermatol Res. 2023;315:1497. [PMID: 36517586]

FURUNCULOSIS (Boils) & CARBUNCLES

ESSENTIALS OF DIAGNOSIS

- Extremely painful inflammatory abscess centered on a hair follicle.
- Coagulase-positive *S aureus* is the usual causative organism.
- Predisposing condition (diabetes mellitus, HIV disease, injection drug use) sometimes present.

General Considerations

A **furuncle (boil)** is a deep-seated infection (abscess), usually caused by *S aureus*, that involves the hair follicle and adjacent subcutaneous tissue. The most common sites of occurrence are the hairy parts exposed to irritation and friction, pressure, or moisture. Because the lesions are autoinoculable, they are often multiple. Diabetes mellitus (especially if using insulin injections), injection drug use, allergy injections, and HIV disease all increase the risk of staphylococcal infections by increasing the rate of carriage. Certain other exposures including hospitalization, athletic teams, prisons, military service, and lack of housing may also increase the risk of infection.

A **carbuncle** consists of several furuncles developing in adjoining hair follicles and coalescing to form a conglomerate, deeply situated mass with multiple drainage points.

Recurrent furunculosis (three or more episodes in 12 months) tends to occur in those with direct contact with other infected individuals, especially family members.

Clinical Findings

A. Symptoms and Signs

Pain and tenderness may be prominent. The abscess is either rounded or conical. It gradually enlarges, becomes fluctuant, and then softens and opens spontaneously after a few days to 1–2 weeks to discharge a core of necrotic tissue and pus. The inflammation occasionally subsides before necrosis occurs.

B. Laboratory Findings

There may be slight leukocytosis. Pus can be cultured to rule out MRSA or other bacteria. Culture of the anterior nares and anogenital area (including the rectum to test for GI carriage) may identify chronic staphylococcal carriage in cases of recurrent cutaneous infection.

Differential Diagnosis

The most common entity in the differential is an inflamed **epidermal inclusion cyst** that suddenly becomes red, tender, and expands greatly in size over one to a few days. The history of a prior cyst in the same location, the presence of a clearly visible cyst orifice, and the extrusion of malodorous cheesy material (rather than purulent material) helps in the diagnosis. Tinea profunda (deep dermatophyte infection of the hair follicle) may simulate recurrent furunculosis. Furunculosis is also to be distinguished from deep mycotic infections, such as sporotrichosis; from other bacterial infections, such as anthrax and tularemia (rare); from atypical mycobacterial infections; and from acne cysts. Hidradenitis suppurativa (acne inversa) presents with recurrent tender, sterile abscesses in the axillae and groin, on the buttocks, or below the breasts. The presence of old scars or sinus tracts plus negative cultures suggests this diagnosis.

Complications

Serious and sometimes fatal complications of staphylococcal infection such as septicemia can occur.

Prevention

Identifying and eliminating the source of infection is critical to prevent recurrences after treatment. The source individual may have chronic dermatitis or be an asymptomatic carrier of MRSA. Nasal carriage of MRSA and the number of children in a household are risk factors for transmission between household members. Local measures, such as meticulous handwashing; no sharing of towels, clothing, and personal hygiene products; avoiding loofas or sponges in the bath or shower; changing underwear, sleepwear, towels, and washcloths daily; aggressive scrubbing of showers, bathrooms, and surfaces with bleach; bleach baths (¼–½ cup per 20 liters of bathwater for 15 minutes three to five times weekly), 4% chlorhexidine washes, and isolation of infected patients who reside in institutions to prevent spread are all effective measures.

Treatment

A. Specific Measures

Incision and drainage are recommended for all loculated suppurations and are the mainstay of therapy. Systemic antibiotics are given only if there are multiple lesions, evidence of surrounding cellulitis, or if the patient is immunosuppressed. Commonly prescribed antibiotics are TMP-SMZ (160/800 or 320/1600 mg orally twice a day for 10 days or 7 days, respectively) or clindamycin (300 mg orally three times daily for 10 days). Other oral antibiotic options include dicloxacillin or cephalexin, 1 g daily in divided doses for 10 days. For suspected MRSA, doxycycline 100 mg twice daily, TMP-SMZ double-strength one tablet twice daily, clindamycin 150–300 mg twice daily, and linezolid 400 mg twice daily for 7–10 days are effective. Recurrent furunculosis may be treated with a combination of cephalexin (250–500 mg orally four times daily) or doxycycline (100 mg orally twice daily) for 2–4 weeks plus either rifampin (300 mg orally twice daily for 5 days) or long-term clindamycin (150–300 mg orally daily for 1–2 months). Shorter courses of antibiotics (7–14 days) plus longer-term daily 4% chlorhexidine whole body washing and intranasal, axilla, and anogenital mupirocin or retapamulin may also cure recurrent furunculosis. Oral vancomycin (1 g twice daily for 5 days) can treat GI carriage of *S aureus*. Family members, pets, and intimate contacts may need evaluation for staphylococcal carrier state and perhaps concomitant treatment. Stopping any high-risk behavior, such as injection drug use, can also prevent recurrence.

B. Local Measures

Avoid over manipulation of inflamed areas. Use moist heat to promote spontaneous lesion drainage. Use surgical incision and drainage for fluctuant nondraining lesions.

Prognosis

Recurrent crops may occur for months or years.

Wong CM et al. Presentations of cutaneous disease in various skin pigmentations: cutaneous abscesses. HCA Healthc J Med. 2022;3:153. [PMID: 37424603]

CELLULITIS

ESSENTIALS OF DIAGNOSIS

- Edematous, expanding, erythematous, warm plaque with or without vesicles or bullae.
- Lower leg is frequently involved.
- Pain, chills, and fever are commonly present.
- Septicemia may develop.

General Considerations

Cellulitis, a diffuse spreading infection of the dermis and subcutaneous tissue, is usually on the lower leg (Figure 6–17) and most commonly due to gram-positive cocci, especially group A β-hemolytic streptococci and *S aureus*. Rarely, gram-negative rods or even fungi can produce a similar picture. In otherwise healthy persons, the most common portal of entry for lower leg cellulitis is interdigital tinea pedis with fissuring. Other predisposing conditions are prior episodes of cellulitis, chronic edema, venous insufficiency with secondary edema, lymphatic obstruction, saphenectomy, and other perturbations of the skin barrier. Bacterial cellulitis is almost never bilateral.

Clinical Findings

A. Symptoms and Signs

Cellulitis begins as a tender small patch. Swelling, erythema, and pain are often present. The lesion expands over hours, so that time from onset to presentation is usually 6–36 hours. As the lesion grows, the patient becomes more ill with progressive chills, fever, and malaise. Lymphangitis and lymphadenopathy are often present. If septicemia develops, hypotension may develop, followed by shock.

B. Laboratory Findings

Leukocytosis or neutrophilia may be present early in the course. Blood cultures are variably positive. If a central ulceration, pustule, or abscess is present, culture may be of value. In immunosuppressed patients, or if an unusual organism is suspected and there is no loculated site to culture, a full-thickness skin biopsy should be sent for histologic evaluation and culture (bacterial, fungal, and mycobacterial). If a primary source for the infection is identified (wound, leg ulcer, toe web intertrigo), cultures from these sites isolate the causative pathogen in half of cases and can be used to guide antibiotic therapy.

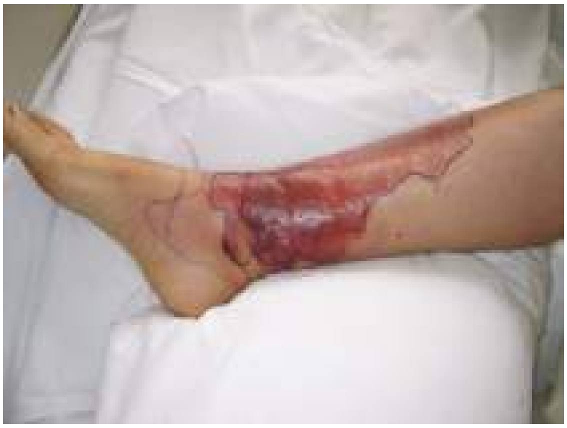

Figure 6–17. **Cellulitis.** (Used, with permission, from Lindy Fox, MD.)

Differential Diagnosis

DVT and necrotizing fasciitis are two potentially life-threatening entities that can mimic cellulitis (ie, present with a painful, red, swollen lower extremity). Necrotizing fasciitis should be suspected in a patient who has a toxic appearance, bullae, crepitus or anesthesia of the involved skin, skin necrosis, and laboratory evidence of rhabdomyolysis (elevated creatine kinase) or disseminated intravascular coagulation. While these findings may be present with severe cellulitis and bacteremia, it is essential to rule out necrotizing fasciitis because rapid surgical debridement is essential. Other noninfectious skin lesions that may resemble cellulitis are termed “pseudocellulitis.” These include sclerosing panniculitis, an acute, exquisitely tender red plaque on the medial lower legs above the malleolus in patients with venous stasis or varicosities, and acute severe contact dermatitis on a limb, which produces erythema, vesiculation, and edema, as seen in cellulitis, but with itching instead of pain. Bilateral lower leg bacterial cellulitis is exceedingly rare, and other diagnoses, especially severe stasis dermatitis (see Figure 14–4), should be considered in this setting. In contrast to cellulitis, severe lower extremity stasis dermatitis usually develops over days to weeks (rather than hours) and is not as tender to palpation. Cryptococcal cellulitis in the organ transplant recipient is often bilateral. The ALT-70 is a predictive model to diagnose cellulitis or a cellulitis mimic and to provide guidance about when a dermatology consultation is needed.

Treatment

Intravenous or parenteral antibiotics may be required for the first 2–5 days, with adequate coverage for *Streptococcus* and *Staphylococcus*. Methicillin-susceptible *S aureus* (MSSA) can be treated with nafcillin, cefazolin, clindamycin, dicloxacillin, cephalexin, doxycycline, or TMP-SMZ. If MRSA is suspected or proven, treatment options include vancomycin, linezolid, clindamycin, daptomycin, doxycycline, or TMP-SMZ. In mild cases or following the initial parenteral therapy, oral dicloxacillin or cephalexin, 250–500 mg four times daily for 5–10 days, is usually adequate. In patients in whom intravenous treatment is not instituted, the first dose of oral antibiotic can be doubled to achieve high blood levels rapidly. Prior episodes of cellulitis, lymphedema, chronic venous insufficiency, peripheral vascular disease, and DVT are associated with an increased risk of recurrent cellulitis. In patients with recurrent lower leg cellulitis (three to four episodes per year), oral penicillin 250 mg twice daily or oral erythromycin 250–500 mg twice daily can decrease the risk of recurrence. Additional measures to prevent recurrences include compression, treating toe web intertrigo and tinea pedis, and controlling venous insufficiency.

When to Admit

- Severe local symptoms and signs.
- Signs of sepsis.
- Elevated WBC count of 10,000/mcL (10 × 10^9/L) or more with marked left shift. Failure to respond to oral antibiotics.

ERYSIPELAS

ESSENTIALS OF DIAGNOSIS

- Edematous, circumscribed, hot, erythematous area, with raised advancing border.
- Central face or lower extremity frequently involved.
- Pain and systemic toxicity may be striking.

General Considerations

Erysipelas is a superficial form of cellulitis that is usually caused by β-hemolytic streptococci.

Clinical Findings

A. Symptoms and Signs

The symptoms are pain, malaise, chills, and moderate fever. A bright red patch appears and then spreads to form a tense, sharply demarcated, glistening, smooth, hot plaque. The sharp margin characteristically advances noticeably in days or even hours. The lesion has a raised edge and may pit slightly with finger pressure. Vesicles or bullae occasionally develop on the surface. The lesion does not usually become pustular or gangrenous and heals without scar formation. Breaks in the skin often provide a portal of entry for the organism. On the face, erysipelas begins near a fissure at the angle of the nose. On the lower extremity, tinea pedis with interdigital fissuring is a common portal of entry.

B. Laboratory Findings

Leukocytosis is almost invariably present; blood cultures may be positive.

Differential Diagnosis

Erysipeloid is a benign bacillary infection by *Erysipelothrix rhusiopathiae* that produces cellulitis of the skin of the fingers or the backs of the hands in fishermen and meat handlers.

Complications

Unless erysipelas is promptly treated, death may result from bacterial dissemination, particularly in older adults.

Treatment

Intravenous antibiotics effective against group A β-hemolytic streptococci and staphylococci should be considered, but outpatient treatment with oral antibiotics has demonstrated equal efficacy. Oral regimens include a 7-day course with penicillin VK (250 mg), dicloxacillin (250 mg), or a first-generation cephalosporin (250 mg) four times a day. Clindamycin (250 mg twice daily orally for 7–14 days) is an option for penicillin-allergic patients.

Prognosis

With appropriate treatment, rapid improvement is expected. The presence of lymphedema carries the greatest risk of recurrence.

Maciej S et al. Severe bullous erysipelas/cellulitis, atypically caused by *Escherichia coli*, in kidney transplant recipient—case report and review of the literature. Transplant Proc. 2024;56:976. [PMID: 38448250]

ERYTHEMA MIGRANS

Erythema migrans is a unique cutaneous eruption that characterizes the localized or generalized early stage of Lyme disease (caused by *Borrelia burgdorferi*) (Figure 6–18) (see also Chapter 39).

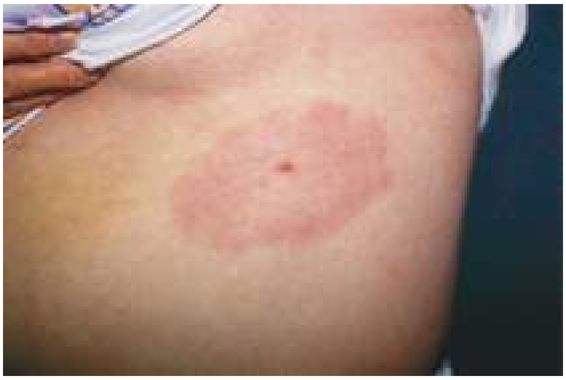

Figure 6–18. **Erythema migrans on trunk. Annular plaque with central clearing and central puncta from the bite.** (Reproduced, with permission, from Soutor C, Hordinsky MK. *Clinical Dermatology*. The McGraw-Hill Companies; 2013.)

PARASITIC INFESTATIONS

SCABIES

ESSENTIALS OF DIAGNOSIS

- Generalized very severe itching; infestation usually spares the head and neck.
- Burrows, vesicles, and pustules, especially on finger webs and in wrist creases.
- Mites, ova, and brown dots of feces (scybala) visible microscopically.
- Red papules or nodules on the scrotum and on the penile glans and shaft are pathognomonic.

General Considerations

Scabies is caused by infestation with *Sarcoptes scabiei*, affecting over 200 million persons worldwide. Close physical contact for 15–20 minutes with an infected person is the typical mode of transmission. However, scabies may be acquired by contact with the bedding of an infested individual. Facility-associated scabies is common, primarily in long-term care facilities, and misdiagnosis is common. Index patients are usually older adults and immunosuppressed. When these patients are hospitalized, hospital-based epidemics can occur and are difficult to eradicate when health care workers become infected and spread the infestation to other patients.

Clinical Findings

A. Symptoms and Signs

Itching is almost always present and can be severe. The lesions consist of generalized excoriations with small pruritic vesicles, pustules, and “burrows” in the interdigital spaces of the hands and feet, on the heels of the palms, wrists, elbows, umbilicus, around the axillae, on or around the areolae (Figure 6–19), or on the penile shaft and scrotum in men. The burrow appears as a short irregular mark, 2–3 mm long and the width of a hair. Characteristic nodular lesions may occur on the scrotum or penis and along the posterior axillary line. The infestation usually spares the head and neck (though these areas may be involved in infants, older adults, and patients with AIDS).

Hyperkeratotic or crusted scabies presents as thick flaking scale. These areas contain millions of mites, and these patients are highly infectious. Pruritus is often absent. Patients with widespread hyperkeratotic scabies are at risk for superinfection with *S aureus*, which in some cases progresses to sepsis if left untreated. Crusted scabies is the cause of 83% of scabies outbreaks in institutions.

B. Laboratory Findings

The diagnosis should be confirmed by microscopic demonstration of the organism, ova, or feces in a mounted specimen, examined with tap water, mineral oil, or KOH. Best results are obtained when multiple lesions are scraped, choosing the best unexcoriated lesions from interdigital webs, wrists, elbows, or feet. A No. 15 blade is used to scrape each lesion until it is flat. Patients with crusted/hyperkeratotic scabies must be evaluated for immunosuppression (especially HIV and HTLV-1 infections) if no iatrogenic cause of immunosuppression is present.

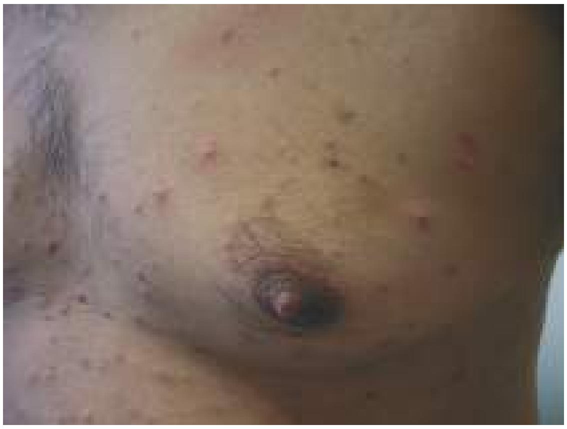

Figure 6–19. Scabies. A polymorphic eruption of papulovesicles and excoriated papules scattered on the chest. (Used, with permission, from Kanade Shinkai, MD.)

Differential Diagnosis

Scabies must be distinguished from the various forms of pediculosis, from bedbug and flea bites, and from other causes of pruritus including dermatitis, nutritional dermatoses, and pruritus with excoriations.

Treatment & Prognosis

Treatment is aimed at killing scabies mites and controlling the dermatitis, which can persist for months after effective eradication of the mites. Bedding and clothing should be laundered or set aside for 14 days in plastic bags. High heat (60°C) is required to kill the mites and ova. Treatment is aimed at all infected persons in a family or institutionalized group. Otherwise, reinfestations will likely occur, which is why scabies in nursing home patients, institutionalized or patients with a mental illness, and patients with AIDS may be much more difficult to treat.

1. Permethrin 5% cream—Treatment with permethrin, a highly effective and safe agent, consists of a single application from the neck down for 8–12 hours then washed off, repeated in 1 week. Patients often continue to itch for several weeks after treatment. Use of triamcinolone 0.1% cream helps resolve the dermatitis.

Pregnant patients should be treated only if they have documented scabies. Permethrin 5% cream once for 12 hours or 5% or 6% sulfur in petrolatum applied nightly for 3 nights from the neck down may be used.

Many failures in normal persons are related to incorrect use or incomplete treatment of the housing unit. In these cases, repeat treatment with permethrin once weekly for 2 weeks, with re-education regarding the method and extent of application, is suggested. In addition, there is a slowly increasing incidence of resistance to permethrin and other anti-scabetic agents.

2. Ivermectin—In immunocompetent individuals, 200 mcg/kg orally is effective in about 75% of cases with a single dose and in 95% of cases with two doses 2 weeks apart. Since the drug is not ovicidal, the second dose theoretically kills eggs that might have hatched after the first dose was given.

Ivermectin is often used in combination with permethrin. In immunosuppressed persons and those with crusted (hyperkeratotic) scabies, multiple doses of ivermectin (every 2 weeks for 2 or 3 doses) plus topical therapy with permethrin every 3 days to once weekly, depending on degree of involvement, may be effective when topical treatment and oral therapy alone fail. A topical keratolytic (urea) should be used to help remove the scale of hyperkeratotic scabies, thereby decreasing the mite load.

Ivermectin can be beneficial in mass treatment to eradicate widespread infection. In endemic areas, mass intervention with ivermectin is effective in controlling both scabies and associated bacterial infections.

3. Spinosad—For treatment-resistant patients, 0.9% spinosad suspension, applied once over a time period longer than 6 hours, can be considered, though efficacy is lower than that for ivermectin or permethrin.

PEDICULOSIS

ESSENTIALS OF DIAGNOSIS

- Pruritus with excoriation.
- Nits on hair shafts; lice on skin or clothes.
- Occasionally, sky-blue macules (maculae ceruleae) on the inner thighs or lower abdomen in pubic lice infestation.

General Considerations

Pediculosis is a parasitic infestation of the skin of the scalp, trunk, or pubic areas. Body lice usually occur among persons who live in overcrowded dwellings with inadequate hygiene facilities. Pubic lice may be sexually transmitted. Head lice may be transmitted by shared use of hats or combs. Adults in contact with children with head lice frequently acquire the infestation.

There are three different varieties: (1) **pediculosis capitis**, caused by *Pediculus humanus* var *capitis* (head louse); (2) **pediculosis corporis**, caused by *Pediculus humanus* var *corporis* (body louse); and (3) **pediculosis pubis**, caused by *Phthirus pubis* (pubic louse, "crabs").

Head and body lice are 3–4 mm long and similar in appearance. The "body louse" can seldom be found on the body because it comes onto the skin only to feed; it must be looked for in the seams of the clothing. Trench fever, relapsing fever, and typhus are transmitted by the body louse in countries where those diseases are endemic. In the United States, *Bartonella quintana* and *Rickettsia typhi*, the organisms that cause trench fever and typhus, have been found in lice infesting persons with housing instability.

Clinical Findings

In body lice infestations, itching may be very intense, and scratching may result in deep excoriations, especially over the upper shoulders, axillae, posterior flanks, and neck. In some cases, only itching is present, with few excoriations seen. Pyoderma (bacterial infection of the skin) may be the presenting sign. Diagnosis is made by examining the seams of clothing for nits and lice. Head lice presents as scalp pruritus often accompanied by erosions on the occipital scalp, posterior neck, and upper back. Diagnosis is made by finding lice on the scalp or small nits resembling pussy willow buds on the scalp hairs close to the skin. Nits are easiest to see above the ears and at the nape of the neck. Pubic lice infestations are occasionally generalized, particularly in hairy individuals; the lice may even be found on the eyelashes and in the scalp. Diagnosis is made by finding lice or nits on pubic hair, body hair, or eyelashes.

Differential Diagnosis

Head lice infestation must be distinguished from seborrheic dermatitis, body lice infestation from scabies and bedbug bites, and pubic lice infestation from anogenital pruritus and eczema.

Treatment

1. Pediculosis capitis—Permethrin 1% cream rinse (Nix) is a topical over-the-counter pediculicide and ovicide. It is applied to the scalp and hair and left on for 8 hours before being rinsed off. Although it is the treatment of choice for head lice, permethrin resistance is common. Malathion lotion 1% (Ovide) is very effective but highly volatile and flammable, so application must be done in a well-ventilated room or out of doors. Topical ivermectin 0.5% lotion, benzyl alcohol 5%, Oxyphthirine® lotion, spinosad 0.9% suspension, dimethicone, and abametapir 0.74% lotion are additional agents that have efficacy against pediculosis capitis; of these, topical ivermectin is the most effective. All infested persons in a household, school, or other facility should ideally be treated at the same time. Other than topical ivermectin, topical therapies should be repeated 7–9 days after the initial treatment. For involvement of eyelashes, petrolatum is applied thickly twice daily for 8 days and the remaining nits plucked off. Systemic treatment options, often used in combination with topical agents, are oral ivermectin (200 mcg/kg orally, repeated in 7 days) (for children older than 5 years and > 15 kg) and oral TMP-SMZ (10 mg TMP/kg/day and 50 mg SMZ/kg/day divided twice daily for 10 days).

2. Pediculosis corporis—Body lice are treated by disposing of the infested clothing and addressing the patient's social situation.

3. Pediculosis pubis—Application of permethrin rinse 1% for 10 minutes or permethrin cream 5% for 8 hours to the pubis is effective. Sexual contacts should be treated. Clothes and bedclothes should be washed and dried at high temperature.

SKIN LESIONS DUE TO OTHER ARTHROPODS

ESSENTIALS OF DIAGNOSIS

- Localized urticarial papules with pruritus.
- Lesions in linear groups of three ("breakfast, lunch, and dinner") are characteristic of bedbugs.
- Furuncle-like lesions containing live arthropods.
- Tender erythematous patches that migrate ("larva migrans").

General Considerations

Some arthropods (eg, mosquitoes and biting flies) are readily detected as they bite. Many others are not because they are too small, because there is no immediate reaction, or because they bite during sleep. Reactions are allergic and may be delayed for hours to days. Patients are most apt to consult a clinician when the lesions are multiple and pruritus is intense.

Many persons react most severely to their earliest contacts with an arthropod, thus presenting with pruritic lesions when traveling, moving into new quarters, etc. Body lice, fleas, bedbugs, and mosquitoes should be considered. Bedbug exposure typically occurs in hotels and in housing with inadequate hygiene but also occurs in stable domiciles. Spiders are often incorrectly believed to be the source of bites, but they rarely attack humans. However, the brown recluse spider (*Loxosceles laeta*, *L reclusa*) may cause severe necrotic reactions and death due to intravascular hemolysis, and the black widow spider (*Latrodectus mactans*) may cause severe systemic symptoms and death. (See also Chapter 43.)

In addition to arthropod bites, the other most common causes of lesions due to exposures include venomous stings (wasps, hornets, bees, ants, scorpions) or bites (centipedes), furuncle-like lesions due to fly maggots or sand fleas in the skin, and a linear creeping eruption due to a migrating larva.

Clinical Findings

The diagnosis may be difficult when the patient has not noticed the initial attack but suffers a delayed reaction. Individual bites are often in clusters and tend to occur either on exposed parts (eg, midges and gnats) or under clothing, especially around the waist or at flexures (eg, small mites or insects in bedding or clothing). The reaction is often delayed for 1–24 hours or more. Pruritus is almost always present and may be all but intolerable once the patient starts to scratch. Secondary infection may follow scratching. Urticarial wheals are common. Papules may become vesicular. The diagnosis is aided by searching for exposure to arthropods and by considering the patient's occupation and recent activities.

The principal arthropods are as follows:

1. **Fleas:** Fleas are bloodsucking ectoparasites that feed on dogs, cats, humans, and other species. Flea saliva produces papular urticaria in sensitized individuals. To break the life cycle of the flea, one must treat the home and pets, using quick-kill insecticides, residual insecticides, and a growth regulator.
2. **Bedbugs:** In crevices of beds or furniture; bites tend to occur in lines or clusters. Papular urticaria is a characteristic lesion of bedbug (*Cimex lectularius*) bites. Bedbugs are not restricted to any socioeconomic group and are a major health problem in some major metropolitan areas, especially in commercial and residential hotels.
3. **Ticks:** Usually picked up by brushing against low vegetation.
4. **Chiggers or red bugs:** These are larvae of trombiculid mites. A few species confined to particular regions and locally recognized habitats (eg, berry patches, woodland edges, lawns, brush turkey mounds in Australia, poultry farms) attack humans, often around the waist, on the ankles, or in flexures, raising intensely itching erythematous papules after a delay of many hours. The red chiggers may sometimes be seen in the center of papules that have not yet been scratched.
5. **Bird and rodent mites:** Larger than chiggers, bird mites infest birds and their nests. Bites are multiple anywhere on the body. Room air conditioning units may transmit outdoor bird mites to inhabitants of the room. Rodent mites from mice or rats may cause similar effects. If the domicile has evidence of rodent activity, then rodent mite dermatitis should be suspected, as the mites are rarely found. Pet rodents or birds may be infested with mites, maintaining the infestation.
6. **Mites in stored products:** These are white and almost invisible and infest products, such as copra, vanilla pods, sugar, straw, cottonseeds, and cereals. Persons who handle these products may be attacked, especially on the hands and forearms and sometimes on the feet.
7. **Caterpillars of moths with urticating hairs:** The hairs are blown from cocoons or carried by emergent moths, causing severe and often seasonally recurrent outbreaks after mass emergence. The gypsy moth is a cause in the eastern United States.
8. **Tungiasis:** Tungiasis is due to the burrowing flea known as *Tunga penetrans* and is found in Africa, the

West Indies, and South and Central America. The female burrows under the skin, sucks blood, swells to 0.5 cm, and then ejects her eggs onto the ground. Ulceration, lymphangitis, gangrene, and septicemia may result, in some cases with lethal effect. Simple surgical removal is usually performed.

Prevention

Arthropod infestations are best prevented by avoidance of contaminated areas, personal cleanliness, and disinfection of clothing, bedclothes, and furniture as indicated. Chiggers and mites can be repelled by permethrin applied to the head and clothing. (It is not necessary to remove clothing.) Bedbugs are no longer repelled by permethrin and can survive for up to 1 year without feeding. Aggressive cleaning, usually requiring removal of the affected occupant from the domicile, may be necessary to eradicate bedbug infestation in a residence.

Treatment

Living arthropods should be removed carefully with tweezers after application of alcohol and preserved in alcohol for identification. In endemic Rocky Mountain spotted fever areas, ticks should not be removed with the bare fingers.

Corticosteroid lotions or creams are helpful for the associated pruritus. Topical antibiotics may be applied if secondary infection is suspected. Localized persistent lesions may be treated with intralesional corticosteroids.

Stings produced by many arthropods may be alleviated by applying papain powder (Adolph's Meat Tenderizer) mixed with water, or aluminum chloride hexahydrate (Xerac AC).

Extracts from venom sacs of bees, wasps, yellow jackets, and hornets are available for immunotherapy of patients at risk for anaphylaxis.

INFLAMMATORY NODULES

ERYTHEMA NODOSUM

ESSENTIALS OF DIAGNOSIS

- Painful nodules without ulceration on anterior aspects of legs.
- Slow regression over several weeks to resemble contusions.
- Women are predominantly affected by a ratio of 10:1 compared to men.
- Some cases associated with infection, IBD, or medication exposure.
- Evaluation for underlying cause is essential.

General Considerations

Erythema nodosum is a symptom complex of panniculitis characterized by tender, erythematous nodules that appear most commonly on the extensor surfaces of the lower legs. It usually lasts about 6 weeks and may recur. Most cases are idiopathic in nature. However, erythema nodosum can be a skin sign of systemic disease. Evaluation and management include making the diagnosis, treating the symptoms, and searching for an underlying cause. The disease may be associated with various infections—streptococcosis, primary coccidioidomycosis, other deep fungal infections, tuberculosis, *Yersinia pseudotuberculosis* and *Y enterocolitica* infection, *Salmonella* and other GI pathogens, diverticulitis, or syphilis. It may accompany sarcoidosis, Behçet disease, and IBD. Erythema nodosum may be associated with pregnancy or with use of oral contraceptives. It may occur secondary to medications or, more rarely, an underlying malignancy.

Clinical Findings

A. Symptoms and Signs

The subcutaneous swellings are exquisitely tender and may be preceded by fever, malaise, and arthralgia. They are most often located on the anterior surfaces of the legs below the knees but may occur on the arms, trunk, and face. The lesions, 1–10 cm in diameter, are at first pink to red; with regression, all the various hues seen in a contusion can be observed (Figure 6–20) but, as a rule, the lesions do not ulcerate.

B. Laboratory Findings

Evaluation of patients presenting with acute erythema nodosum should include a careful history (including medication exposures) and physical examination. Significant findings include a history of prior upper respiratory infection, diarrheal illness, exposure to tuberculosis, or symptoms of any deep fungal infection endemic to the area. In patients lacking an obvious drug or medical cause, a CXR, a purified protein derivative or blood interferon γ release assay (such as QuantiFERON) (see Pulmonary Tuberculosis in Chapter 9), and two consecutive ASO/DNAse B titers at 2- to 4-week intervals should be obtained. Coccidioidomycosis should be looked for in patients from endemic areas. If no underlying cause is found, only a small percentage of patients will go on to develop a significant underlying illness over the next year.

Differential Diagnosis

Unlike other forms of panniculitis, a defining feature of erythema nodosum is that it does not ulcerate. Erythema induratum from tuberculosis is seen on the posterior surfaces of the legs and may ulcerate. Lupus panniculitis presents as tender nodules in fatty areas of the buttocks and posterior arms and heals with depressed scars. In polyarteritis nodosa, the subcutaneous nodules are often associated with fixed livedo reticularis. In its late stages, erythema nodosum must be distinguished from simple bruises and contusions.

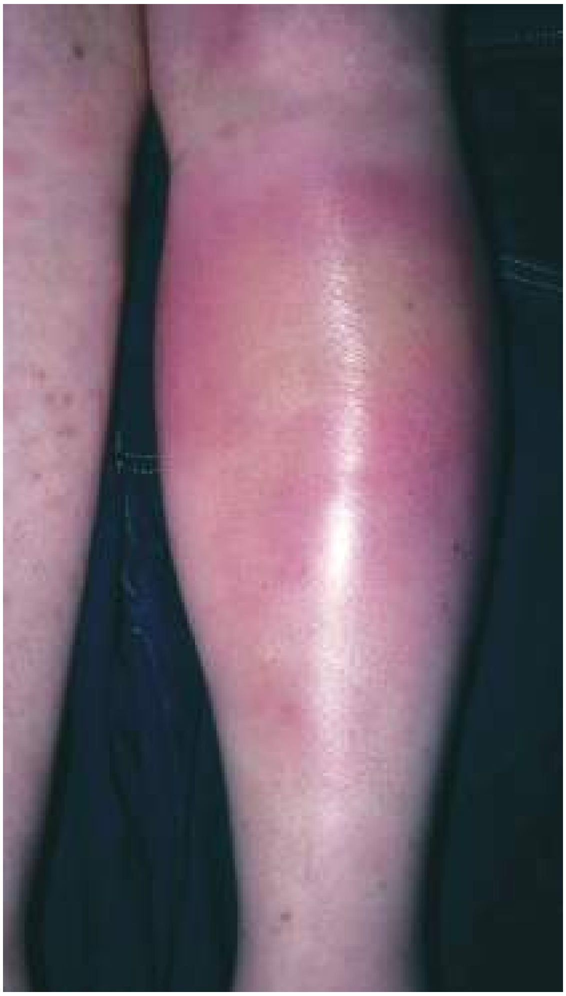

Figure 6–20. Erythema nodosum. (Used, with permission, from TG Berger, MD, Dept Dermatology, UCSF.)

Treatment

The underlying cause should be identified and treated. Primary therapy is with NSAIDs in usual doses. Saturated solution of potassium iodide, 5–15 drops by mouth three times daily, results in prompt involution in many cases. Complete bed rest may be advisable if the lesions are painful. Systemic therapy directed against the lesions themselves may include corticosteroid therapy (see Chapter 30) (unless contraindicated by associated infection), dapsone, colchicine, or hydroxychloroquine.

Prognosis

The lesions usually disappear after about 6 weeks but may recur.

SCALING DISORDERS

ATOPIC DERMATITIS

ESSENTIALS OF DIAGNOSIS

- Pruritic, xerotic, exudative, or lichenified eruption on face, neck, upper trunk, wrists, and hands and in the antecubital and popliteal folds.
- Personal or family history of atopy (eg, asthma, allergic rhinitis, atopic dermatitis).
- Tendency to recur.
- Onset in childhood most common; onset after age 30 is uncommon.

General Considerations

Atopic dermatitis (also known as eczema) has distinct presentations in persons of different ages and races. Diagnostic criteria for atopic dermatitis must include pruritus, typical morphology and distribution (flexural lichenification, hand eczema, nipple eczema, and eyelid eczema in adults), onset in childhood, and chronicity. Also helpful are (1) a personal or family history of atopy (asthma, allergic rhinitis, atopic dermatitis), (2) xerosis-ichthyosis, (3) facial pallor with infraorbital darkening, (4) elevated serum IgE, and (5) repeated skin infections.

Clinical Findings

A. Symptoms and Signs

Itching is a key clinical feature and may be severe and prolonged. Ill-defined, scaly, red plaques affect the face, neck, and upper trunk. The flexural surfaces of elbows and knees are often involved. In chronic cases, the skin is dry and lichenified. In patients with darker skin with severe disease, pigmentation may be lost in lichenified areas. During acute flares, widespread redness with weeping, either diffusely or in discrete plaques, is common. Most patients with atopic dermatitis have skin disease before age 5; therefore, a new diagnosis of atopic dermatitis in an adult over age 30 should be made only after consultation with a dermatologist.

B. Laboratory Findings

Food allergy is an uncommon cause of flares of atopic dermatitis in adults. Eosinophilia and increased serum IgE levels may be present.

Differential Diagnosis

Atopic dermatitis must be distinguished from irritant or allergic contact dermatitis. Seborrheic dermatitis is less pruritic, with frequent scalp and central face involvement, greasy and scaly lesions, and responds quickly to therapy. Psoriasis is marked by sharply demarcated thickly scaled plaques on elbows, knees, scalp, and intergluteal cleft.

Secondary staphylococcal or herpetic infections may exacerbate atopic dermatitis and should be considered during hyperacute, weeping flares. An infra-auricular fissure is a cardinal sign of secondary staphylococcal infection.

Treatment

Patient education regarding gentle skin care and proper use of medications is critical to successful management of atopic dermatitis.

A. General Measures

Atopic patients have hyperirritable skin. Anything that dries or irritates the skin may trigger dermatitis. Atopic individuals are sensitive to low humidity and often flare in the winter. Adults with atopic disorders should not bathe more than once daily. Soap should be confined to the armpits, groin, scalp, and feet. Washcloths and brushes should not be used. After rinsing, the skin should be patted dry (not rubbed) and then immediately—within minutes—covered with a thin film of an emollient or a corticosteroid as needed. Plain petrolatum can be used if contact dermatitis resulting from additives in medication is suspected. Skin may be irritated by rough fabrics, including wools and acrylics. Cottons are preferable, but synthetic blends also are tolerated. Other triggers may include sweating, ointments, and heat.

B. Local Treatment

Corticosteroids should be applied sparingly to the dermatitis once or twice daily. Their potency should be appropriate to the severity of the dermatitis. In general, for treatment of lesions on the body (excluding genitalia, axillary or crural folds), one should begin with triamcinolone 0.1% or a stronger corticosteroid, then taper to hydrocortisone or another slightly stronger mild corticosteroid (alclometasone, desonide). **It is vital that patients taper off corticosteroids and substitute emollients as the dermatitis clears to avoid side effects of corticosteroids**. Tapering is also important to avoid dermatitis flares that may follow abrupt cessation. Tacrolimus ointment (Protopic 0.03% or 0.1%), pimecrolimus cream (Elidel 1%), crisaborole (Eucrisa 2%), ruxolitinib (Opzelura 1.5%), and roflumilast cream (Zoryve 15%) are nonsteroidal topical medications that may be effective in managing atopic dermatitis when applied daily or twice daily (see Table 6–2). These noncorticosteroid medications prevent complications of long-term corticosteroid use, including atrophy or striae. They are safe for application on the face and eyelids but are more expensive than generic topical corticosteroids.

There is a US FDA black box warning for both topical tacrolimus and pimecrolimus due to concerns about the development of T-cell lymphoma. A systematic review and meta-analysis found a weak association between topical calcineurin inhibitor use and lymphoma; however, the absolute risk is very low. The number needed to harm is estimated at 30,000 adults and 200,000 children.

The treatment of atopic dermatitis is dictated by the pattern of the dermatitis—acute/weepy, subacute/scaly, or chronic/lichenified.

1. Acute weeping lesions—Staphylococcal or herpetic superinfection should be excluded by bacterial or viral culture, or both. Use water or aluminum subacetate solution (Domeboro or burow solution), or colloidal oatmeal as a bath or as wet dressings for 10–30 minutes two to four times daily. Lesions on extremities may be bandaged for protection at night. Use high-potency corticosteroids after soaking but spare the face and body folds. Tacrolimus is usually not tolerated at this stage. Systemic corticosteroids may be required. An allergic or irritating exposure should also be considered when acute weeping lesions are present since contact dermatitis is more likely to develop in atopic patients.

2. Subacute or scaly lesions—The lesions are dry but still red and pruritic. Mid- to high-potency corticosteroids in ointment form should be continued until skin lesions are cleared and itching is decreased substantially. At that point, patients should begin a 2- to 4-week taper from twice-daily to daily dosing with topical corticosteroids to reliance on emollients, with occasional use of corticosteroids only to inflamed areas. It is preferable to switch to daily use of a low-potency corticosteroid instead of further tapering the frequency of usage of a more potent corticosteroid. Tacrolimus and pimecrolimus may be substituted if corticosteroids cannot be stopped completely.

3. Chronic, dry, lichenified lesions—Thickened and usually well demarcated, they are best treated with high-potency to ultra–high-potency corticosteroid ointments. Nightly occlusion for 2–6 weeks may enhance the initial response. Adding tar preparations, such as liquor carbonis detergens 10% in Aquaphor or 2% crude coal tar may be beneficial.

4. Maintenance treatment—Once symptoms have improved, constant application of effective moisturizers is recommended to prevent flares. In patients with moderate disease, use of topical anti-inflammatories only on weekends or three times weekly can prevent flares.

C. Systemic and Adjuvant Therapy

Increasingly, providers try to avoid the use of systemic steroids in the treatment of atopic dermatitis. Systemic corticosteroids are indicated only for severe acute exacerbations. Oral prednisone dosages should be high enough to suppress the dermatitis quickly, usually starting with 1 mg/kg daily and tapering off over a period of 2–4 weeks. Owing to the chronic nature of atopic dermatitis and the side effects of long-term systemic corticosteroids, **ongoing use of these agents is not recommended for maintenance therapy**. Bedtime doses of hydroxyzine, diphenhydramine, or doxepin may be helpful via their sedative properties to mitigate perceived pruritus. Dupilumab and the newer IL-13 inhibitor tralokinumab are targeted immunomodulators with minimal systemic adverse effects (hypersensitivity). Janus kinase (JAK) inhibitors (upadacitinib, abrocitinib), cyclosporine, mycophenolate mofetil, methotrexate, or azathioprine may also be used for the most severe and recalcitrant cases.

Complications of Treatment

The clinician should monitor for skin atrophy. Fissures, crusts, erosions, or pustules may indicate staphylococcal or herpetic infection clinically. Eczema herpeticum (herpes simplex superinfection) is manifested by monomorphic vesicles, crusts, or scalloped erosions superimposed on atopic dermatitis or other extensive eczematous processes and is treated with oral or intravenous acyclovir. Systemic anti-staphylococcal antibiotics should be given only if indicated and guided by bacterial culture. Cultures to exclude methicillin-resistant *S aureus* are recommended. In this setting, continuing and augmenting the topical anti-inflammatory treatment often improves the dermatitis despite the presence of infection.

Prognosis

Atopic dermatitis runs a chronic or intermittent course. Affected adults may have only hand dermatitis. Prognostic factors for persistence into adulthood include generalized disease or onset early in childhood and asthma. Only 40–60% of these patients have lasting remissions.

LICHEN SIMPLEX CHRONICUS (Circumscribed Neurodermatitis)

ESSENTIALS OF DIAGNOSIS

- Chronic itching and scratching.
- Lichenified lesions with exaggerated skin lines overlying a thickened, well-circumscribed, scaly plaque.
- Predilection for nape of neck, wrists, external surfaces of forearms, lower legs, and genitals.

General Considerations

Lichen simplex chronicus represents a self-perpetuating scratch-itch cycle that is hard to disrupt.

Clinical Findings

Intermittent itching incites the patient to scratch the lesions and may interfere with sleep. Dry, hypertrophic, lichenified plaques appear on the neck, wrists, ankles, or perineum (Figure 6–21). The patches are rectangular, thickened, and hyperpigmented. The skin lines are exaggerated.

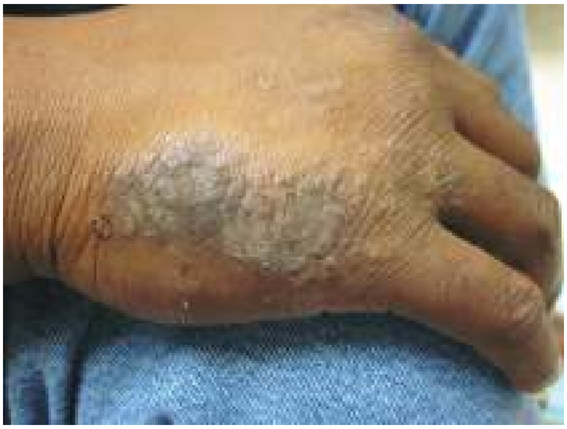

Figure 6–21. Lichen simplex chronicus on the hand. (Used, with permission, from Lindy Fox, MD.)

Differential Diagnosis

This disorder can be differentiated from plaque-like lesions such as psoriasis (redder lesions having whiter scales on the elbows, knees, and scalp and nail findings) (Figure 6–22), lichen planus (violaceous, usually smaller polygonal papules), and nummular (coin-shaped) dermatitis. Lichen simplex chronicus may complicate chronic atopic dermatitis or scabetic infestation.

Treatment

For lesions in extragenital regions, ultra-high potency topical corticosteroids are effective, with or without occlusion, when used twice daily for several weeks (Table 6–2). In some patients, flurandrenolide (Cordran) tape may be effective since it prevents scratching and rubbing of the lesion. The injection of triamcinolone acetonide suspension (5–10 mg/mL) into the lesions may occasionally be curative. Continuous occlusion with a flexible hydrocolloid dressing for 7 days at a time for 1–2 months may also be helpful. For genital lesions, see the section Pruritus Ani.

Prognosis

The disease tends to remit during treatment but may recur or develop at another site.

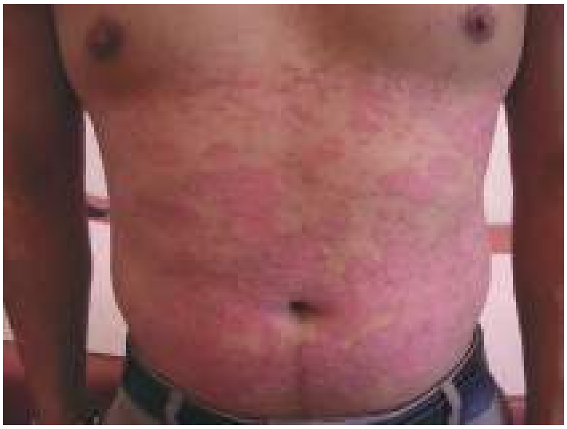

Figure 6–22. **Extensive plaque psoriasis involving trunk of person with dark skin type.** (Used, with permission, from Kanade Shinkai, MD.)

PSORIASIS

ESSENTIALS OF DIAGNOSIS

- Silvery scales on bright red, well-demarcated plaques, usually on the knees, elbows, and scalp.
- Nails: pitting and onycholysis (separation of the nail plate from the bed).
- Mild itching is common.
- May be associated with psoriatic arthritis.
- Histopathology is helpful.

General Considerations

Psoriasis is a common benign, chronic inflammatory skin disease with both a genetic basis and known environmental triggers. Injury or irritation of normal skin tends to induce lesions of psoriasis at the site (Koebner phenomenon). Obesity worsens psoriasis, and significant weight loss may lead to substantial improvement. Psoriasis has several variants—the most common is the plaque type, and hand involvement is also common. Eruptive (guttate) psoriasis consisting of numerous, smaller lesions 3–10 mm in diameter occurs occasionally after streptococcal pharyngitis. Rarely, life-threatening forms (generalized pustular psoriasis and erythrodermic psoriasis) may occur.

Clinical Findings

There are often no symptoms, but itching may occur and be severe. Favored sites include the scalp, elbows, knees, palms and soles, and nails. The lesions are red, sharply defined plaques covered with silvery scale (Figure 6–22). The glans penis and vulva may be affected. Occasionally, only the flexures (axillae, inguinal areas) are involved (termed inverse psoriasis). Fine stippling (“pitting”) in the nails is highly suggestive of psoriasis (Figure 6–23) as is onycholysis. The combination of red plaques with silvery scales on elbows and knees, with scaliness in the scalp or nail findings, is diagnostic. Patients with psoriasis often have a pink or red intergluteal fold. Not all patients have findings in all locations. Some patients have mainly hand or foot psoriasis with minimal findings elsewhere. There may be associated arthritis that is most commonly distal and oligoarticular, although polyarticular, axial, and arthritis mutilans involvement may occur. The psychosocial impact of psoriasis is a major factor in determining the treatment of the patient.

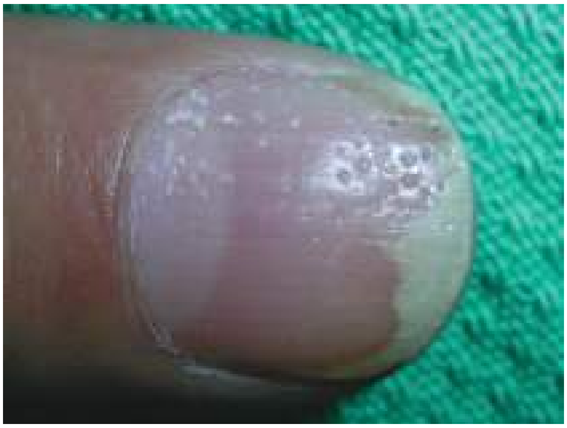

Figure 6–23. Nail pitting due to psoriasis in a patient with dark skin. (Reproduced, with permission, from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine*, 2nd ed. McGraw-Hill, 2013.)

Differential Diagnosis

Psoriasis lesions are well demarcated and affect extensor surfaces—in contrast to atopic dermatitis, with poorly demarcated plaques in flexural distribution. In body folds, scraping and culture for *Candida* and examination of scalp and nails will distinguish inverse psoriasis from intertrigo and candidiasis. Dystrophic changes in nails may mimic onychomycosis, and a KOH preparation or fungal culture is valuable in diagnosis. The cutaneous features of reactive arthritis, pityriasis rosea, SLE, and syphilis mimic psoriasis.

Treatment

There are many therapeutic options in psoriasis to be chosen according to the extent (body surface area [BSA] affected) and the presence of other findings (for example, arthritis). Certain medications, such as β-blockers, antimalarials, statins, lithium, and prednisone tapering, may flare or worsen psoriasis. Patients with moderate to severe psoriasis should be managed by or in conjunction with a dermatologist.

A. Limited Disease

For patients with large plaques and < 10% of the BSA involved, the easiest regimen is to use a high-potency to ultra–high-potency topical corticosteroid cream or ointment. It is best to restrict the ultra–high-potency corticosteroids to 2–3 weeks of twice-daily use and then use them in a pulse fashion three or four times on weekends or switch to a mid-potency corticosteroid. Topical corticosteroids rarely induce a lasting remission. Initially, patients may be treated with twice-daily topical corticosteroids plus a vitamin D analog (calcipotriene ointment 0.005% or calcitriol ointment 0.003%) twice daily. This rapidly clears the lesions; eventually, the topical corticosteroids are stopped, and once- or twice-daily application of the vitamin D analog is continued long-term. Calcipotriene usually cannot be applied to the groin or face because of irritation. Treatment of extensive psoriasis with vitamin D analogs may result in hypercalcemia so that the maximum dose for calcipotriene is 100 g/week and for calcitriol it is 200 g/week. Calcipotriene is incompatible with many topical corticosteroids (but not halobetasol), so if used concurrently, it must be applied at a different time. For patients with numerous small papules and plaques, such as guttate psoriasis, narrowband UVB phototherapy is the best therapy.

For thick plaques on the scalp, start with a daily tar shampoo. Additional treatments include 6% salicylic acid gel (eg, Keralyt), P & S solution (phenol, mineral oil, and glycerin), or fluocinolone acetonide 0.01% in oil (Derma-Smoothe/FS) under a shower cap at night, and shampoo in the morning. In order of increasing potency, triamcinolone 0.1%, fluocinolone, betamethasone dipropionate, amcinonide, and clobetasol are available in solution form for use on the scalp twice daily. Tacrolimus ointment 0.1% or 0.03% or pimecrolimus cream 1% may be effective in intertriginous, genital, and facial psoriasis, where potent corticosteroids are not recommended due to skin atrophy. Two additional nonsteroidal topical therapies approved to treat psoriasis are roflumilast cream 0.3% (phosphodiesterase-4 inhibitor) and tapinarof cream 1% (aryl hydrocarbon receptor agonist).

B. Moderate Disease

Psoriasis affecting 10–30% of the patient's BSA is frequently treated with narrowband UVB phototherapy, either in a medical office or via a home light unit. Systemic agents listed below may also be used.

C. Moderate to Severe Disease

If psoriasis in a given location is severe or involves > 30% of the body surface, it is difficult to treat with topical agents. These patients may be best managed in partnership with a dermatologist, especially when considering systemic therapy. The treatment of choice is outpatient narrowband UVB (NB-UVB) three times weekly. Clearing occurs in an average of 7 weeks, and maintenance may be required. Psoriatic arthritis may require distinct treatments and benefits from management in partnership with a rheumatologist or dermatologist.

Methotrexate is effective for severe psoriasis in doses up to 25 mg once weekly according to published protocols. Long-term methotrexate use may be associated with cirrhosis. After receiving a 3.5–4-g cumulative dose, the patient should be referred to a hepatologist for evaluation. Administration of folic acid, 1–2 mg daily, can eliminate nausea caused by methotrexate without compromising efficacy.

Acitretin, a synthetic retinoid, is most effective for pustular psoriasis in oral dosages of 0.5–0.75 mg/kg/day. Liver enzymes and serum lipids must be checked periodically. Because acitretin is a teratogen and persists for 2–3 years in fat, women of childbearing age must wait at least 3 years after completing acitretin treatment before considering pregnancy. When used as single agents, retinoids will flatten psoriatic plaques but will rarely result in complete clearing. Retinoids find their greatest use when combined with phototherapy—either UVB or PUVA, with which they are synergistic.

Among the systemic therapies for psoriasis, the IL-12/23 monoclonal antibodies (ustekinumab), IL-23 monoclonal antibodies (guselkumab, risankizumab, and tildrakizumab), oral tyrosine kinase 2 (TYK2) inhibitors (deucravacitinib), and IL-17 monoclonal antibodies (bimekizumab, secukinumab, brodalumab, and ixekizumab) are generally the most effective options. The TNF inhibitors etanercept, infliximab, certolizumab, and adalimumab are effective in pustular and chronic plaque psoriasis and are also effective for the associated arthritis. Infliximab provides the most rapid response and can be used for severe pustular or erythrodermic flares. Etanercept is used more frequently for long-term treatment at a dose of 50 mg subcutaneously twice weekly for 3 months, then 50 mg once weekly. All TNF inhibitors can also induce or worsen psoriasis. The oral phosphodiesterase-4 inhibitor apremilast is an approved option for psoriasis and psoriatic arthritis with minimal immunosuppressive effects and requires no laboratory monitoring. Deucravacitinib, an oral TYK2 inhibitor, is approved for moderate-to-severe plaque psoriasis and has the benefit of once-daily dosing. The IL-36 receptor antibody spesolimab remains the only therapy approved specifically for generalized pustular psoriasis. Cyclosporine dramatically improves psoriasis and may be used to control severe cases. Rapid relapse (rebound) frequently occurs after cessation of therapy, so another agent must be added if cyclosporine is stopped.

▶ Prognosis

The course of psoriasis may be chronic and unpredictable, and it may be refractory to treatment. Patients (especially those older than 40 years) should be monitored for metabolic syndrome, which correlates with the severity of their skin disease. Complications of systemic therapy occur, and active monitoring for infection is needed.

PITYRIASIS ROSEA

ESSENTIALS OF DIAGNOSIS

- Oval, fawn-colored, scaly eruption following cleavage lines of trunk.
- Herald patch precedes eruption by 1–2 weeks.
- Occasional pruritus.

General Considerations

Pityriasis rosea is a common mild, acute inflammatory disease that is 50% more common in females. Young adults are principally affected, mostly in the spring or fall. Concurrent household cases have been reported.

Clinical Findings

Itching is common but usually mild. The diagnosis is made by finding one or more classic lesions, such as oval, fawn-colored plaques up to 2 cm in diameter. The centers of a few lesions may have a characteristic crinkled or "cigarette paper" appearance and a collarette scale, ie, a thin bit of scale that is bound at the periphery and free in the center. Lesions follow cleavage lines on the trunk (so-called Christmas tree pattern, Figure 6–24), and the proximal portions of the extremities are often involved. A variant that affects the flexures (axillae and groin), so-called inverse pityriasis rosea, and a papular variant, especially in patients with more darkly pigmented skin types, also occur. An initial lesion ("herald patch") that is often larger than the later lesions often precedes the general eruption by 1–2 weeks. The eruption usually lasts 6–8 weeks and heals without scarring.

Differential Diagnosis

Serologic testing for syphilis should be performed if clinical risk factors are present. Palmar and plantar or mucous membrane lesions or adenopathy are features suggestive of secondary syphilis. Tinea corporis may present with a few red, slightly scaly plaques. Typically, the number of plaques of tinea corporis is significantly fewer than the number seen in pityriasis rosea. A KOH examination should be performed to exclude a fungal cause. Seborrheic dermatitis on occasion presents on the body with poorly demarcated patches over the sternum, in the pubic area, and in the axillae. Tinea versicolor lacks the typical collarette-rimmed lesions. Guttate or plaque psoriasis is an important diagnostic consideration and biopsy can help differentiate these from pityriasis rosea. Certain medications and immunizations rarely may induce a skin eruption mimicking pityriasis rosea. A pityriasis rosea–like eruption has been reported in association with SARS-CoV-2 infection and COVID-19 vaccination.

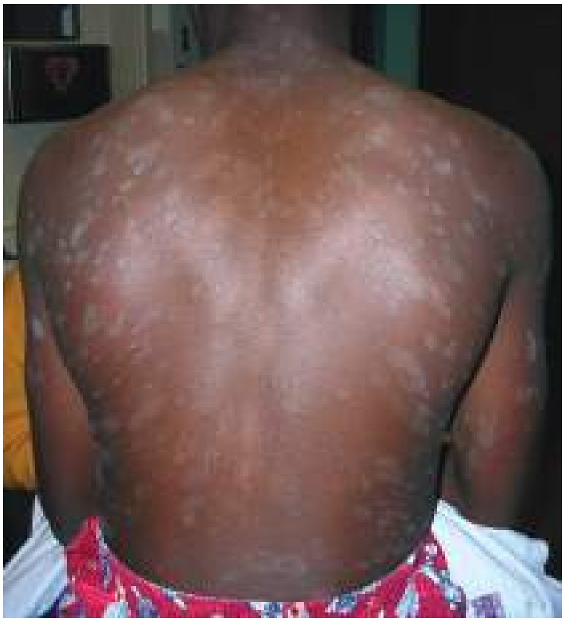

Figure 6–24. Pityriasis rosea with scaling lesions following skin lines and resembling a Christmas tree. (Used, with permission, from EJ Mayeaux, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley HS. *The Color Atlas and Synopsis of Family Medicine*, 3rd ed. McGraw-Hill, 2019.)

Treatment

Pityriasis rosea often requires no treatment unless patients are symptomatic. In darker-skinned individuals, more aggressive management may be indicated because dyspigmentation of lesions may result. While well-designed clinical trials have not demonstrated highly effective treatments, most dermatologists recommend UVB treatments or a short course of prednisone for severe or severely symptomatic cases. For mild to moderate cases, topical corticosteroids of medium strength (triamcinolone 0.1%) and oral antihistamines may be used if pruritus is bothersome. The role of macrolide antibiotics is not evidence-based.

Prognosis

Pityriasis rosea is usually an acute self-limiting illness that typically disappears in about 6 weeks, although prolonged variants have been reported.

SEBORRHEIC DERMATITIS

ESSENTIALS OF DIAGNOSIS

- Dry scales and underlying erythema.
- Scalp, central face, presternal, interscapular areas, umbilicus, and body folds.

General Considerations

Seborrheic dermatitis is an acute or chronic dermatitis that often coexists with psoriasis and is associated with inflammation due to *Malassezia* species.

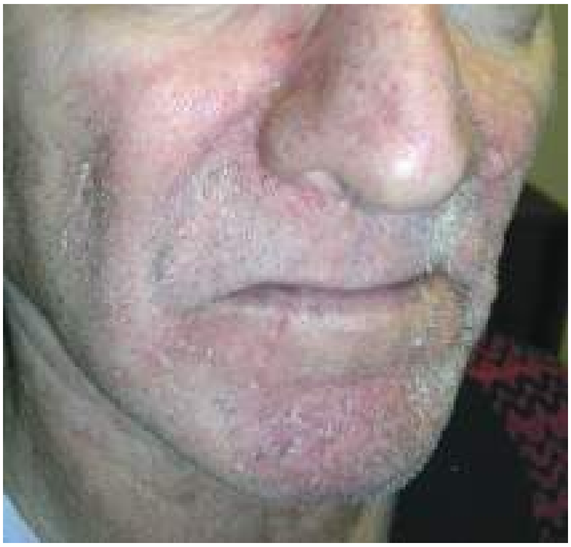

Figure 6–25. **Close-up of seborrheic dermatitis showing flaking skin and erythema around the beard region.** (Reproduced, with permission, from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine*, 2nd ed. McGraw-Hill, 2013.)

Clinical Findings

The scalp, face, chest, back, umbilicus, eyelid margins, genitalia, and body folds have dry scales (dandruff) or oily yellowish scurf (Figure 6–25). Pruritus is a variable finding. Patients with Parkinson disease, patients with HIV, and patients who become acutely ill often have seborrheic dermatitis.

Differential Diagnosis

There is a spectrum from seborrheic dermatitis to scalp psoriasis. Extensive seborrheic dermatitis may simulate intertrigo in flexural areas, but scalp, face, and sternal involvement suggests seborrheic dermatitis.

Treatment

A. Seborrhea of the Scalp

Shampoos that contain zinc pyrithione or selenium are used daily if possible. These may be alternated with ketoconazole shampoo (1% or 2%) used twice weekly. A combination of shampoos is used in refractory cases. Tar shampoos are also effective for milder cases and for scalp psoriasis. Topical corticosteroid solutions or lotions are then added if necessary and are used twice daily. (See treatment for scalp psoriasis, above.)

B. Facial Seborrheic Dermatitis

The mainstay of therapy is a mild corticosteroid (hydrocortisone 1%, alclometasone, desonide) used intermittently and not near the eyes. If the disorder cannot be controlled with intermittent use of a mild topical corticosteroid alone, ketoconazole 2% cream is added twice daily. Topical tacrolimus and pimecrolimus are steroid-sparing alternatives and may be more effective than antifungal therapy.

C. Seborrheic Dermatitis of Nonhairy or Intertriginous Areas

Low-potency corticosteroid creams (ie, 1% or 2.5% hydrocortisone, desonide, or alclometasone dipropionate) are highly effective when applied twice daily for 5–7 days and then once or twice weekly for maintenance as necessary. Selenium lotion, ketoconazole, or clotrimazole gel or cream may be a useful adjunct. Tacrolimus or pimecrolimus topically can obviate the use of corticosteroids in chronic cases. Roflumilast foam 0.3%, a topical (phosphodiesterase-4) PDE-4 inhibitor, was approved in 2023 for the treatment of seborrheic dermatitis in people aged 9 and older. It can be used on all affected areas of the body, including hair-bearing areas.

D. Involvement of Eyelid Margins

"Marginal blepharitis" usually responds to gentle cleaning of the lid margins nightly as needed, with undiluted baby shampoo or eyelid cleanser using a cotton swab.

Prognosis

The tendency is for lifelong recurrences. Individual outbreaks may last weeks, months, or years.

Blauvelt A et al. Roflumilast foam 0.3% for adolescent and adult patients with seborrheic dermatitis: a randomized, double-blinded, vehicle-controlled, phase 3 trial. J Am Acad Dermatol. 2024;90:986. [PMID: 38253129]

LICHEN PLANUS

ESSENTIALS OF DIAGNOSIS

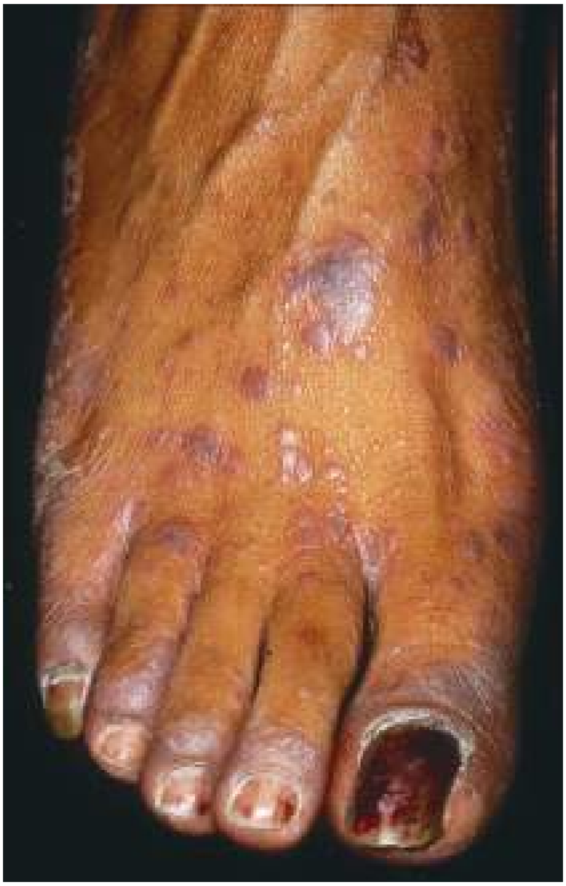
- Pruritic, violaceous, flat-topped papules with fine white streaks and symmetric distribution.
- Lacy or erosive lesions of the buccal, vulvar, and vaginal mucosa; nail dystrophy.
- Commonly seen along linear scratch marks (Koebner phenomenon) on anterior wrists, penis, and legs.
- Diagnostic histopathology.

General Considerations

Lichen planus is an inflammatory pruritic disease of the skin and mucous membranes characterized by distinctive papules with a predilection for the flexor surfaces and trunk. The prevalence in the United States is 0.39%. The three cardinal findings are typical skin lesions, mucosal lesions, and histopathologic features of band-like infiltration of lymphocytes in the upper dermis. Allergy to mercury and other metal-containing amalgams can trigger oral lesions identical to lichen planus.

Clinical Findings

The lesions are violaceous, flat-topped, angulated papules, up to 1 cm in diameter, discrete or in clusters (Figure 6–26), with very fine white streaks (Wickham striae) on the flexor surfaces of the wrists and ankles; on lower back; and on mucous membranes, including the penis, lips, tongue, buccal, vulvar, vaginal, esophageal, and anorectal mucosa. Itching is mild to severe. The papules may become bullous or eroded. The disease may be generalized. Mucous membrane lesions have a lacy white network overlying them that may be confused with leukoplakia. The presence of oral and vulvovaginal lichen planus in the same patient is common. Patients with both these mucous membranes involved are at much higher risk for esophageal lichen planus. Lichen planus is also a cause of alopecia and nail dystrophy. The Koebner phenomenon (appearance of lesions in areas of trauma) may be seen.



▲ **Figure 6–26.** Lichen planus. (Used, with permission, from TG Berger, MD, Dept Dermatology, UCSF.)

A special form of lichen planus is the erosive or ulcerative variety, a major problem in the mouth or genitalia. Squamous cell carcinoma develops in up to 5% of patients with erosive oral or genital lichen planus and may occur in esophageal lichen planus. There is also an increased risk of squamous cell carcinoma developing in lesions of hypertrophic lichen planus on the lower extremities.

Differential Diagnosis

Lichen planus must be distinguished from similar lesions produced by medications and other papular lesions, such as psoriasis, lichen simplex chronicus, graft-versus-host disease, and syphilis. Lichen planus on the mucous membranes must be differentiated from leukoplakia. Erosive oral lesions require biopsy and often direct immunofluorescence for diagnosis since lichen planus may simulate other erosive diseases, especially autoimmune blistering diseases that involve the oral mucosa.

Treatment

A. Topical Therapy

Superpotent topical corticosteroids applied twice daily are most helpful for localized disease in nonflexural areas. Alternatively, high-potency corticosteroid cream or ointment may be used nightly under thin, pliable plastic film.

Topical tacrolimus appears effective in oral and vaginal erosive lichen planus, but long-term therapy is required to prevent relapse. If tacrolimus is used, lesions must be observed carefully for development of squamous cell carcinoma. Since absorption can occur through mucous membranes, serum tacrolimus levels should be checked at least once if widespread mucosal application (> 5–10 cm^2) is used. If the erosive oral lichen planus lesions are adjacent to a metal-containing amalgam, removal of the amalgam may result in clearing of the erosions.

B. Systemic Therapy

NB-UVB, bath PUVA, oral PUVA, and the combination of an oral retinoid plus PUVA (re-PUVA) are all forms of phototherapy that can improve lichen planus. Hydroxychloroquine (5 mg/kg once daily), acitretin (10–25 mg orally daily), cyclosporine (3–5 mg/kg orally daily), and mycophenolate mofetil (1–3 g orally daily) can also be effective in mucosal and cutaneous lichen planus. Apremilast, oral JAK inhibitors, and anti-IL-12/23 and anti-IL-17 agents have been used with success in refractory cases. Systemic corticosteroids may be required in severe cases or in circumstances where the most rapid response to treatment is desired. Unfortunately, relapse almost always occurs as the corticosteroids are tapered, making this therapy an impractical option for the management of chronic lichen planus.

Prognosis

Lichen planus is a benign disease, but it may persist for months or years and may be recurrent. Hypertrophic lichen planus and oral lesions tend to be especially persistent, and neoplastic degeneration has been described in chronically eroded lesions.

CUTANEOUS LUPUS ERYTHEMATOSUS

ESSENTIALS OF DIAGNOSIS

- Localized violaceous red plaques, usually on the head (discoid lupus erythematosus) or the trunk.
- Scaling, follicular plugging, atrophy, dyspigmentation, and telangiectasia of involved areas.
- Photosensitivity.
- Distinctive histology.

General Considerations

Common forms of cutaneous lupus include chronic cutaneous lupus erythematosus (CCLE), of which discoid lupus erythematosus (DLE) is the most common subtype, and erythematous nonscarring red plaques of subacute cutaneous lupus erythematosus (SCLE). All occur most frequently in photoexposed areas. Permanent hair loss and loss of pigmentation are common sequelae of discoid lesions.

SLE is discussed in Chapter 23. Patients with SLE frequently have acute cutaneous lupus erythematosus (ACLE) lesions but may also have CCLE or SCLE lesions. Ten percent of patients with SLE have discoid skin lesions, and 5% of patients with discoid lesions have SLE.

Clinical Findings

A. Symptoms and Signs

Symptoms are usually mild. In DLE, the lesions consist of violaceous-to-red, well-defined, single or multiple plaques, 5–20 mm in diameter, usually on the face, scalp, and external ears (conchal bowl). In discoid lesions, there is atrophy, telangiectasia, central depigmentation or scarring, a hyperpigmented rim, and follicular plugging. On the scalp, significant permanent hair loss may occur. In SCLE, the lesions are erythematous annular or psoriasiform plaques up to several centimeters in diameter and favor the upper chest and back.

B. Laboratory Findings

In patients with DLE, SLE should be considered if the following findings are present: positive ANA, or other serologic studies (eg, anti-double-stranded DNA or anti-Smith antibody), high ESR, proteinuria, hypocomplementemia, widespread lesions (not localized to the head), nail fold changes (dilated or thrombosed nail fold capillary loops), or arthralgias with or without arthritis. Patients with marked photosensitivity and symptoms otherwise suggestive of lupus may have negative ANA tests but are positive for antibodies against Ro/SSA or La/SSB (SCLE).

Differential Diagnosis

The diagnosis is based on the clinical appearance confirmed by skin biopsy in all cases. In DLE, the scale is dry and “thumbtack-like” and thus distinguished from that of seborrheic dermatitis and psoriasis. Older lesions have hyperpigmented borders, depigmented central scarring, or areas of hair loss that also differentiate lupus from these diseases. A number of medications may induce SCLE with a positive Ro/SSA.

Treatment

A. General Measures

Use photoprotective clothing and broad-spectrum sunblock of SPF of 30 or higher daily. UVA coverage is essential in photosensitive patients. Avoid radiation therapy or medications that are potentially photosensitizing when possible.

B. Local Treatment

For limited lesions, the following should be tried before systemic therapy: high-potency corticosteroid creams applied each night and covered with airtight, thin, pliable plastic film (eg, Saran Wrap); flurandrenolide (Cordran) tape; or ultra–high-potency corticosteroid cream or ointment applied twice daily without occlusion.

C. Local Infiltration

Triamcinolone acetonide suspension, 2.5–10 mg/mL, may be injected into DLE lesions once a month.

D. Systemic Treatment

1. Antimalarials—These medications should be used only when the diagnosis is secure because they have been associated with flares of psoriasis, which is in the differential diagnosis.

a. Hydroxychloroquine sulfate—Daily dose of no more than 5 mg/kg orally for several months may be effective and is often used prior to chloroquine. A minimum 3-month trial is recommended. Screening for ocular toxicity is needed.

b. Chloroquine sulfate—250 mg orally daily may be effective in some cases when hydroxychloroquine is not.

2. Isotretinoin—Isotretinoin, 1 mg/kg/day orally, is effective in hypertrophic DLE lesions.

3. Thalidomide—Thalidomide is effective in refractory cases in doses of 50–300 mg orally daily. Monitor for neuropathy. Lenalidomide (5–10 mg orally daily) may also be effective with less risk for neuropathy.

Isotretinoin, thalidomide, and lenalidomide are teratogens and should be used with appropriate contraception and monitoring in women of childbearing age.

Prognosis

The disease is persistent but not life-endangering unless systemic lupus is present. Treatment with one or more antimalarials is effective in more than half of cases. Patients with cutaneous lupus erythematosus should be examined and tested annually (CBC and UA) to screen for early signs of systemic involvement. Although the only morbidity may be cosmetic, this can have significant quality of life impact in more darkly pigmented patients with widespread disease. Scarring alopecia can be prevented or lessened with close attention and aggressive therapy. Over years, DLE tends to become inactive. Drug-induced SCLE usually resolves over months when the inciting medication is stopped.

VESICULAR & BLISTERING DERMATOSES

CONTACT DERMATITIS

ESSENTIALS OF DIAGNOSIS

- Erythema and edema, with pruritus, vesicles, bullae, weeping, or crusting.
- **Irritant contact dermatitis:** occurs only in area of direct contact with irritant.
- **Allergic contact dermatitis:** extends beyond area of direct contact with allergen; positive patch test.

General Considerations

Contact dermatitis (irritant or allergic) is an acute or chronic dermatitis that results from direct skin contact with chemicals or allergens. Eighty percent of cases are due to excessive exposure to or additive effects of universal irritants (eg, soaps, detergents, organic solvents) and are called **irritant contact dermatitis**. The most common causes of **allergic contact dermatitis** are poison ivy or poison oak, topically applied antimicrobials (especially bacitracin and neomycin), anesthetics (benzocaine), preservatives, jewelry (nickel), rubber, essential oils, propolis (from bees), vitamin E, and adhesive tape. Occupational exposure is an important cause of allergic contact dermatitis.

Clinical Findings

A. Symptoms and Signs

1. Allergic contact dermatitis—The acute phase is characterized by intense pruritus, tiny vesicles, and weepy and crusted lesions (Figure 6–27). The lesions, distributed on exposed parts or in unusual asymmetric patterns, consist of erythematous macules, papules, and vesicles and may occur beyond the contact area, distinguishing it from irritant dermatitis. The affected area may also be edematous and warm with honey-colored crusting, simulating—and at times complicated by—bacterial or viral infection. The pattern of the eruption may be diagnostic (eg, typical linear streaked vesicles on the extremities in poison oak or ivy dermatitis). The location often suggests the cause: scalp involvement suggests hair dyes or shampoos; face involvement suggests creams, cosmetics, soaps, shaving materials, nail polish; and neck involvement suggests jewelry, hair dyes. Reactions may not develop for 48–72 hours after exposure.

2. Irritant contact dermatitis—The rash is erythematous and scaly (less likely vesicular) and occurs only in the direct sites of contact with the irritant. Resolving or chronic contact dermatitis presents with scaling, erythema, and possibly thickened skin. Itching, burning, and stinging may be severe in both allergic and irritant contact

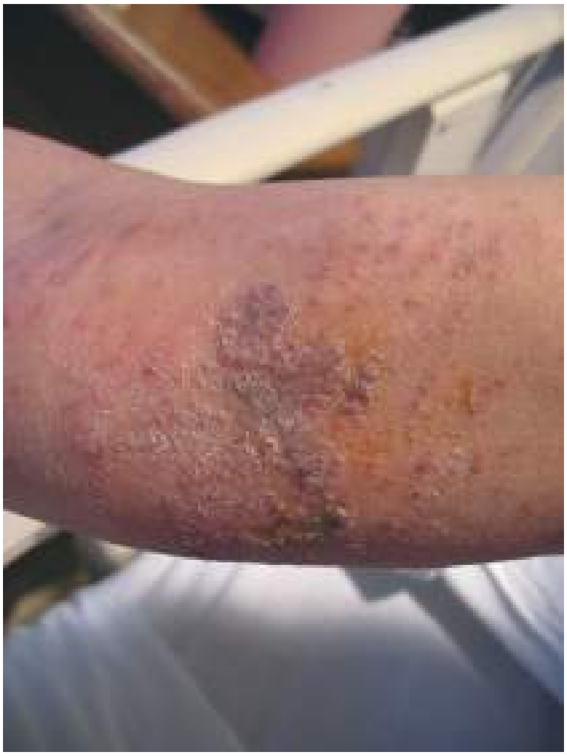

Figure 6–27. Allergic contact dermatitis to an adhesive dressing in a patient with darker skin. Key features are erythematous papules with impetigo-like honey-colored crusting. (Used, with permission, from Kanade Shinkai, MD.)

dermatitis. Reactions may develop within 24 hours of contact exposure.

B. Laboratory Findings

Gram stain and culture will rule out impetigo or secondary infection (impetiginization). After the episode of allergic contact dermatitis has cleared, patch testing may be useful if the triggering allergen is not known.

Differential Diagnosis

Asymmetric distribution, blotchy erythema around the face, linear lesions, and a history of exposure help distinguish acute contact dermatitis from other skin lesions. The most commonly mistaken diagnosis is impetigo, herpetic infection, or cellulitis. Chronic allergic contact dermatitis must be differentiated from scabies, particularly if itching is generalized, atopic dermatitis, and pompholyx.

Prevention

Removal of the causative oil by washing with liquid soap may be effective if done within 30 minutes after exposure to poison oak or ivy. Goop (oil remover) and Tecnu (chemical inactivator) have similar efficacy but are more expensive. Over-the-counter barrier creams may be effective when applied prior to exposure and prevent/reduce the severity of the dermatitis.

The mainstay of prevention is identification of the agent causing the dermatitis and strict avoidance of exposure or use of protective clothing and gloves. Some allergens will transmit through latex gloves. In industry-related cases, prevention may require special accommodations or retraining the worker.

Treatment

A. Overview

Localized involvement (except on the face) can often be managed solely with topical agents. While local measures are important, severe or widespread involvement is difficult to manage without systemic corticosteroids because even the highest-potency topical corticosteroids seem not to work well on vesicular and weepy lesions. **Irritant contact dermatitis** is treated by protection from the irritant and use of topical corticosteroids as for atopic dermatitis (described above). The treatment of **allergic contact dermatitis** is detailed below.

B. Local Measures

1. Acute weeping dermatitis—Gentle cleansing and drying compresses (such as Domeboro) are recommended. Calamine lotion or zinc oxide paste may be used between wet dressings, especially for involvement of intertriginous areas or when oozing is not marked. Lesions on the extremities may be bandaged with wet dressings for 30–60 minutes several times a day. High-potency topical corticosteroids in gel or cream form (eg, fluocinonide, clobetasol, or halobetasol) may help suppress acute contact dermatitis and relieve itching. This treatment should be followed by tapering of the number of applications per day or use of a mid-potency corticosteroid, such as triamcinolone 0.1% cream, to prevent rebound of the dermatitis. A soothing formulation is 2 oz of 0.1% triamcinolone acetonide cream in 7.5 oz Sarna lotion (0.5% camphor, 0.5% menthol, 0.5% phenol) mixed by the patient.

2. Subacute dermatitis (subsiding)—Mid-potency (triamcinolone 0.1%) to high-potency corticosteroids (clobetasol, fluocinonide, desoximetasone) are the mainstays of therapy.

3. Chronic dermatitis (dry and lichenified)—High-potency to superpotency corticosteroids are used in ointment form. Occlusion may be helpful on the hands.

C. Systemic Therapy

For acute severe cases, prednisone may be given orally for 12–21 days. Prednisone, 60 mg for 4–7 days, 40 mg for 4–7 days, and 20 mg for 4–7 days, without a further taper is one useful regimen. The key is to use enough corticosteroid (and as early as possible) to achieve a clinical effect and to taper slowly over 2–3 weeks to avoid rebound.

Prognosis

Allergic contact dermatitis is self-limited if re-exposure is prevented but often takes 2–3 weeks for full resolution. Removal of the causative agent is paramount to avoid recurrences.

POMPHOLYX

ESSENTIALS OF DIAGNOSIS

- Pruritic "tapioca" vesicles of 1–2 mm on the palms, soles, and sides of fingers.
- Vesicles may coalesce to form multiloculated blisters.
- Scaling and fissuring may follow drying of the blisters.
- Appearance in the third decade, with lifelong recurrences.

General Considerations

Pompholyx, or vesiculobullous dermatitis of the palms and soles, is formerly known as dyshidrosis or dyshidrotic eczema. About half of patients have an atopic background, and many patients report flares with stress. Patients with

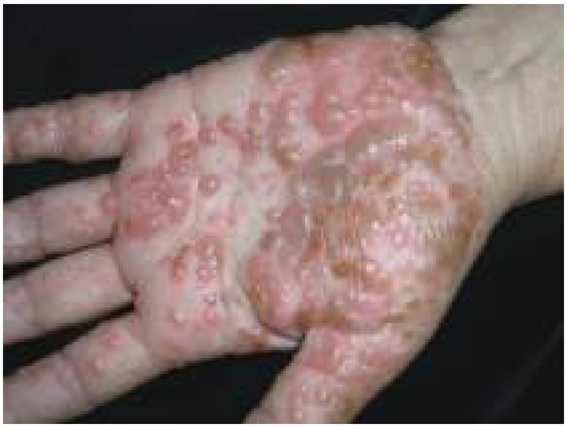

Figure 6–28. Severe pompholyx. (Reproduced, with permission, from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine*, 2nd ed. McGraw-Hill, 2013.)

widespread dermatitis due to any cause may develop pompholyx-like eruptions as a part of an autoeczematization response.

Clinical Findings

Small clear vesicles resembling grains of tapioca stud the skin at the sides of the fingers and on the palms (Figure 6–28) and may also affect the soles, albeit less frequently. They may be associated with intense itching. Later, the vesicles dry and the area becomes scaly and fissured.

Differential Diagnosis

Unroofing the vesicles and examining the blister roof with a KOH preparation will reveal hyphae in cases of bullous tinea. Patients with inflammatory tinea pedis may have a vesicular autoeczematization of the palms. NSAIDs may produce an eruption very similar to that of vesiculobullous dermatitis on the hands.

Prevention

There is no known way to prevent attacks if the condition is idiopathic. About one-third to one-half of patients with vesiculobullous hand dermatitis have a relevant contact allergen, especially nickel. Patch testing and avoidance of identified allergens can lead to improvement.

Treatment

Topical and systemic corticosteroids help some patients dramatically; however, systemic corticosteroids are generally not appropriate therapy. A high-potency topical corticosteroid used early may help abort the flare and ameliorate pruritus. Topical corticosteroids are also important in treating the scaling and fissuring that are seen after the vesicular phase. It is essential that patients avoid anything that irritates the skin; they should wear cotton gloves inside vinyl gloves when doing dishes or other wet chores and use a hand cream after washing the hands. Patients respond to UVB therapy and injection of botulinum toxin into the palms as for hyperhidrosis.

Prognosis

For most patients, the disease is an inconvenience. For some, vesiculobullous hand eczema can be incapacitating.

PORPHYRIA CUTANEA TARDA

ESSENTIALS OF DIAGNOSIS

- Noninflammatory blisters on sun-exposed sites, especially the dorsal surfaces of the hands.
- Hypertrichosis, skin fragility.
- Associated liver disease.
- Elevated urine porphyrins.

General Considerations

Porphyria cutanea tarda is the most common type of porphyria. Cases are sporadic or hereditary. The disease is associated with ingestion of certain medications (eg, estrogens) and alcoholic liver disease, hemochromatosis, and hepatitis C.

Clinical Findings

A. Symptoms and Signs

Patients report painless blistering and fragility of the skin of the dorsal surfaces of the hands (Figure 6–29). Facial hypertrichosis and hyperpigmentation are common.

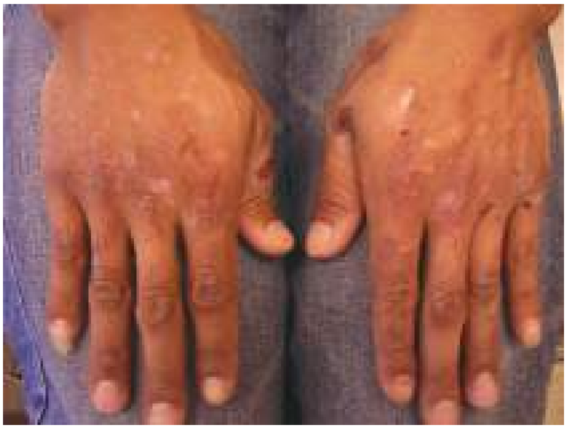

Figure 6–29. Porphyria cutanea tarda of hands in a patient with darker skin. (Used, with permission, from Kanade Shinkai, MD.)

B. Laboratory Findings

Urinary uroporphyrins are elevated twofold to fivefold above coproporphyrins. Patients may also have abnormal liver biochemical tests, evidence of hepatitis C infection, increased liver iron stores, and hemochromatosis gene mutations.

Differential Diagnosis

Skin lesions identical to those of porphyria cutanea tarda may be seen in patients who undergo dialysis and in those who take certain medications (tetracyclines, voriconazole, and NSAIDs, especially naproxen). In this so-called pseudoporphyria, the biopsy results are the same as those associated with porphyria cutanea tarda, but urine porphyrins are normal.

Prevention

Photoprotective clothing is required. The lesions are triggered by sun exposure, but the wavelength of light triggering the lesions is beyond that absorbed by sunscreens.

Treatment

Stopping all triggering medications and reducing or stopping alcohol consumption may lead to improvement in most cases. Phlebotomy at a rate of 1 unit every 2–4 weeks will gradually lead to improvement. Very low-dose antimalarial medication (as low as 200 mg of hydroxychloroquine orally twice weekly), alone or in combination with phlebotomy, increases porphyrin excretion and improves the skin disease. Deferasirox, an iron chelator, can also be beneficial. Treatment is continued until the patient is asymptomatic. Urine porphyrins may be monitored.

Prognosis

Most patients improve with treatment. Sclerodermoid skin lesions may develop on the trunk, scalp, and face.

DERMATITIS HERPETIFORMIS

Dermatitis herpetiformis is an uncommon disease manifested by intensely pruritic papules, vesicles, and papulovesicles mainly on the elbows, knees, buttocks, posterior neck, and scalp. The histopathology is distinctive. Circulating antibodies to tissue transglutaminase are present in 90% of cases. Three-fourths of patients have gluten-sensitive enteropathy with villous atrophy on small bowel biopsy; however, GI symptoms are subclinical in most. Ingestion of gluten is the cause of dermatitis herpetiformis, and strict long-term avoidance of dietary gluten may eliminate the need for treatment or decrease the dose of dapsone (initial treatment dose is 100–200 mg orally daily) required to control the disease.

Lovell KK et al. Dapsone use in dermatology. Am J Clin Dermatol. 2024;25:811. [PMID: 39078587]

PEMPHIGUS

ESSENTIALS OF DIAGNOSIS

- Relapsing crops of bullae, often fragile and leading to erosions.
- Often preceded by mucous membrane bullae, erosions, and ulcerations.
- Superficial detachment of the skin after pressure or trauma variably present (Nikolsky sign).
- Acantholysis on biopsy.
- Immunofluorescence studies and serum ELISA for pathogenic antibodies are confirmatory.

General Considerations

Pemphigus is an uncommon intraepidermal blistering disease occurring on skin and mucous membranes. It is caused by autoantibodies to adhesion molecules expressed in the skin and mucous membranes. The bullae appear spontaneously and are tender and painful when they rupture. Drug-induced pemphigus has been reported. There are several forms of pemphigus: pemphigus vulgaris and its variant, pemphigus vegetans; and the more superficially blistering pemphigus foliaceus and its variant, pemphigus erythematosus. All forms may present at any age but most commonly in middle age. The vulgaris form begins in the mouth in over 50% of cases. The foliaceus form may be associated with other autoimmune diseases or may be drug-induced. Paraneoplastic pemphigus, a unique form of the disorder, is associated with numerous benign and malignant neoplasms, most frequently chronic lymphocytic leukemia, Castleman disease, B cell lymphoma, plasmacytoma, and thymoma. Associated bronchiolitis obliterans is characteristic.

Clinical Findings

A. Symptoms and Signs

Pemphigus is characterized by an insidious onset of flaccid bullae, crusts, and erosions in crops or waves (Figure 6–30). In pemphigus vulgaris, lesions often appear first on the oral mucous membranes. These rapidly become erosive. The scalp is another site of early involvement. Rubbing a cotton swab or finger laterally on the surface of uninvolved skin may cause easy separation of the epidermis (Nikolsky sign). Downward pressure on a

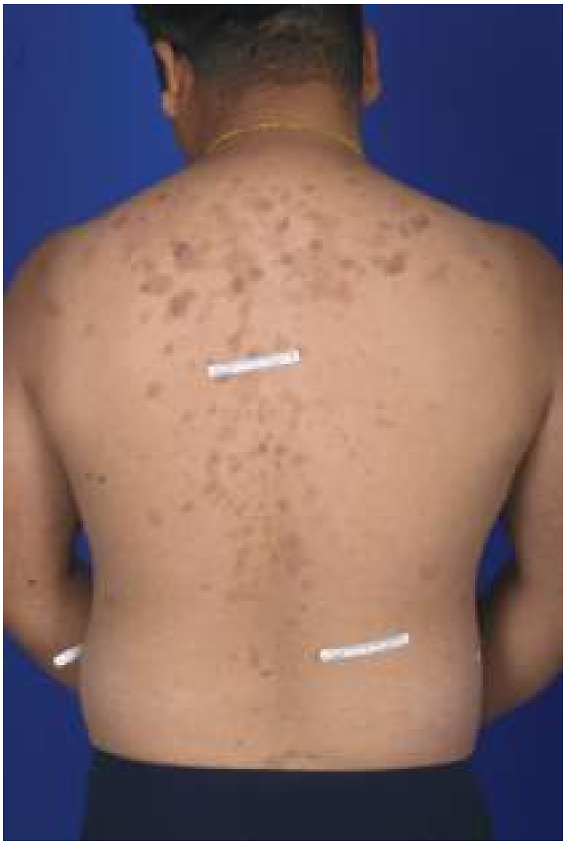

Figure 6–30. Pemphigus vulgaris on the back. (Reproduced, with permission, from Kelly AP, Taylor SC, Lim HW, Serrano AMA. *Taylor and Kelly's Dermatology for Skin of Color*, 2e. McGraw-Hill; 2016.)

fresh bulla may cause lateral spread (Asboe-Hansen sign). Pemphigus vegetans presents as erosive vegetating plaques, most often in intertriginous areas. Pemphigus foliaceus is a superficial form of pemphigus where cutaneous lesions present as flaccid bullae that quickly evolve into superficial erosions and thin pink plaques with overlying scale. Pemphigus erythematosus has overlapping features of pemphigus foliaceus and lupus erythematosus. It presents with flaccid bullae that develop overlying scale and crust in a photodistributed area. Mucosal lesions are rare with both pemphigus foliaceus and pemphigus erythematosus. Paraneoplastic pemphigus is histologically and immunologically distinct from other forms of the disease. Oral lesions predominate and cutaneous erythematous plaques resembling erythema multiforme are characteristic. Survival rates are low because of the underlying malignancy.

B. Laboratory Findings

The diagnosis is made by light microscopy, direct and indirect immunofluorescence (IIF) microscopy, and ELISA to detect autoantibodies to intercellular adhesion molecules (desmoglien 1 and 3).

Differential Diagnosis

Blistering diseases include erythema multiforme, Stevens-Johnson syndrome (SJS)/toxic epidermal necrolysis (TEN), drug eruptions, bullous impetigo, contact dermatitis, dermatitis herpetiformis, and bullous pemphigoid, but flaccid blisters are not typical of these diseases, and acantholysis is not seen on biopsy. All these diseases have clinical characteristics and immunofluorescence test results that distinguish them from pemphigus. Pemphigus foliaceus must be distinguished from subacute cutaneous lupus erythematosus.

Complications

Secondary infection commonly occurs; this is a major cause of morbidity and mortality. Disturbances of fluid, electrolyte, and nutritional intake can occur as a result of painful oral ulcers.

Treatment

A. General Measures

Patients with severe disease should be hospitalized at bed rest and provided intravenous antibiotics and feedings as indicated. Anesthetic troches used before eating ease painful oral lesions.

B. Systemic Measures

Pemphigus requires systemic therapy as early in its course as possible. Initial therapy is with prednisone 1–2 mg/kg orally daily. In all but the mildest cases, a steroid-sparing agent is added from the beginning, since the disease course is long and the steroid-sparing agents take several weeks to exert their activity. Rituximab (1 g intravenously on days 1 and 15 as induction therapy followed by 500 mg intravenously every 6 months as maintenance therapy) is FDA approved for the treatment of pemphigus vulgaris, associated with induction of a complete remission, and considered by many experts to be first-line therapy. Repeated courses are efficacious and well tolerated in patients who do not achieve complete remission or relapse. Azathioprine (2–4 mg/kg orally daily) and mycophenolate mofetil (1–3 g orally daily) are other therapeutic options. In refractory cases, monthly intravenous immunoglobulin (IVIG) (2 g/kg intravenously over 3–4 days), pulse intravenous corticosteroids, cyclophosphamide, or plasmapheresis can be used.

C. Local Measures

In patients with limited disease, skin and mucous membrane lesions should be treated with topical corticosteroids. Secondary infection requires appropriate systemic and local antibiotic therapy.

Prognosis

Without antibiotic or corticosteroid treatment, the disease is fatal within 5 years. The course tends to be chronic in most patients; however, up to one-third experience remission. Infection is the most frequent cause of death, usually from *S aureus* septicemia.

BULLOUS PEMPHIGOID

Bullous pemphigoid is a relatively benign pruritic disease characterized by tense blisters in flexural areas, usually remitting in 5 or 6 years, with a course characterized by exacerbations and remissions. Most affected persons are over the age of 60 and men are affected twice as frequently as women. The appearance of blisters may be preceded by pruritic urticarial or edematous lesions for months. Oral lesions are present in one-third of cases. The disease may occur in various forms, including localized, vesicular, vegetating, erythematous, erythrodermic, and nodular. Drugs may induce bullous pemphigoid. The most common offender is furosemide. Immunotherapy for malignancies with PD-1 inhibitors can cause drug-induced bullous pemphigoid.

The diagnosis is made by biopsy with direct immunofluorescence examination and serum antibody testing. Light microscopy shows a subepidermal blister. With direct immunofluorescence, IgG and C3 are found at the dermal-epidermal junction. ELISA tests for bullous pemphigoid antibodies (BP 180 or BP 230) are 87% sensitive and 95% specific. If the patient has mild disease, ultrapotent topical corticosteroids may be adequate. Prednisone (0.5–1 mg/kg orally daily) is often used to achieve rapid control of more widespread disease. Doxycycline (100 mg orally twice a day), alone or combined with nicotinamide (500 mg orally three times daily)—not nicotinic acid or niacin—may control the disease in patients with mild to moderate disease who cannot use corticosteroids or may allow for decreasing or eliminating corticosteroids after control is achieved. Dapsone (50–200 mg orally daily) is particularly effective in mucous membrane pemphigoid. If these medications are not effective, methotrexate (5–25 mg orally weekly), azathioprine (2–4 mg/kg orally daily), or mycophenolate mofetil (1–3 g orally daily) may be used as steroid-sparing agents. Intravenous immunoglobulin, rituximab, omalizumab, and dupilumab have been used with success in refractory cases.

PUSTULAR DISORDERS

ACNE VULGARIS

ESSENTIALS OF DIAGNOSIS

- Almost universal in puberty; may begin in premenarchal girls and present or persist into the fourth or fifth decade.
- Comedones are the hallmark. Severity varies from comedonal to papular or pustular inflammatory acne to cysts or nodules.
- Face, neck, and upper trunk may be affected.
- Scarring may be a sequela of the disease or picking by the patient.

General Considerations

Acne vulgaris is polymorphic. Open and closed comedones, papules, pustules, and cysts are found.

In younger persons, acne vulgaris is more common and more severe in males. Acne may persist into adulthood. Twelve percent of women and 3% of men over age 25 have acne vulgaris. This rate does not decrease until the fourth or fifth decade of life. The skin lesions parallel sebaceous activity. Pathogenic events include plugging of the infundibulum of the follicles, retention of sebum, overgrowth of the acne bacillus (*Cutibacterium acnes*) with resultant release of and irritation by accumulated fatty acids, and foreign-body reaction to extrafollicular sebum. Antibiotics may help control acne because of their antibacterial or anti-inflammatory properties.

Hyperandrogenism may be a cause of acne in women and may be accompanied by hirsutism or irregular menses. Polycystic ovary syndrome (PCOS) is the most common identifiable cause. Acne may develop in patients who use systemic corticosteroids or topical fluorinated corticosteroids on the face. Acne may be exacerbated or caused by cosmetic creams or oils as well as androgenic supplements or masculinizing hormone therapy in transgender individuals.

Clinical Findings

There may be mild tenderness, pain, or itching. The lesions occur mainly over the face, neck, upper chest, back, and shoulders. Comedones (tiny, flesh-colored, white or black noninflamed superficial papules that give the skin a rough texture or appearance) are the hallmark of acne vulgaris. Inflammatory papules, pustules, ectatic pores, acne cysts, and scarring are also seen (Figure 6–31).

Acne may have different presentations at different ages. Preteens often present with comedones as their first lesions. Inflammatory lesions in young teenagers are often found in the middle of the face, extending outward as the patient becomes older. Adult females may present with comedonal or papular lesions especially on the chin and jawline.

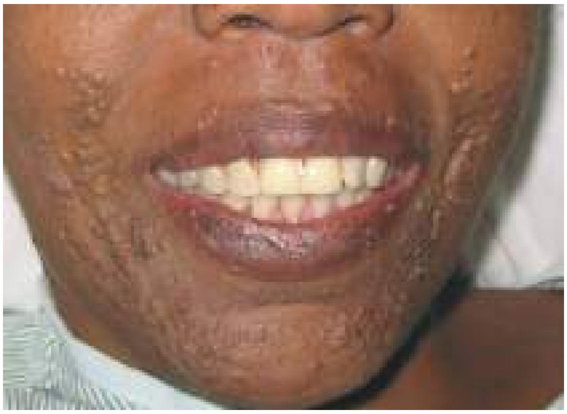

Figure 6–31. Acne vulgaris. Extensive comedones and hyperpigmented macules are present in patient with dark skin. (Used, with permission, from Kanade Shinkai, MD.)

Differential Diagnosis

In adults, rosacea presents with papules and pustules in the middle third of the face, but absence of truncal involvement, telangiectasia, flushing, and the absence of comedones distinguish rosacea from acne vulgaris. A pustular eruption on the face in patients receiving antibiotics or with otitis externa should be investigated with culture to rule out a gram-negative folliculitis. Pustules on the face can also be caused by dermatophytic or demodex infection. Lesions on the back are more problematic. When they occur alone, staphylococcal folliculitis, miliaria ("heat rash") or, uncommonly, *Pityrosporum* folliculitis should be suspected. Bacterial culture, trial of an antistaphylococcal antibiotic, and observing the response to therapy will help in the differential diagnosis. In patients with HIV infection, folliculitis is common and may be either staphylococcal folliculitis or eosinophilic folliculitis (typically pruritic tumid papules on the face and neck).

Complications

Cyst formation, pigmentary changes, scarring, and poor quality of life may result.

Treatment

A. General Measures

1. Education of the patient—Education on proper use of medications and cosmetics is paramount. Because lesions take 4–6 weeks to improve, clinical improvement should be measured by the number of new lesions forming after 6–8 weeks of therapy. Additional time (3–4 months) will be required to see improvement on the back and chest, as these areas are slowest to respond. Avoid topical exposure to oils, cocoa butter (theobroma oil), and greases in cosmetics, including hair products. Scarring may occur with or without the patient manipulating the lesions. It is essential that the patient be educated in a supportive way about this complication. Anxiety and depression are common in patients with excoriated acne.

2. Diet—A low glycemic diet has been associated with improvement and lower incidence of acne. This improvement was associated with a reduction in insulin resistance. Hyperinsulinemia has also been associated with acne in both eumenorrheic women and individuals with PCOS.

B. Comedonal Acne

Treatment of acne is based on the type and severity of lesions. Comedones require treatment different from that of pustules and cystic lesions. In assessing severity, take the sequelae of the lesions into account. An individual who gets only a few new lesions per month that scar or leave postinflammatory hyperpigmentation must be treated much more aggressively than a comparable patient whose lesions clear without sequelae. Hygiene plays little role in acne treatment, and a mild soap is almost always recommended. The agents effective in comedonal acne are listed below in the order in which they should be tried.

1. Topical retinoids—Tretinoin is very effective for comedonal and papular acne, but its usefulness is limited by irritation. Start with 0.025% cream (not gel) and have the patient use it at first twice weekly at night, increasing frequency to nightly as tolerated. A few patients cannot tolerate this low-strength preparation more than three times weekly, which may still promote improvement. A lentil-sized amount is sufficient to cover the entire face. To avoid irritation, have the patient wait 20 minutes after washing to apply. For patients irritated by standard tretinoin preparations, other options are adapalene gel 0.1% and reformulated tretinoin (Renova, Retin A Micro, Avita). Although the absorption of tretinoin is minimal, its use during pregnancy is contraindicated. Patients should be warned that their acne may flare in the first 4 weeks of treatment.

2. Benzoyl peroxide—Benzoyl peroxide products are available in concentrations of 2.5%, 4%, 5%, 8%, and 10%, but 2.5% is as effective as 10% and less irritating. In general, water-based and not alcohol-based gels should be used to decrease irritation. Single formulations of benzoyl peroxide in combination with several other topical agents, including adapalene and topical antibiotics (erythromycin, clindamycin phosphate), are available.

C. Papular or Cystic Inflammatory Acne

Brief treatment (3 weeks to 3 months) with topical or oral antibiotics is the mainstay for treatment of inflammatory acne that does not respond to topical therapy with retinoids or benzoyl peroxide. Topical clindamycin phosphate and erythromycin are used only for mild papular acne or for patients who refuse or cannot tolerate oral antibiotics. To decrease resistance, benzoyl peroxide should be used in combination with the topical antibiotic.

1. Mild acne—The first choice of topical antibiotics in terms of efficacy and relative lack of induction of resistant *C acnes* is the combination of erythromycin or clindamycin with benzoyl peroxide topical gel or wash (Table 6–2). These may be used once or twice daily. The addition of tretinoin cream or gel at night, or topical clascoterone cream twice daily, may increase improvement since they work via a different mechanism. Topical retinoids should be used for long-term maintenance therapy.

2. Moderate acne—Common oral antibiotics used for acne include doxycycline (100 mg twice daily), minocycline (50–100 mg once or twice daily), TMP-SMZ (one double-strength tablet twice daily), or a cephalosporin (cefadroxil or cephalexin 500 mg twice daily), which should be used in combination with benzoyl peroxide to minimize development of antibiotic resistance. Sarecycline, a narrow-spectrum tetracycline-class antibiotic dosed by weight at 1.5 mg/kg once daily, is another option that is generally well-tolerated, but its high current cost makes it less preferred compared to the aforementioned antibiotics. It may take 3 months or more for truncal acne to resolve with oral antibiotic treatment. In general, discontinuing antibiotics immediately without adjunctive topical therapy results in prompt recurrence. Topical retinoids are excellent for long-term maintenance following antibiotics. Subantimicrobial dosing of doxycycline (40–50 mg orally daily) can be used in patients who require long-term systemic therapy. Combination oral contraceptives or spironolactone (50–200 mg orally daily) are highly effective alternatives in women with treatment-resistant acne. Tetracycline, minocycline, and doxycycline are contraindicated in pregnancy, but certain oral erythromycins or cephalosporins may be used.

3. Severe acne—

A. Isotretinoin—A vitamin A analog, isotretinoin is used for the treatment of severe acne that has not responded to conventional therapy. An oral dosage of 0.5–1 mg/kg/day for 20 weeks for a cumulative dose of at least 120 mg/kg is usually adequate for treating and preventing the recurrence of severe cystic acne. Patients should be offered isotretinoin therapy before they experience significant acne scarring. *Isotretinoin is absolutely contraindicated during pregnancy because of its teratogenicity.* Two forms of effective contraception must be used; abstinence is an acceptable alternative. Informed consent must be obtained before its use, and patients must be enrolled in a monitoring program (iPledge). In addition to its teratogenicity, isotretinoin has numerous side effects and should only be prescribed by clinicians well aware of these issues. Cheilitis, dry skin, and photosensitivity are almost universal side effects. Consider ordering laboratory tests, including triglyceride levels and liver enzyme tests (particularly ALT, which is the most liver-specific enzyme), in patients before treatment and after achieving therapeutic dosing; monitoring through the entire treatment may not be high value. Monthly pregnancy testing is required for individuals of childbearing potential.

Abnormal laboratory tests, especially elevated liver enzymes and triglyceride levels, return to normal quickly upon conclusion of therapy. The medication may induce long-term remissions in up to 70% of persons, or acne may recur that is more easily controlled with conventional therapy. Occasionally, a second course is needed if acne does not respond or recurs.

B. Intralesional injection—Intralesional injection of dilute suspensions of triamcinolone acetonide (2.5 mg/mL, 0.05 mL per lesion) will often hasten the resolution of deeper papules and occasional cysts.

C. Scar revision—Cosmetic improvement may be achieved by excision and punch-grafting of deep scars and by physical or chemical abrasion of inactive acne lesions, particularly flat, superficial scars.

Prognosis

Acne vulgaris eventually remits spontaneously, but when this will occur cannot be predicted. The condition may persist throughout adulthood and may lead to severe scarring if left untreated. Patients treated with antibiotics continue to improve for the first 3–6 months of therapy. Relapse during treatment may suggest the emergence of resistant *C acnes*. The disease is chronic and tends to flare intermittently despite treatment. Remissions following systemic treatment with isotretinoin may be lasting in up to 70% of cases. Relapses after isotretinoin usually occur within 3 years and require a second course in up to 20% of patients.

ROSACEA

ESSENTIALS OF DIAGNOSIS

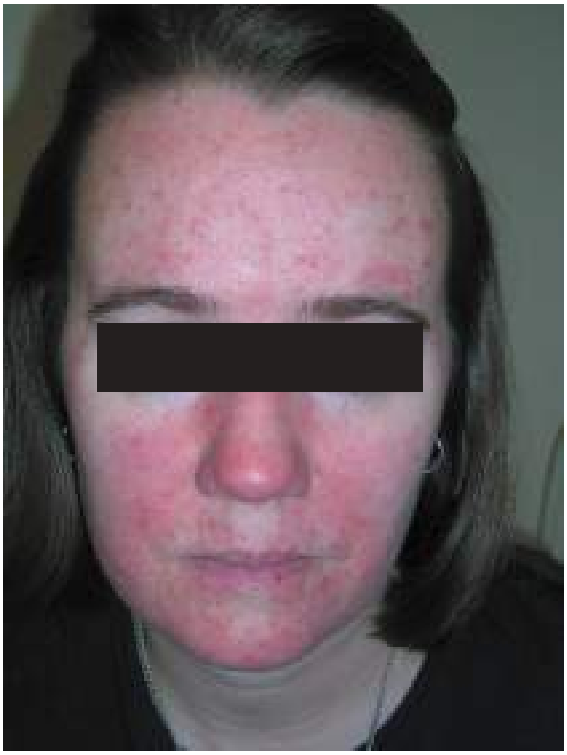
- A chronic disorder affecting the face.
- Neurovascular component: erythema and telangiectasis and a tendency to flush easily.
- Acneiform component: papules and pustules may be present.
- Glandular component: sebaceous hyperplasia and fibrosis of affected areas (eg, rhinophyma).

General Considerations

Rosacea is a common condition that presents in adulthood. The pathogenesis of this chronic disorder is not known. Topical corticosteroids applied to the face can induce rosacea-like conditions.

Clinical Findings

Patients frequently report flushing or exacerbation of their rosacea due to heat, hot drinks, spicy food, sunlight, exercise, alcohol, emotions, or menopausal flushing.



▲ **Figure 6–32.** Rosacea in a 34-year-old woman showing erythema, papules, and pustules covering much of the face. (Reproduced, with permission, from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine*, 2nd ed. McGraw-Hill, 2013.)

The cheeks, nose, chin, and ears—at times the entire face—may be affected. No comedones are seen. In its mildest form, erythema and telangiectasias are seen on the cheeks. Inflammatory papules may be superimposed on this background and may evolve to pustules (Figure 6–32). Associated seborrhea may be found. Some patients describe burning or stinging with episodes of flushing and extremely cosmetic-intolerant skin. Patients may have associated ophthalmic disease, including blepharitis, keratitis, and chalazion, which often requires topical or systemic antibiotic or immunosuppressive therapy.

Differential Diagnosis

Rosacea is distinguished from acne by the presence of the neurovascular component and the absence of comedones. Lupus is often misdiagnosed, but the presence of pustules excludes that diagnosis.

Treatment

Educating patients to avoid the factors they know to produce exacerbations is important. Patients should wear a broad-spectrum mineral-based sunscreen; zinc- or titanium-based sunscreens are tolerated best. Medical management is most effective for the inflammatory papules and pustules and the erythema that surrounds them. Rosacea is usually a lifelong condition, so maintenance therapy is required. Most treatments target the papulopustular and cystic components. Only certain topical agents (brimonidine and oxymetazoline) and laser benefit erythema. Telangiectasias are benefited by laser therapy, and phymatous overgrowth of the nose can be treated by surgical reduction. Rhinophyma must be managed using surgical reduction.

A. Local Therapy

Avoidance of triggers (especially alcohol and spicy or hot foods) and drinking ice water may be effective in reducing facial erythema and flushing. Metronidazole (cream, gel, or lotion), 0.75% applied twice daily or 1% applied once daily, and ivermectin 1% cream applied once daily are effective topical treatments. Another effective treatment includes topical clindamycin (solution, gel, or lotion) 1% applied twice daily. Response is noted in 4–8 weeks. Sulfur-sodium sulfacetamide-containing topicals are helpful in patients only partially responsive to topical antibiotics. Topical retinoids or topical tacrolimus ointment (0.1%) can be carefully added for maintenance. Topical brimonidine tartrate gel 0.33% or oxymetazoline 1% cream can temporarily reduce the erythema, and laser treatment has longer-term benefit for erythema.

B. Systemic Therapy

Oral tetracyclines should be used when topical therapy is inadequate. Minocycline or doxycycline, 50–100 mg orally once or twice daily, is effective. Metronidazole or amoxicillin, 250–500 mg orally twice daily, or rifaximin, 400 mg orally three times daily (for 10 days), may be used in refractory cases. Side effects are few, although metronidazole may cause a disulfiram-like effect when the patient ingests alcohol and neuropathy with long-term use. Long-term maintenance with subantimicrobial dosing of minocycline or doxycycline is recommended once the initial flare of rosacea has resolved. Isotretinoin may succeed where other measures fail. A dosage of 0.5–1 mg/kg/day orally for 12–28 weeks is recommended, although very low-dose isotretinoin may also be effective. See precautions above.

Prognosis

Rosacea tends to be a persistent process. With the regimens described above, it can usually be controlled adequately.

HIDRADENITIS SUPPURATIVA

ESSENTIALS OF DIAGNOSIS

- Chronic, recurrent, painful deep-seated nodules, abscesses, draining sinus tracts, and scars.
- Lesions typically involve axillae, inguinal areas, submammary folds, and perianal area.
- Often associated with obesity.

General Considerations

Hidradenitis suppurativa (HS) is a chronic inflammatory skin condition that significantly impairs patients' quality of life. It is typified by recurrent painful nodules, abscesses, and draining sinus tracts primarily in intertriginous areas. Obesity is commonly associated with HS, and significant weight loss may lead to marked improvement. HS can produce disfigurement, embarrassment, mental health disorders, and work/social impairment.

Clinical Findings

Lesions include deep-seated nodules, abscesses, and sinus tracts that rupture and form scars. Pain is common and can be severe, disabling, or both. Lesions most frequently occur in the axillae and inguinal areas, but may also favor the submammary folds, perineal area, buttocks, mons pubis, scalp, postauricular area, and the back. A clinical diagnosis of HS is based upon three criteria: characteristic lesions, predilection for flexural sites, and lesion recurrence. There are multiple scoring systems used to assess disease severity, with the Hurley system most frequently used. The severity and psychosocial impact of HS are major factors in determining optimal treatment.

Differential Diagnosis

HS is commonly misdiagnosed as folliculitis, furunculosis/carbunculosis, or cutaneous abscess(es). As such, there is often a significant delay (average of 7 years) between symptom onset and the establishment of the correct diagnosis.

Treatment

The treatment of HS has been difficult because of continued uncertainty regarding the disease pathophysiology. Established successful therapies included anti-inflammatory agents, antibiotics, and surgery. New therapies that specifically target cytokines involved in HS pathogenesis have been recently identified. Weight loss and smoking cessation counseling should be recommended.

A. Mild Disease

For patients with mild disease (ie, Hurley stage 1), antibiotic monotherapy is often used as first-line treatment because HS lesions frequently are colonized with bacteria, and antibiotics have anti-inflammatory properties. Most commonly utilized are topical clindamycin 1% (applied twice daily) or oral doxycycline (100 mg twice daily). Therapy of up to 3 months is required to achieve maximal efficacy. Additionally, a combination of antibacterial soap, warm compresses, and sodium dusidate 2% ointment can decrease lesion size and symptoms.

Surgical and other procedural interventions are another treatment option. Deroofing or laser treatment can improve symptoms. Incision and drainage can be used in the acute setting for the treatment of painful, fluctuant abscesses.

B. Moderate to Severe Disease

Moderate to severe HS (Hurley stages 2 or 3) is difficult to treat with antibiotic monotherapy or surgical intervention alone. Such patients may be best managed with systemic therapies in partnership with a dermatologist. The TNF inhibitor adalimumab and the IL-17 inhibitor secukinumab are approved by the FDA for treatment of moderate to severe HS. Maximal efficacy usually requires 3–6 months of continuous therapy. Additional non–FDA-approved biologic agents that can be considered include other TNF inhibitors (infliximab, etanercept, golimumab), IL-17 inhibitors (bimekizumab, ixekizumab), IL-12/23 inhibitors (ustekinumab), the IL-1 inhibitor anakinra, and oral JAK inhibitors (specifically, tofacitinib).

Non-biologic systemic therapies may be used alone or in conjunction with other treatments. These include combination oral clindamycin/rifampin 300 mg/300 mg twice daily for at least 10 weeks, intravenous ertapenem 1 g daily for about 2 months, intralesional or oral corticosteroids (or both), and oral retinoids (isotretinoin, acitretin). In women, hormonal agents can be considered, including spironolactone, oral contraceptives, finasteride, and dutasteride. Laser therapy and surgery can be helpful in the treatment of moderate to severe HS. Wide excision is the only treatment that is potentially curative.

Prognosis

The course of HS is generally chronic, unpredictable, and often refractory to treatment. Patients should be monitored for metabolic syndrome and other comorbidities (eg, IBD). Monitoring for infection, other adverse events, and complications of systemic therapy is required.

MILIARIA (Heat Rash)

ESSENTIALS OF DIAGNOSIS

- Burning, itching, superficial aggregated, small vesicles, papules, or pustules on covered areas of the skin, usually the trunk.
- More common in hot, moist climates.
- Rare forms associated with fever and even heat prostration.

General Considerations

Miliaria occurs most commonly on the trunk and intertriginous areas. A hot, moist environment is the most frequent cause. Occlusive clothing, fever while bedridden, and medications that enhance sweat gland function (eg, clonidine, β-blockers, opioids) may increase the risk. Plugging of the ostia of sweat ducts occurs, with ultimate rupture of the sweat duct, producing an irritating, stinging reaction.

Clinical Findings

The usual symptoms are burning and itching. The histologic depth of sweat gland obstruction determines the clinical presentation: miliaria crystallina in the superficial (subcorneal) epidermis, miliaria rubra in the deep epidermis, and miliaria profunda in the dermis. The lesions consist of small (1–3 mm) nonfollicular lesions. Subcorneal thin-walled, discrete clear fluid-filled vesicles are termed "miliaria crystallina." When fluid is turbid and lesions present as vesicopustules or pustules, they are called miliaria pustulosa. Miliaria rubra (prickly heat) presents as pink papules. Miliaria profunda presents as nonfollicular skin-colored papules that develop after multiple bouts of miliaria rubra. In a hospitalized patient, the reaction virtually always affects the back.

Differential Diagnosis

Miliaria is to be distinguished from a drug eruption and folliculitis.

Prevention

Use of a topical antibacterial preparation, such as chlorhexidine, prior to exposure to heat and humidity may help prevent the condition. Frequent turning or sitting of the hospitalized patient may reduce miliaria on the back.

Treatment

The patient should keep cool and wear light clothing. A mid-potency corticosteroid (triamcinolone acetonide, 0.1%) in a lotion or cream may be applied two to four times daily. Secondary infections (superficial pyoderma) are treated with appropriate antistaphylococcal antibiotics. Anticholinergic medications (eg, glycopyrrolate 1 mg orally twice a day or topically applied) may be helpful in severe cases.

Prognosis

Miliaria is usually a mild disorder, but severe forms (tropical anhidrosis and asthenia) result from interference with the heat-regulating mechanism.

ERYTHEMAS

REACTIVE ERYTHEMAS

URTICARIA & ANGIOEDEMA

ESSENTIALS OF DIAGNOSIS

- Evanescent wheals or hives with or without angioedema.
- Intense itching; very rarely, pruritus may be absent.
- Urticaria is divided into acute and chronic forms.
- Most episodes are acute and self-limited (1–2 weeks).
- Chronic urticaria (lasting > 6 weeks) may have an autoimmune basis.

General Considerations

Urticaria involves hives, angioedema, or both. It may be acute or chronic (more than 6-week duration). Chronic urticaria is further divided into chronic spontaneous urticaria and chronic inducible urticaria. Chronic inducible urticaria is reproducibly triggered by specific exposures. Examples include cholinergic urticaria, solar urticaria, cold urticaria, dermatographism, and delayed pressure urticaria. True urticaria should be differentiated from diseases that present with similar lesions that are not true urticaria (eg, adult-onset Still disease, urticarial vasculitis, and cryopyrin-associated periodic syndromes). Some patients with chronic spontaneous urticaria demonstrate autoantibodies directed against mast cell IgE receptors.

Clinical Findings

A. Symptoms and Signs

Lesions are itchy, red swellings of a few millimeters to many centimeters (Figure 6–33). The morphology of the lesions may vary over a period of minutes to hours, resulting in geographic or bizarre patterns. Individual lesions in true urticaria last < 24 hours and often only 2–4 hours. Angioedema is involvement of deeper subcutaneous tissue with swelling of the lips, eyelids, palms, soles, and genitalia. **Angioedema is no more likely than urticaria to be**

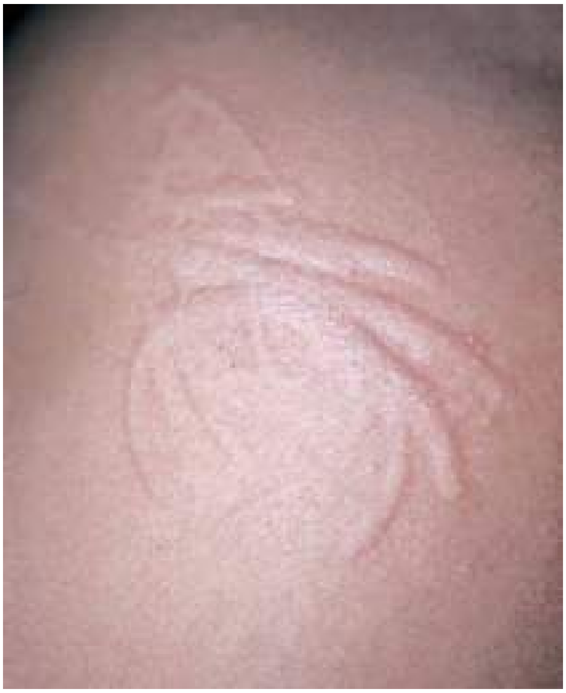

Figure 6–33. Urticaria. (Used, with permission, from TG Berger, MD, Dept Dermatology, UCSF.)

associated with systemic complications, such as laryngeal edema or hypotension. Dermatographism is induced by scratching the skin and can be elicited during the clinic visit. The wheals of cholinergic urticaria are 2–3 mm in diameter with a large surrounding red flare.

B. Laboratory Findings

The most common causes of acute urticaria are foods, upper respiratory infections, and medications. The cause of chronic spontaneous urticaria is often not found. Although laboratory studies are not generally helpful in the evaluation of acute or chronic urticaria, a CBC with differential, ESR, CRP, TSH, and liver biochemical tests may be appropriate for some patients with chronic urticaria. Elevated inflammatory markers suggest an alternate diagnosis. In patients with individual lesions that persist past 24 hours, skin biopsy may confirm neutrophilic urticaria or urticarial vasculitis. A functional ELISA test looking for antibodies against the high-affinity receptor for IgE (Fc-Epislon RI) can identify those who may have an autoimmune basis for their chronic urticaria.

Differential Diagnosis

Papular urticaria resulting from insect bites persists for days. A central punctum can usually be seen. Streaked urticarial lesions may be seen in the 24–48 hours before blisters appear in acute allergic plant dermatitis, eg, poison ivy, oak, or sumac. Urticarial responses to heat, sun, water, and pressure are quite rare. Urticarial vasculitis is defined as cutaneous vasculitis where the skin lesions clinically mimic urticaria. Lesions last longer than 24 hours and often sting or burn rather than itch. Patients do not respond to antihistamines. Urticarial vasculitis may be caused by viral hepatitis and may be seen as part of serum sickness. In hereditary angioedema, there is generally a positive family history and GI or respiratory symptoms. Wheals are not part of the syndrome, and the angioedema is not pruritic.

Treatment

A. General Measures

The etiology of acute urticaria is found in less than half of cases. The etiology of chronic urticaria is found in even fewer cases. In general, a careful history and physical examination are helpful, but extensive costly workups for chronic spontaneous urticaria are not indicated. Patients with chronic autoimmune urticaria may have other autoimmune diseases and be more difficult to treat. In cases of chronic inducible urticaria, exposure to physical factors, such as heat, cold, sunlight, pressure, heat induced by exercise, excitement, and hot showers, should be modulated.

B. Systemic Treatment

The mainstay of treatment initially includes H_1-antihistamines, often starting with second-generation antihistamines. Second-generation H_1-antihistamines include fexofenadine (180 mg orally once daily) or cetirizine or loratadine (10 mg orally daily). Less than 40% of chronic urticaria cases respond to standard H_1-blockade, and higher doses of second-generation antihistamines (up to four times the standard recommended dose) increase the likelihood of response to therapy to 60%. Combining antihistamines (eg, fexofenadine plus cetirizine) at these higher doses can be done safely to achieve remission in refractory cases. First-generation H_1-antihistamines such as hydroxyzine, 10–25 mg orally two or three times daily, or as a single nightly dose of 25–75 may be added to this regimen.

Cyproheptadine, 4 mg orally four times daily, may be especially useful for cold urticaria.

Doxepin (a tricyclic antidepressant with potent antihistaminic properties), 10–75 mg orally at bedtime, can be very effective in chronic urticaria. It has anticholinergic side effects and is sedating.

If a skin biopsy of a lesion of chronic urticaria identifies neutrophils as a significant component of the inflammatory infiltrate, dapsone or colchicine (or both) may be useful.

Although systemic corticosteroids will usually suppress acute and chronic urticaria, corticosteroids are rarely indicated and should be avoided if possible, as, once withdrawn, urticaria recurs. Omalizumab is approved for the treatment of refractory chronic urticaria and should be considered when severe chronic urticaria fails to respond to high-dose antihistamines. Dupilumab, cyclosporine (3–5 mg/kg/day), mycophenolate mofetil (1–3 g daily), and other immunosuppressives may be effective in severe cases of chronic urticaria.

C. Local Treatment

Local treatment is rarely rewarding.

Prognosis

Acute urticaria usually lasts only a few days to weeks. Half of patients whose urticaria persists for longer than 6 weeks will have it for years.

ERYTHEMA MULTIFORME/STEVENS-JOHNSON SYNDROME/TOXIC EPIDERMAL NECROLYSIS

ESSENTIALS OF DIAGNOSIS

Erythema multiforme

- Herpes simplex is most common cause.
- Cutaneous lesions are true three-ring targets.
- Presents on the extensor surfaces, palms, soles, or mucous membranes.
- Disease remains localized.

Stevens-Johnson syndrome and toxic epidermal necrolysis

- Stevens-Johnson syndrome: < 10% body surface area (BSA) detachment.
- Stevens-Johnson syndrome/toxic epidermal necrolysis overlap: 10–30% BSA detachment.
- Toxic epidermal necrolysis: > 30% BSA detachment.
- Medications are most common cause.
- Cutaneous lesions are targetoid but often not true three-ring targets.
- Favors the trunk.
- Involves two or more mucous membranes.
- May progress to significant BSA involvement and may be life-threatening.

General Considerations

Erythema multiforme is an acute inflammatory skin disease that was traditionally divided into minor and major types based on the clinical findings. Approximately 90% of cases of erythema multiforme minor follow outbreaks of herpes simplex and are preferably termed "herpes-associated erythema multiforme." The term "erythema multiforme major" has largely been abandoned.

SJS is defined as atypical target lesions with < 10% BSA detachment; TEN is defined as lesions with > 30% BSA detachment; and patients with SJS/TEN overlap have between 10% and 30% BSA detachment. The abbreviation SJS/TEN is often used to refer to these three variants of what is considered one syndrome. SJS/TEN is characterized by toxicity and involvement of two or more mucosal surfaces (often oral and conjunctival but can involve any mucosal surface, including respiratory epithelium). SJS/TEN is most often caused by oral (rarely topical) medications, especially sulfonamides, NSAIDs, allopurinol, and anticonvulsants. In certain races, polymorphisms of antigen-presenting major histocompatibility (MHC) loci increase the risk for the development of SJS/TEN. *Mycoplasma pneumoniae* may trigger a mucocutaneous reaction with skin and oral lesions closely resembling SJS in children/young adults that tends not to progress to TEN-like disease and carries an overall good prognosis.

Clinical Findings

A. Symptoms and Signs

A classic target lesion, as in herpes-associated erythema multiforme, consists of three concentric zones of color change, predominantly on acral surfaces (hands, feet, elbows, and knees) (Figure 6–34). SJS/TEN presents with raised purpuric target-like lesions, with only two zones of color change and a central blister, or nondescript reddish or purpuric macules favoring the trunk and proximal upper extremities (Figure 6–35). Pain on eating, swallowing, and urination can occur if relevant mucosae are involved.

B. Laboratory Findings

Skin biopsy is diagnostic. Direct immunofluorescence studies are negative. Blood tests are not useful for diagnosis.

Differential Diagnosis

Urticaria and drug eruptions are the chief entities that must be differentiated from erythema multiforme. In true

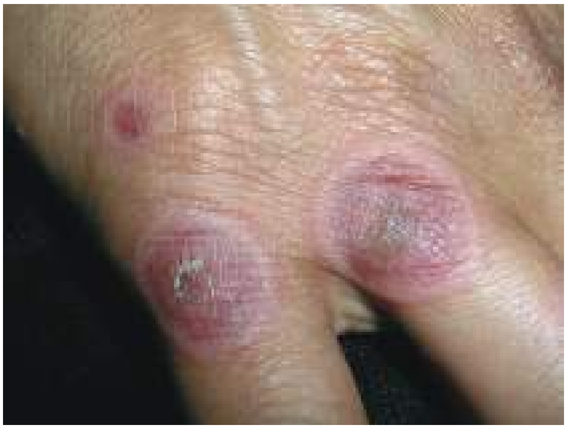

Figure 6–34. Erythema multiforme with classic target lesions. Note the three zones of color change. (Reproduced, with permission, from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine*, 2nd ed. McGraw-Hill, 2013.)

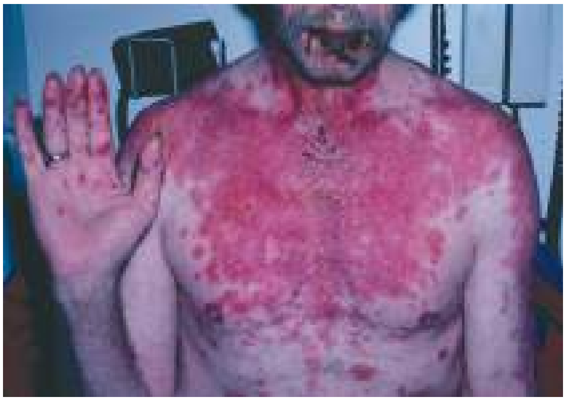

Figure 6–35. Stevens-Johnson syndrome. (Used, with permission, from TG Berger, MD, Dept Dermatology, UCSF.)

urticaria, lesions are not purpuric or bullous, last < 24 hours, and respond to antihistamines. The differential diagnosis of SJS/TEN includes autoimmune bullous diseases (eg, pemphigus vulgaris, bullous pemphigoid, and linear IgA bullous dermatosis), acute SLE, vasculitis, and Sweet syndrome. The presence of a blistering eruption requires biopsy and dermatologic consultation for appropriate diagnosis and treatment.

Complications

The tracheobronchial mucosa, conjunctiva, genital, and urethral mucosa may be involved and may result in scarring in severe cases.

Treatment

A. General Measures

Toxic epidermal necrolysis is best treated in an acute care environment, which may include an ICU or a burn unit. Patients should be admitted if mucosal involvement interferes with hydration and nutrition or extensive blistering develops. Open lesions should be managed like second-degree burns. Immediate discontinuation of the inciting medication (before blistering occurs) is a significant predictor of outcome. Delay in establishing the diagnosis and inadvertently continuing the offending medication results in higher morbidity and mortality.

B. Specific Measures

Oral and topical corticosteroids are useful in the oral variant of erythema multiforme. Oral acyclovir prophylaxis of herpes simplex infections may be effective in preventing recurrent herpes-associated erythema multiforme minor.

The most important aspect of treatment for SJS/TEN is to stop the offending medication and to move patients with > 25–30% BSA involvement to an appropriate acute care environment. Nutritional and fluid support and high vigilance for infection are the most important aspects of care. Reviews of systemic treatments for SJS and TEN have been conflicting. Some data support the use of corticosteroids. If corticosteroids are tried, they should be used early, before blistering occurs, and in high doses (prednisone 1–2 mg/kg/day). IVIG (3–4 g given over 3–4 days) used early in the course has resulted in decreased mortality in some studies. Cyclosporine (3–5 mg/kg/day for 7 days) may also be effective. Etanercept is the treatment of choice in some centers.

C. Local Measures

Topical corticosteroids are not very effective in this disease (except the oral variant).

Prognosis

Erythema multiforme minor usually lasts 2–6 weeks and may recur. SJS/TEN may be serious with a mortality of 30% in cases with > 30% BSA involvement. The ABCD-10 and SCORTEN are severity of illness scales that predict mortality in SJS/TEN.

When to Refer

- Refer to an ophthalmologist when ocular involvement is present because vision loss is a major consequence of SJS/TEN.
- Refer to a urologist, gynecologist, or both when genitourinary involvement is present.

EXFOLIATIVE DERMATITIS
(Exfoliative Erythroderma)

ESSENTIALS OF DIAGNOSIS

- Desquamation and erythema over most of the body.
- Itching, malaise, fever, chills, weight loss.

General Considerations

Erythroderma describes generalized redness of > 90% of the skin surface. Erythroderma may be acute (presenting as erythema without scale) or subacute to chronic (presenting as widespread redness and scaling and referred to as exfoliative erythroderma). A preexisting dermatosis is the cause of exfoliative dermatitis in two-thirds of cases, including psoriasis, atopic dermatitis, contact dermatitis, pityriasis rubra pilaris, and seborrheic dermatitis. Reactions to topical or systemic medications account for 15% of cases, cancer 10% (most commonly cutaneous T-cell lymphoma), idiopathic 10%. Crusted scabies can present as an exfoliative erythroderma and is highly contagious. Without a clear-cut prior history of skin disease or medication exposure, it is often not possible to make a specific diagnosis of the underlying condition at the time of initial presentation. Definitive diagnosis may require continued observation.

Clinical Findings

A. Symptoms and Signs

Symptoms may include itching, weakness, malaise, fever, and weight loss. Chills are prominent. Erythema and desquamation are widespread. Loss of hair and nails can occur. Generalized lymphadenopathy may be due to lymphoma or leukemia or may be reactive. The mucosae are typically spared.

B. Laboratory Findings

A skin biopsy is required and may show changes of a specific inflammatory dermatitis or cutaneous T-cell lymphoma. In Sézary syndrome, helpful findings include peripheral leukocytes with clonal rearrangements of the T-cell receptor and flow cytometry demonstrating a CD4:CD8 ratio > 10:1 and loss of CD4 T cell markers such as CD7 and CD26. Skin biopsy is nonspecific in 50% of cases.

Complications

Protein and electrolyte loss as well as dehydration may develop in patients with generalized inflammatory exfoliative erythroderma; sepsis may occur.

Treatment

A. Topical Therapy

Home treatment is with cool to tepid baths and application of mid-potency corticosteroids under wet dressings or with occlusion with plastic wrap. If the condition becomes unmanageable in an outpatient setting, the patient should be hospitalized.

B. Specific Measures

Stop all medications, if possible. Systemic corticosteroids may provide marked improvement in severe or fulminant exfoliative dermatitis but should be avoided long-term (see Chapter 30). For cases of psoriatic erythroderma and pityriasis rubra pilaris, acitretin, methotrexate, cyclosporine, or a TNF inhibitor may be indicated. Erythroderma secondary to lymphoma or leukemia requires specific topical or systemic chemotherapy. Suitable antibiotic medications with coverage for *Staphylococcus* should be given when there is evidence of bacterial infection.

Prognosis

Careful follow-up may be necessary to identify the cause of exfoliative erythroderma. Most patients improve or recover completely, but some require long-term therapy. Deaths are rare in the absence of cutaneous T-cell lymphoma. A minority of patients will suffer from undiminished erythroderma for indefinite periods.

Pang Y et al. Deciphering the etiologies of adult erythroderma: an updated guide to presentations, diagnostic tools, pathophysiologies, and treatments. Am J Clin Dermatol. 2024;25:927. [PMID: 39348008]

PHOTODERMATITIS

ESSENTIALS OF DIAGNOSIS

- Painful or pruritic erythema, edema, or vesiculation on sun-exposed surfaces (face, neck, hands, and "V" of the chest).
- Inner upper eyelids and area under the chin are spared.

General Considerations

Photodermatitis is a cutaneous reaction to UV radiation. It comprises four groups: (1) primary, idiopathic immunologically mediated photodermatoses; (2) drug- or chemical-induced photodermatoses; (3) dermatoses that are worsened or aggravated by UV exposure; and (4) genetic diseases with mutations predisposing to photodermatitis.

Primary photodermatoses include polymorphic light eruption, chronic actinic dermatitis, and actinic prurigo. Drug- or chemical-induced photodermatitis may be either exogenous or endogenous in origin. Porphyria cutanea tarda and pellagra are examples of endogenous phototoxic dermatoses. Exogenous drug- or chemical-induced photodermatitis manifests either as phototoxicity (a nonimmunologic, UV-induced cytoxic injury presenting as a sunburn-like reaction) or as photoallergy (a true immunologic reaction that presents with dermatitis). There may be some clinical overlap between these two.

Drug-induced phototoxicity is triggered by UVA. The most common medications causing a phototoxic reaction are vemurafenib, NSAIDs, voriconazole, tetracyclines, quinolones, hydrochlorothiazide, amiodarone, and chlorpromazine. Other potent photosensitizers include TMP/SMZ, quinine or quinidine, griseofulvin, eculizumab, topical and systemic retinoids (tretinoin, isotretinoin, acitretin), and calcium channel blockers.

Contact photosensitivity may occur with plants, perfumes, and sunscreens. The sunscreen oxybenzone (a benzophenone) is a common cause of photoallergic dermatitis. Dermatoses that are worsened or aggravated by UV exposure include SLE and dermatomyositis. Three percent of persons with atopic dermatitis, especially middle-aged women, are photosensitive.

Clinical Findings

A. Symptoms and Signs

The acute inflammatory phase of phototoxicity, if severe enough, is accompanied by pain, fever, GI symptoms, malaise, and even prostration. Signs include erythema, edema, and possibly vesiculation and oozing on exposed surfaces. Peeling of the epidermis and pigmentary changes often result. The key to diagnosis is localization of the rash to photoexposed areas, though eruptions may become generalized with time to involve photoprotected areas. The lower lip may be affected.

B. Laboratory Findings

Blood and urine tests are generally not helpful unless porphyria cutanea tarda is suggested by the presence of blistering, scarring, milia (white cysts 1–2 mm in diameter) and skin fragility of the dorsal hands, and facial hypertrichosis. Eosinophilia may be present in chronic photoallergic responses.

Differential Diagnosis

The differential diagnosis is long. If a clear history of the use of a topical or systemic photosensitizer is not available, and if the eruption is persistent, then a workup including biopsy and light testing may be required. Photodermatitis must be differentiated from contact dermatitis that may develop from one of the many substances in sunscreens, as these may often have a similar distribution. Sensitivity to actinic rays may also be part of a more serious condition, such as porphyria cutanea tarda or lupus erythematosus. These disorders are diagnosed by appropriate blood or urine tests. Polymorphous light eruption (PMLE) is a common idiopathic photodermatitis and often has its onset in the third to fourth decades, except in American Indian persons and Latinas/Latinos, in whom it may present in childhood. PMLE is chronic in nature. Transitory periods of spontaneous remission do occur.

Complications

Some individuals continue to chronically react to light even when they are no longer exposed to photosensitizing medications.

Prevention

While sunscreens are useful agents in general and should be used by persons with photosensitivity, patients may react to such low amounts of energy that sunscreens alone may not be sufficient protection against photodermatoses. Sunscreens with an SPF of 30–60 and broad UVA coverage, containing dicamphor sulfonic acid (Mexoryl SX), avobenzone (Parasol 1789), titanium dioxide, and micronized zinc oxide, are especially useful in patients with photoallergic dermatitis. Photosensitivity due to porphyria is not prevented by sunscreens and requires barrier protection (clothing) to prevent outbreaks.

Treatment

A. Specific Measures

Medications should be suspected in cases of photosensitivity even if the particular medication (such as hydrochlorothiazide) has been used for months.

B. Local Measures

When the eruption is vesicular or weepy, treatment is similar to that of any acute dermatitis, using cooling and soothing wet dressings.

Sunscreens should be used as described above. Mid-potency to high-potency topical corticosteroids are of limited benefit in phototoxic reactions but may help in PMLE and photoallergic reactions. Since the face is often involved, close monitoring for corticosteroid side effects is recommended.

C. Systemic Measures

Aspirin may have some value for fever and pain of acute sunburn. Systemic corticosteroids in doses as described for acute contact dermatitis may be required for severe acute photosensitivity reactions. Otherwise, different photodermatoses are treated in specific ways.

Patients with chronic primary photodermatoses may require systemic treatment with hydroxychloroquine (5 mg/kg once daily), dupilumab, or immunosuppressives, such as azathioprine (50–300 mg once daily) or cyclosporine (3–5 mg/kg once daily).

Prognosis

The most common phototoxic sunburn reactions are usually benign and self-limited. PMLE and some cases of photoallergy can persist for years.

DRUG ERUPTION (Dermatitis Medicamentosa)

ESSENTIALS OF DIAGNOSIS

- Usually, abrupt onset of widespread, symmetric erythematous eruption.
- May mimic any inflammatory skin condition.
- Constitutional symptoms (malaise, arthralgia, headache, and fever) may be present.

General Considerations

Rashes are among the most common adverse reactions to medications and occur in 2–3% of hospitalized patients. There are multiple different types of cutaneous reactions to medications. Penicillins, cephalosporins, and NSAIDs are the most common cause of urticarial drug eruptions. Antibiotics, anticonvulsants, allopurinol, and NSAIDs are common causes of maculopapular or morbilliform reactions. Drug-induced hypersensitivity reaction (DIHS) (also known as drug eruption with eosinophilia and systemic symptoms [DRESS] syndrome) is most often caused by anticonvulsants, allopurinol, and sulfonamides. SJS and TEN most commonly occur in response to antibiotics, sulfonamides, anticonvulsants, allopurinol, and NSAIDs. Phenolphthalein, pyrazolone derivatives, tetracyclines, NSAIDs, TMP-SMZ, and barbiturates are the major causes of fixed drug eruptions. Calcium channel blockers are a common cause of pruritus and eczemas in older adults. Immune checkpoint inhibitors and biologic agents can cause a variety of drug reactions.

Certain genetic polymorphisms of antigen-presenting MHC loci increase the risk for the development of severe drug eruptions, including SJS/TEN and DIHS. Pharmacogenetic testing can help predict who is at risk for and therefore should avoid certain medication exposures.

Clinical Findings

A. Symptoms and Signs

Drug eruptions are generally classified as "simple" or "complex," referring to the risk of morbidity and mortality associated with the specific eruption. Simple morbilliform or maculopapular drug eruptions involve an exanthem, usually appear in the second week of medication therapy, and have no associated constitutional symptoms or abnormal laboratory findings. Complex drug eruptions include DIHS and SJS/TEN.

DIHS occurs later than the simple morbilliform drug eruptions with signs and symptoms developing 2–6 weeks after the medication has been started and has associated constitutional symptoms and abnormal laboratory findings. These may include fevers, chills, hematologic abnormalities (especially eosinophilia and atypical lymphocytosis), and abnormal liver or kidney function. Coexistent reactivation of certain viruses, especially HHV-6, but also Epstein-Barr virus, cytomegalovirus, HHV-7, and parvovirus B19, may be present and may be important in the pathogenesis of these complex drug eruptions. Table 6–3 summarizes the types of skin reactions, their appearance and distribution, and the common offenders in each case.

B. Laboratory Findings

Routinely ordered blood work is of no value in the diagnosis of simple drug eruptions, except upon initial evaluation to ensure that there is no systemic involvement. In complex drug eruptions, the CBC, liver biochemical tests, and kidney function tests should be monitored. Skin biopsies may be helpful in making the diagnosis. Serum PCR for HHV-6, HHV-7, Epstein-Barr virus, cytomegalovirus, and parvovirus B19 is sometimes performed.

Differential Diagnosis

Observation after discontinuation, which may be a slow process, helps establish the diagnosis. Rechallenge, though of theoretical value, may pose a danger to the patient and is best avoided.

Complications

Some cutaneous drug reactions may be associated with visceral involvement. The organ systems involved depend on the individual medication or drug class. Most common is an infectious mononucleosis-like illness and hepatitis associated with administration of anticonvulsants. Myocarditis may be a serious complication of drug-induced hypersensitivity syndrome and may present acutely or months after initial rash onset. Months after recovering from DIHS, patients may suffer hypothyroidism or other autoimmune phenomena.

Treatment

A. General Measures

Systemic manifestations are treated as they arise (eg, anemia, icterus, purpura). Antihistamines may be of value in urticarial and angioneurotic reactions. Epinephrine 1:1000, 0.5–1 mL intravenously or subcutaneously, should be used as an emergency measure. In DIHS, corticosteroids are typically required; the most common regimen is oral prednisone, 1–1.5 mg/kg/day, which is tapered slowly over a minimum of 6 weeks, since rapid taper leads to rebound and more recalcitrant disease. In the case of allopurinol-induced DIHS, starting a steroid-sparing agent (eg, mycophenolate mofetil) at the time of prednisone initiation is recommended because allopurinol-induced DIHS tends to rebound after corticosteroid discontinuation. Treatment in this special case often takes up to 12 months.

B. Local Measures

SJS/TEN with extensive blistering eruptions resulting in erosions and superficial ulcerations demands hospitalization and nursing care in an acute care unit. See Erythema Multiforme/Stevens-Johnson Syndrome/Toxic Epidermal Necrolysis, above.

Prognosis

Drug rash usually disappears upon withdrawal of the medication and proper treatment. DIHS may be associated with autoimmune phenomena, including abnormal thyroid function. This can occur months after the hypersensitivity syndrome has resolved.

Calle AM et al. DRESS syndrome: a literature review and treatment algorithm. World Allergy Organ J. 2023;16:100673. [PMID: 37082745]

Table 6–3. Skin reactions due to systemic medications.

Reaction	Appearance	Distribution and Comments	Common Offenders
Allergic vasculitis	The primary lesion is typically a 2–3 mm purpuric papule. Other morphologies include urticaria that lasts over 24 hours, vesicles, bullae, or necrotic ulcers.	Most severe on the legs.	Sulfonamides, phenytoin, propylthiouracil.
Drug exanthem	Morbilliform, maculopapular, exanthematous reactions.	The most common skin reaction to medications. Initially begins on trunk 7–10 days after the medication has been started. Spreads to extremities and begins to clear on the trunk over 3–5 days. In previously exposed patients, the rash may start in 2–3 days. Fever may be present.	Antibiotics (especially ampicillin and TMP-SMZ), sulfonamides and related compounds (including thiazide diuretics, furosemide, and sulfonylurea hypoglycemic agents), and barbiturates.
Drug-related subacute cutaneous lupus erythematosus (Drug-induced SLE rarely produces a skin reaction)	May present with a photosensitive rash, annular lesions, or psoriasis on upper trunk.	Less severe than SLE, sparing the kidneys and CNS. Recovery often follows medication withdrawal.	Diltiazem, etanercept, hydrochlorothiazide, infliximab, lisinopril, terbinafine.
Erythema nodosum	Inflammatory cutaneous nodules.	Usually limited to the extensor aspects of the legs. May be accompanied by fever, arthralgias, and pain.	Oral contraceptives.
Drug-induced hypersensitivity syndrome	Erythroderma	Entire skin surface. Typically associated with elevated liver biochemical tests, eosinophilia, and AKI. Eruption begins between 2 and 6 weeks after first dose of medication.	Allopurinol, sulfonamides, aromatic anticonvulsants, NSAID, dapsone, lamotrigine.
Fixed drug eruptions	Single or multiple demarcated, round, erythematous plaques that often become hyperpigmented.	Recur at the same site when the medication is repeated. Hyperpigmentation, if present, remains after healing.	Antimicrobials, analgesics (acetaminophen, ibuprofen, and naproxen), barbiturates, heavy metals, antiparasitic agents, antihistamines, phenolphthalein.
Lichenoid and lichen planus–like eruptions	Pruritic, erythematous to violaceous polygonal papules that coalesce or expand to form plaques.	May be in photo- or nonphotodistributed pattern.	Carbamazepine, furosemide, hydroxychloroquine, phenothiazines, β-blockers, quinidine, quinine, sulfonylureas, tetracyclines, thiazides, and triprolidine.
Photosensitivity: increased sensitivity to light, often of UVA wavelengths, but may be due to UVB or visible light as well	Sunburn, vesicles, papules in photodistributed pattern.	Exposed skin of the face, the neck, and the backs of the hands and, in women, the lower legs. Exaggerated response to UV light.	Sulfonamides and sulfonamide-related compounds (thiazide diuretics, furosemide, sulfonylureas), tetracyclines, phenothiazines, sulindac, amiodarone, voriconazole, and NSAIDs.
Pigmentary changes	Flat hyperpigmented areas.	Forehead and cheeks (chloasma, melasma). The most common pigmentary disorder associated with drug ingestion. Improvement is slow despite stopping the medication.	Oral contraceptives are the usual cause. Diltiazem causes facial hyperpigmentation that may be difficult to distinguish from melasma.
	Blue-gray discoloration.	Light-exposed areas.	Chlorpromazine and related phenothiazines.

(*continued*)

Table 6–3. Skin reactions due to systemic medications. (continued)

Reaction	Appearance	Distribution and Comments	Common Offenders
	Brown or blue-gray pigmentation.	Generalized.	Heavy metals (silver, gold, bismuth, and arsenic).
	Blue-black patches on the shins.		Minocycline, chloroquine.
	Blue-black pigmentation of the nails and palate and depigmentation of the hair.		Chloroquine.
	Slate-gray color.	Primarily in photoexposed areas.	Amiodarone.
	Brown discoloration of the nails.	Especially in more darkly pigmented patients.	Hydroxyurea.
Pityriasis rosea–like eruptions	Oval, red, slightly raised patches with central scale.	Mainly on the trunk.	Barbiturates, bismuth, captopril, clonidine, methopromazine, metoprolol, metronidazole, and tripelennamine.
Psoriasiform eruptions	Scaly red plaques.	May be located on trunk and extremities. Palms and soles may be hyperkeratotic. May cause psoriasiform eruption or worsen psoriasis.	Antimalarials, lithium, β-blockers, and TNF inhibitors.
SJS/TEN	Target-like lesions. Bullae may occur. Mucosal involvement.	Usually trunk and proximal extremities.	Sulfonamides, anticonvulsants, allopurinol, NSAIDs, lamotrigine.
Urticaria	Red, itchy wheals that vary in size from < 1 cm to many centimeters. May be accompanied by angioedema.	Chronic urticaria is rarely caused by medications.	Acute urticaria: penicillins, NSAIDs, sulfonamides, opioids, and salicylates. Angioedema is common in patients receiving ACE inhibitors and ARBs.

SJS/TEN, Stevens-Johnson syndrome/toxic epidermal necrolysis; TMP-SMZ, trimethoprim-sulfamethoxazole.

MISCELLANEOUS

PRURITUS

Pruritus is the sensation that provokes a desire to scratch. Pruritus as a medical complaint is 40% as common as low back pain. Older Asian men are most significantly affected, with 20% of all health care visits in Asian men over the age of 65 involving the complaint of itch. The quality of life of a patient with chronic pruritus is the same as a patient undergoing hemodialysis. Better understanding of the role of pruritogens (interleukins-31, -4, -13 and thymic stromal lymphopoietin) in the pathophysiology of itch has enabled recent therapeutic advances.

Dry skin is the first cause of itch that should be sought since it is common and easily treated. The next step is to determine whether a primary skin lesion with associated pruritus is present. Examples of primary cutaneous pruritic diseases include scabies, atopic dermatitis, insect bites, pediculosis, contact dermatitis, drug reactions, urticaria, psoriasis, lichen planus, bullous pemphigoid, and fiberglass dermatitis, all of which have recognizable morphologies. The treatment of an underlying primary skin condition usually results in control of the associated pruritus.

Persistent pruritus not explained by cutaneous disease or association with a primary skin eruption should prompt a staged workup for systemic causes. Common causes of pruritus associated with systemic diseases include endocrine disorders (eg, hypo- or hyperthyroidism or hyperparathyroidism), psychiatric disturbances, lymphoma, leukemia, internal malignant disorders, iron deficiency anemia, HIV, hypercalcemia, low vitamin D levels, cholestasis, and some neurologic disorders. Calcium channel blockers can cause pruritus with or without eczema, even years after they have been started, and it may take up to 1 year for pruritus to resolve after the calcium channel blocker has been stopped.

Treatment

The treatment of chronic pruritus can be frustrating. Most cases of pruritus are not mediated by histamine, hence the poor response of many patients to antihistamines. Emollients for dry skin are listed in Table 6–2. Emollient creams (preferred over lotions) should be generously applied from neck to toe immediately after towel drying and again one more time per day. Neuropathic pruritus responds to neurally acting agents, such as gabapentin (starting at 300 mg orally at around 4 PM and a second dose of 600 mg orally at bedtime) or pregabalin (150 mg orally daily). Combinations of antihistamines, doxepin, gabapentin, pregabalin, mirtazapine, and opioid antagonists can be attempted in refractory cases. In cancer-associated and other forms of pruritus, aprepitant 80 mg orally daily for several days can be dramatically effective. Pruritus in conjunction with uremia and hemodialysis and to a lesser degree the pruritus of liver disease may be helped by phototherapy with UVB or PUVA. Difelikefalin is currently the only treatment approved specifically for pruritus associated with CKD in those receiving hemodialysis. Other therapies that may relieve the pruritus of CKD include gabapentin or mirtazapine. Nemolizumab (IL-31 inhibitor) and dupilumab (IL-4/13 inhibitor) are each approved to treat prurigo nodularis.

Prognosis

Elimination of external factors and irritating agents may give complete relief. Pruritus accompanying a specific skin disease will subside when the skin disease is controlled. Pruritus accompanying serious internal disease may not respond to any type of therapy.

ANOGENITAL PRURITUS

ESSENTIALS OF DIAGNOSIS

- Anogenital itching, chiefly nocturnal.
- Skin findings are highly variable, ranging from none to excoriations and inflammation of any degree, including lichenification.

General Considerations

Anogenital pruritus may be due to a primary inflammatory skin disease (intertrigo, psoriasis, lichen simplex chronicus, seborrheic dermatitis, lichen sclerosus), contact dermatitis (soaps, wipes, colognes, douches, and topical treatments), irritating secretions (diarrhea, leukorrhea, or trichomoniasis), infections (candidiasis, dermatophytosis, erythrasma), or oxyuriasis (pinworms). Erythrasma is diagnosed by coral-red fluorescence with Wood light and cured with erythromycin. Squamous cell carcinoma of the anus and extramammary Paget disease are rare causes of genital pruritus.

In pruritus ani, hemorrhoids are often found, and leakage of mucus and bacteria from the distal rectum onto the perianal skin may be important in cases in which no other skin abnormality is found.

Many women experience pruritus vulvae. Pruritus vulvae does not usually involve the anal area, though anal itching may spread to the vulva. In men, pruritus of the scrotum is most commonly seen in the absence of pruritus ani.

Up to one-third of unidentified causes of anogenital pruritus may be due to nerve impingements of the lumbosacral spine, so evaluation of lumbosacral spine disease is appropriate if no skin disorder is identified and topical therapy is ineffective.

Clinical Findings

A. Symptoms and Signs

The only symptom is itching. Physical findings are usually not present, but there may be erythema, fissuring, maceration, lichenification, excoriations, or changes suggestive of candidiasis or tinea.

B. Laboratory Findings

Microscopic examination or culture of tissue scrapings may reveal yeasts or fungi. Stool examination may show pinworms. Radiologic studies may demonstrate lumbar-sacral spinal disease.

Differential Diagnosis

The etiologic differential diagnosis consists of *Candida* infection, parasitosis, local irritation from contactants or irritants, nerve impingement, and other primary skin disorders of the genital area, such as psoriasis, seborrhea, intertrigo, or lichen sclerosus.

Prevention

Instruct the patient in proper anogenital hygiene after treating systemic or local conditions.

Treatment

Treating constipation, preferably with high-fiber management (psyllium), may help. Instruct the patient to use very soft or moistened tissue or cotton after bowel movements and to clean the perianal area thoroughly with cool water if possible. Women should use similar precautions after urinating. Patch testing reveals clinically relevant allergy in about 20% of patients, often to methylchloroisothiazolinone or methylisothiazolinone, preservatives commonly found in “baby wipes” and other personal care products.

Pramoxine cream or lotion or hydrocortisone-pramoxine (Pramosone), 1% or 2.5% cream, lotion, or ointment, is helpful for anogenital pruritus and should be applied after a bowel movement. Topical doxepin cream 5% is similarly effective but may be sedating. Topical calcineurin inhibitors (tacrolimus 0.03%) improve pruritus ani in patients with atopic dermatitis. Underclothing should be changed daily, and in men, the seam of their "boxers" should not rub against or contact the scrotum. Balneol Perianal Cleansing Lotion or Tucks premoistened pads, ointment, or cream may be very useful for pruritus ani. About one-third of patients with scrotal or anal pruritus will respond to capsaicin cream 0.006%. Gabapentin or pregabalin may be helpful in cases where topical therapies have failed. The use of high-potency topical corticosteroids should be avoided in the genital area.

Prognosis

Although benign, anogenital pruritus is often persistent and recurrent.

Balfour A et al. Anogenital pruritus is associated with anxiety, depression, and other psychiatric disorders. Int J Womens Dermatol. 2024;10:e168. [PMID: 38989111]

Rupert J et al. Pruritus: diagnosis and management. Am Fam Physician. 2022;105:55. [PMID: 35029946]

PIGMENTARY DISORDERS

Although the color of skin may be altered by many diseases and agents, the vast majority of patients have either an increase or decrease in pigment secondary to an inflammatory disease, such as acne or atopic dermatitis.

Other pigmentary disorders include those resulting from exposure to exogenous pigments, such as carotenemia, argyria, and tattooing. Other endogenous pigmentary disorders are attributable to metabolic substances (eg, hemosiderin [iron]) in purpuric processes, to homogentisic acid in ochronosis, and bile pigments.

Classification

Disorders of hyper- or hypopigmentation may be considered to be primary or secondary to other disorders. Depigmentation, the absence of all pigment, should be differentiated from hypopigmentation, in which the affected skin is lighter than baseline skin color, but not completely devoid of pigment.

The evaluation of pigmentary disorders is helped by Wood light, which accentuates epidermal pigmentation in hyperpigmented disorders and highlights complete loss of pigment in depigmentating disorders. Depigmentation, as seen in vitiligo, enhances with Wood light examination, whereas postinflammatory hypopigmentation does not.

A. Primary Pigmentary Disorders

1. Hyperpigmentation—The disorders in this category are nevoid, congenital, or acquired. Nevoid and congenital disorders include pigmented nevi, mosaic hyperpigmentation, ephelides (juvenile freckles), and lentigines (senile freckles). Hyperpigmentation due to systemic diseases may be seen in association with Addison disease, vitamin B_{12} deficiency, hemochromatosis, and Wilson disease. Melasma (chloasma) occurs as patterned hyperpigmentation of the face, most commonly as a direct effect of estrogens. It may occur during pregnancy, exposure to oral contraceptives, or be idiopathic. Although more common in women, melasma affects men and persons of all skin tones.

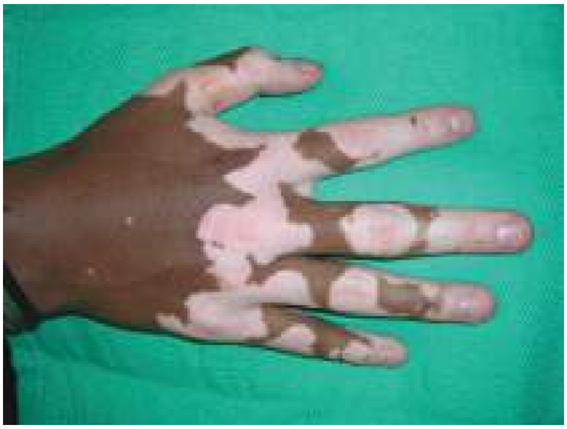

Figure 6–36. Depigmented—vitiligo. (Reproduced, with permission, from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine*, 3rd ed. McGraw-Hill, 2019.)

2. Hypopigmentation and depigmentation—Depigmenting disorders in this category are vitiligo, albinism, and piebaldism. In vitiligo, pigment cells (melanocytes) are destroyed (Figure 6–36). Vitiligo, present in approximately 1% of the population, may be associated with other autoimmune disorders, such as autoimmune thyroid disease, pernicious anemia, diabetes mellitus, and Addison disease.

B. Secondary Pigmentary Disorders

Any damage to the skin (irritation, allergy, infection, excoriation, burns, or dermatologic therapy, such as chemical peels and freezing with liquid nitrogen) may result in hyper- or hypopigmentation. Several disorders of clinical importance are described below.

1. Hyperpigmentation—The most common type of secondary hyperpigmentation occurs after another inflammatory dermatologic condition, such as acne, lichen planus, or eczema, and is most commonly seen in moderately pigmented skin tones. It is called post-inflammatory hyperpigmentation. Hemosiderin deposition, as in stasis dermatitis, may lead to hyperpigmentation that is red-brown in color.

Pigmentation may be produced by certain medications, eg, chloroquine, chlorpromazine, minocycline (Figure 6–37), and amiodarone. Fixed drug eruptions to phenolphthalein (in laxatives), TMP-SMZ, NSAIDs, and tetracyclines also lead to hyperpigmentation, typically in annular patches.

2. Hypopigmentation—Hypopigmentation may complicate atopic dermatitis, lichen planus, psoriasis, discoid lupus, and lichen simplex chronicus. It may also be post-traumatic or iatrogenic (eg, due to the use of superpotent topical corticosteroids) or both. *Clinicians must exercise*

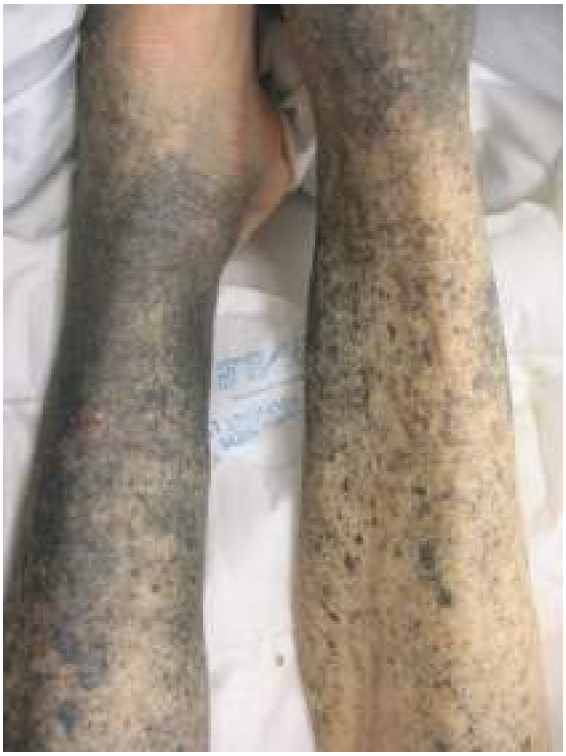

Figure 6–37. Minocycline hyperpigmentation. (Used, with permission, from Lindy Fox, MD.)

special care in using liquid nitrogen on any patients with darker skin tones since doing so may result in hypopigmentation or depigmentation, at times permanent. Intralesional or intra-articular injections of high concentrations of corticosteroids may also cause localized temporary hypopigmentation. Depigmentation indistinguishable from vitiligo is a known complication of immune checkpoint inhibitor therapy for melanoma.

Complications

Actinic keratoses and skin cancers are more likely to develop in persons with vitiligo. Severe emotional trauma may occur in extensive vitiligo or severe cases of hypo- and hyperpigmentation, particularly in persons with darker skin tones.

Treatment & Prognosis

A. Hyperpigmentation

Therapeutic bleaching preparations generally contain hydroquinone. Hydroquinone has occasionally caused unexpected hypo- or hyperpigmentation, or secondary ochronosis and pigmented milia with prolonged use.

The role of exposure to UV light cannot be overstressed as a factor promoting or contributing to most disorders of hyperpigmentation, and such exposure should be minimized. Melasma, ephelides, and postinflammatory hyperpigmentation may be treated with varying success with 4% hydroquinone and a sunscreen containing UVA photoprotectants (Avobenzone, Mexoryl, zinc oxide, titanium dioxide). Tretinoin cream, 0.025–0.1%, may be added. Adjuvant topical options for melasma include kojic acid, ascorbic acid, cysteamine, niacinamide, and azelaic acid. Superficial melasma responds well to topical therapy, but if there is predominantly dermal deposition of pigment (does not enhance with Wood light), the prognosis is poor. Response to therapy may take months and requires avoidance of sunlight. Hyperpigmentation often recurs after treatment if the skin is exposed to UV light. Tranexamic acid, 250 mg twice a day for 8–12 weeks, is an oral treatment for melasma. It should not be used in patients with hypercoagulability. Acne with postinflammatory hyperpigmentation responds well to azelaic acid and tretinoin since both address acne and hyperpigmentation. Solar lentigines respond to liquid nitrogen application. Tretinoin 0.1% cream or tazarotene 0.1% used over 10 months can fade solar lentigines, facial hyperpigmentation, and postinflammatory hyperpigmentation. Lasers are available for the removal of epidermal and dermal pigment and should be considered for patients whose responses to medical treatment are inadequate.

B. Hypopigmentation

In secondary hypopigmentation, repigmentation may occur spontaneously. Cosmetics such as Covermark and Dermablend are highly effective for concealing disfiguring patches. Therapy of vitiligo is long and tedious, and the patient must be strongly motivated. If < 20% of the skin is involved (most cases), topical tacrolimus 0.1% twice daily is the first-line therapy. A superpotent corticosteroid may also be used, but local skin atrophy from prolonged use may ensue. Topical ruxolitinib (JAK inhibitor) cream is FDA-approved for the treatment of vitiligo. With 20–25% involvement, narrowband UVB or oral PUVA is the best option. Severe phototoxic response (sunburn) may occur with PUVA. The face and upper chest respond best, and the fingertips and the genital areas do not respond as well to treatment. Years of treatment may be required.

ALOPECIA

Classification

Alopecias are divided into scarring and nonscarring forms. When evaluating a patient who reports hair loss, it is most important to determine if follicular markings (the opening where hair exits the skin) are present or absent. Present follicular markings suggest a nonscarring alopecia; absent follicular markings suggest a scarring alopecia.

Nonscarring Alopecia

Nonscarring alopecia may occur in association with various systemic diseases, such as SLE, secondary syphilis, hyper- or hypothyroidism, iron deficiency anemia, vitamin D deficiency, and pituitary insufficiency. Prompt and adequate control of the underlying disorder usually leads to hair regrowth. Specific types of nonscarring alopecia are described below.

Androgenetic alopecia, the most common form of alopecia, is of genetic predetermination. In men, the earliest changes occur at the anterior portions of the calvarium on either side of the "widow's peak" and on the crown (vertex). The extent of hair loss is variable and unpredictable. Minoxidil 5% is available over the counter and can be recommended for persons with recent onset (< 5 years) and smaller areas of alopecia. Approximately 40% of patients treated twice daily for a year will have moderate to dense growth. Finasteride (Propecia), 1 mg orally daily, has similar efficacy and may be additive to minoxidil. Dutasteride, 0.5 mg orally daily, may be considered as an alternative to finasteride.

Androgenetic alopecia also occurs in women. Classically, there is retention of the anterior hairline while there is diffuse thinning of the vertex scalp hair and a widening of the part. Treatment includes topical minoxidil (5% once daily) and, in women not of childbearing potential, finasteride at doses up to 2.5 mg/day orally. Spironolactone 50–200 mg daily may be used in premenopausal women. Low-dose oral minoxidil (0.25–1 mg daily in women and 2.5–5 mg daily in men) is also safe and effective. A workup consisting of determination of serum testosterone, DHEAS, iron, total iron-binding capacity, ferritin, thyroid function tests, vitamin D level, and a CBC will identify most other causes of hair thinning in premenopausal women. Women who describe thin hair but show little evidence of alopecia need follow-up because > 50% of the scalp hair can be lost before the clinician can perceive it.

Telogen effluvium is a transitory increase in the number of hairs in the telogen (resting) phase of the hair growth cycle. This may occur spontaneously; appear at the termination of pregnancy; be precipitated by severe illness, "crash dieting," high fever, stress from surgery, shock, malnutrition, or iron deficiency; or be provoked by hormonal contraceptives. Whatever the cause, telogen effluvium usually has a latent period of 4 months. The prognosis is generally good. The condition is diagnosed by the presence of large numbers of hairs with white bulbs coming out upon gentle tugging of the hair. Patients will describe excessive shedding of hair without scalp itching or scaling. Counts of hairs lost by the patient on combing or shampooing often exceed 150 per day, compared to an average of 70–100. If iron deficiency is suspected, a serum ferritin should be obtained, and any value < 40 ng/mL followed with supplementation.

Alopecia areata is of unknown cause but is believed to be an immunologic process. It presents as hairless patches that are perfectly smooth and without scarring. Tiny hairs 2–3 mm in length, called "exclamation hairs," may be seen. Telogen hairs are easily dislodged from the periphery of active lesions. The beard, brows, and lashes may be involved. Involvement may extend to all of the scalp hair (**alopecia totalis**) or to all scalp and body hair (**alopecia universalis**). Severe forms may be treated by systemic corticosteroid therapy, although recurrences follow discontinuation of therapy. Alopecia areata is occasionally associated with autoimmune disorders, including Hashimoto thyroiditis, pernicious anemia, Addison disease, and vitiligo. Additional comorbidities may include SLE, atopy, and mental health disease.

Intralesional corticosteroids are first-line treatment for alopecia areata. Triamcinolone acetonide in a concentration of 2.5–10 mg/mL is injected in aliquots of 0.1 mL at approximately 1- to 2-cm intervals, not exceeding a total dose of 30 mg per month for adults. Alopecia areata is usually self-limiting, with complete regrowth of hair in up to 50% of patients with focal disease in the first year. Some mild cases are resistant to treatment, as are the extensive totalis and universalis types. Support groups for patients with extensive alopecia areata are beneficial. Oral JAK inhibitors (eg, baricitinib and ritlecitinib) are FDA-approved therapeutic options for patients with highly morbid disease, although relapse is the rule once the medication has been stopped. Efficacy of topical JAK inhibitors for alopecia areata is under investigation.

In **trichotillomania** (the pulling out of one's own hair), the patches of hair loss are irregular, with short, growing hairs almost always present, since they cannot be pulled out until they are long enough. The patches are often unilateral, occurring on the same side as the patient's dominant hand. The patient may be unaware of the habit. *N*-acetylcysteine (1200–2400 mg orally per day for 12 weeks) may be effective.

Scarring (Cicatricial) Alopecia

Cicatricial alopecia may occur following any type of trauma or inflammation that may scar hair follicles. Examples include chemical or physical trauma, bacterial or fungal infections, severe herpes zoster, chronic discoid lupus erythematosus (DLE), systemic sclerosis (scleroderma), and excessive ionizing radiation. The specific cause is often suggested by the history, the distribution of hair loss, and the appearance of the skin, as in DLE. Specific dermatologic diseases of the scalp that result in scarring alopecia include lichen planopilaris, frontal fibrosing alopecia, dissecting cellulitis of the scalp, central centrifugal cicatrical alopecia, and folliculitis decalvans. Biopsy is useful in the diagnosis of scarring alopecia, but specimens must be taken from the active border and not from the scarred central zone. Scarring alopecias are irreversible and permanent. It is important to diagnose and treat the scarring process as early in its course as possible.

NAIL DISORDERS

1. Morphologic Nail Abnormalities

Classification

Acquired nail disorders may be classified as local or associated with systemic or generalized skin diseases.

A. Local Nail Disorders

1. Onycholysis (distal separation of the nail plate from the nail bed, usually of the fingers) is caused by excessive exposure to water, soaps, detergents, alkalies, and industrial cleaning agents. Candidal infection of the nail folds and subungual area, nail hardeners, drug-induced photosensitivity, hyper- or hypothyroidism, and psoriasis may cause onycholysis.
2. Distortion of the nail, including nail splitting, occurs as a result of chronic inflammation or infiltration of the nail matrix underlying the eponychial fold. Such changes may be caused by impingement on the nail matrix by inflammatory diseases (eg, psoriasis, lichen planus, eczema), warts, tumors, or cysts.
3. Discoloration and crumbly thickened nails are noted in dermatophyte infection and psoriasis.
4. Allergic reactions (to resins in undercoats and polishes or to nail glues) are characterized by onycholysis or by grossly distorted, hypertrophic, and misshapen nails.
5. Paronychia is inflammation of the lateral or proximal nail folds. Acute paronychia presents as a painful erythematous papulonodule or frank abscess of the nail fold and is most commonly due to infection with *S aureus* (Figure 6–38). Chronic paronychia is most often caused by irritation from water or chemicals with resultant inflammation and possible *Candida* superinfection.

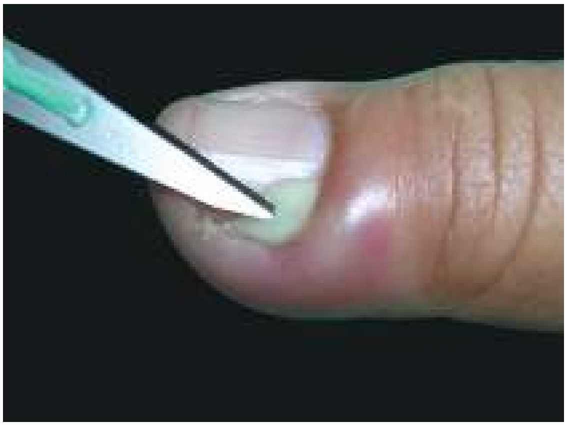

Figure 6–38. Acute paronychia with incision and drainage. (Reproduced, with permission, from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley HS. *The Color Atlas and Synopsis of Family Medicine*, 3rd ed. McGraw-Hill, 2019.)

B. Nail Changes Associated with Systemic or Generalized Skin Diseases

1. Beau lines (transverse furrows) affect all nails and classically develop after a serious systemic illness.
2. Atrophy of the nails may be related to trauma or to vascular or neurologic disease.
3. Clubbed fingers may be due to the prolonged hypoxemia associated with cardiopulmonary disorders (Figure 6–39) (see Chapter 9).
4. Spoon nails may be seen in anemic patients.
5. Stippling or pitting of the nails is seen in psoriasis, alopecia areata, and hand eczema (Figure 6–23).
6. Nail hyperpigmentation may be caused by many chemotherapeutic agents, but especially the taxanes.

Differential Diagnosis

Onychomycosis may cause nail changes identical to those seen in psoriasis. Careful examination for more characteristic lesions elsewhere on the body is essential to the diagnosis of the nail disorders. Cancer should be suspected (eg, Bowen disease or squamous cell carcinoma) as the cause of any persistent solitary subungual or periungual lesion.

Complications

Toenail changes may lead to an ingrown nail—in turn often complicated by bacterial infection and occasionally

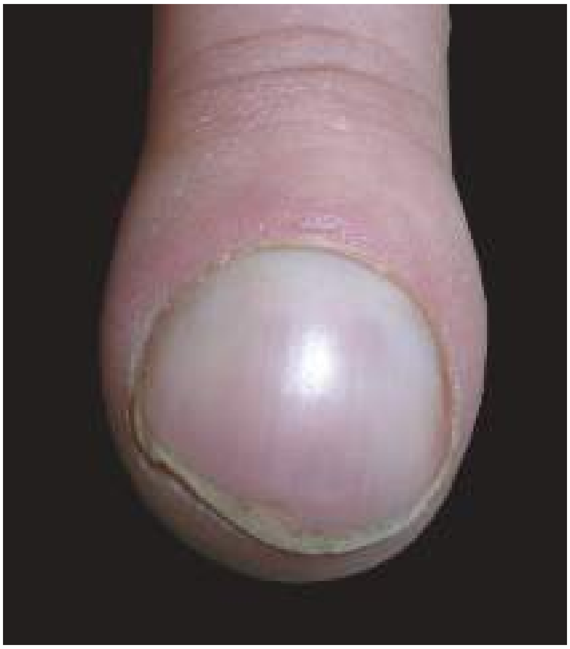

Figure 6–39. Clubbing of the finger in a 31-year-old man with congenital heart disease. Note the thickening around the proximal nail folds. (Reproduced, with permission, from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine*, 3rd ed. McGraw-Hill, 2019.)

by exuberant granulation tissue. Poor manicuring and poorly fitting shoes may contribute to this complication. Cellulitis may result.

Treatment & Prognosis

Treatment consists usually of careful debridement and manicuring and, above all, reduction of exposure to irritants (soaps, detergents, alkali, bleaches, solvents, etc). Longitudinal grooving due to temporary lesions of the matrix, such as warts, synovial cysts, and other impingements, may be cured by removal of the offending lesion.

Acute paronychia is treated with topical antibiotics and drainage of the abscess, if present. To incise and drain an acute staphylococcal paronychia, insert a flat metal spatula or sharpened hardwood stick into the nail fold where it adjoins the nail. This will release pus from a mature lesion (Figure 6–38).

Treatment of chronic paronychia includes minimizing wetwork and toxic contactants, wearing gloves while performing tasks that expose the skin to water, minimizing trauma to the nail folds, and a combination of topical corticosteroids and an anticandidal twice daily to the affected area.

2. Tinea Unguium (Onychomycosis)

Tinea unguium is a trichophyton infection of one or more (but rarely all) fingernails or toenails. The species most commonly found is *T rubrum*. "Saprophytic" fungi may rarely cause onychomycosis (< 5% of cases). Evidence supporting a genetic defect in the innate and adaptive immune system may explain why some persons suffer from chronic tinea pedis and onychomycosis.

The nails are lusterless, brittle, and hypertrophic, and the substance of the nail is friable. Laboratory diagnosis is mandatory since only 50% of dystrophic nails are due to dermatophytosis. Portions of the nail should be clipped, digested with 10% KOH, and examined under the microscope for hyphae. Fungi may also be cultured from debris collected from underneath the nail plate. Periodic acid-Schiff stain of a histologic section of the nail plate also demonstrates the fungus readily. Each technique is positive in only 50% of cases so several different tests may need to be performed. Periodic acid-Schiff staining of nail plate coupled with fungal culture has a sensitivity of 96%.

Onychomycosis is difficult to treat because of the long duration of therapy required and the frequency of recurrences. Fingernails respond more readily than toenails. For toenails, treatment is indicated for patients with discomfort, inability to exercise, diabetes, and immune compromise.

In general, systemic therapy is required to effectively treat nail onychomycosis. Although historically topical therapy has had limited value, evidence suggests that efinaconazole 10% performs better than other topical treatment options like ciclopirox. Tavaborole 5% solution is also approved for the treatment of onychomycosis, but its clearance rates do not appear to be as good as those of efinaconazole. Adjunctive value of surgical procedures is unproven, and the efficacy of laser treatments is lacking, especially with regard to long-term cures.

Fingernails can virtually always be cured, and toenails are cured 35–50% of the time and are clinically improved about 75% of the time. In all cases, before treatment, the diagnosis should be confirmed. The costs of the various treatment options should be known and the most cost-effective treatment chosen. Medication interactions must be avoided. Ketoconazole, due to its higher risk for hepatotoxicity, is not recommended to treat any form of onychomycosis. For fingernails, ultramicronized griseofulvin 250 mg orally three times daily for 6 months can be effective. Alternative treatments are (in order of preference) oral terbinafine, 250 mg daily for 6 weeks; oral itraconazole, 200–400 mg daily for 7 days each month for 2 months; and oral itraconazole, 200 mg daily for 2 months. Off-label use of fluconazole, 150–400 mg once weekly for 6–9 months, can also be effective, but there is limited evidence for this option. Once clear, fingernails usually remain free of disease for some years.

Onychomycosis of the toenails does not respond to griseofulvin therapy. The best treatment, which is also FDA-approved, is oral terbinafine 250 mg daily for 12 weeks. Pulse terbinafine therapy with two cycles of 4 weeks on and 4 weeks off may be as efficacious as continuous oral therapy. Liver biochemical tests should be performed before oral terbinafine therapy. Because the risk of idiosyncratic liver injury is very low (transaminitis occurs in < 0.5% of patients) and the presentation of drug-induced liver injury is usually symptomatic (jaundice, malaise, abdominal pain), routine hepatic monitoring in healthy adults without known hepatic disease is not required. The dose might need adjustment in patients with reduced creatinine clearance. Itraconazole, 200 mg daily for 12 weeks, or pulse oral itraconazole, 200 mg twice daily for 1 week per month for 3 months, is inferior to standard terbinafine treatments, but it is an acceptable alternative for those unable to take terbinafine. The courses of terbinafine or itraconazole may need to be repeated 6 months after the first treatment cycle if fungal cultures of the nail are still positive. Fluconazole may be used off label at 150 mg weekly until the nail has grown out completely (12–18 month for toenails).

Treatment failures are multifactorial but may occur because of mixed infection with non-dermatophyte molds or reinfection. Culture of the nail to determine the organism responsible for infection is critical to choosing the correct therapy. In addition, part of the complete therapeutic regimen for onychomycosis should include replacing or sanitizing potential fungal reservoirs such as socks, shoes, and other textiles. Infected household members should also be treated. Shoes or sandals should be worn in high-risk areas (public showers or pools). Continued prophylactic therapy with topicals such as efinaconazole twice a week to nails and a topical antifungal cream to the feet should be continued for several years or longer after clearance of onychomycosis.

Yousefian F et al. Treatment options for onychomycosis: efficacy, side effects, adherence, financial considerations, and ethics. J Clin Aesthet Dermatol. 2024;17:24. [PMID: 38495549]

Disorders of the Eyes & Lids

7

Jacque L. Duncan, MD
Neeti B. Parikh, MD
Gerami D. Seitzman, MD

REFRACTIVE ERRORS

Refractive error is the most common cause of reduced clarity of vision (visual acuity).

Use of a pinhole will overcome most refractive errors and thus allows their identification as a cause of reduced visual acuity. Refractive error can be treated with glasses, contact lenses, or surgery.

▶ Treatment

A. Contact Lenses

An estimated 40.9 million US adults wear contact lenses, mostly for correction of refractive errors, though decorative-colored contact lenses are used.

The major risk from contact lens wear is corneal infection, potentially a blinding condition. Such infections occur more often with soft lenses, particularly extended wear, for which there is at least a fivefold increase in risk of corneal infection compared with daily wear. Decorative contact lenses have a high prevalence of microbial contamination. Contact lens wearers should be made aware of the risks they face and ways to minimize them, such as avoiding overnight wear or use of lenses past their replacement date and maintaining meticulous lens hygiene, including not using tap water or saliva for lens cleaning. Contact lenses should be removed whenever there is ocular discomfort or redness.

Waghmare SV et al. A review of contact lens-related risk factors and complications. Cureus. 2022;14:e30118. [PMID: 36381898]

B. Surgery

Various surgical techniques can reduce refractive errors. Laser refractive surgery reshapes the middle layer (stroma) of the cornea with an excimer laser.

Other refractive surgery techniques are extraction of the crystalline lens with insertion of a single vision, multifocal, or accommodative intraocular lens as occurs after cataract extraction; insertion of an intraocular lens without removal of the crystalline lens (phakic intraocular lens); and intrastromal corneal ring segments.

Jabbour S et al. Refractive surgery in the US in 2021. JAMA. 2021;326:77. [PMID: 34228079]

C. Reduction of Rate of Progression of Nearsightedness

The rate at which nearsightedness progresses can be reduced by topical atropine rigid contact lens wear during sleep (orthokeratology); and various types of soft contact lenses and spectacles, but their long-term efficacy and safety are uncertain.

▶ When to Refer

Any contact lens wearer with an acute painful red eye must be referred emergently for ophthalmologic evaluation.

DISORDERS OF THE LIDS & LACRIMAL APPARATUS

1. Hordeolum

Hordeolum is an acute infection that is commonly due to *Staphylococcus aureus*. It is characterized by a localized red, swollen, acutely tender area on the upper or lower lid.

Internal hordeolum is a meibomian gland abscess that usually points onto the conjunctival surface of the lid.

External hordeolum (or stye) is an abscess of the gland of Zeis. It is usually smaller than an internal hordeolum and on the lid margin.

Warm compresses are helpful. Incision may be indicated if resolution does not begin within 48 hours. An antibiotic ointment (ophthalmic bacitracin or erythromycin) applied to the lid every 3 hours may be beneficial during the acute stage. Internal hordeolum may lead to generalized cellulitis of the lid.

2. Chalazion

Chalazion is a common granulomatous inflammation of a meibomian gland that may follow an internal hordeolum.

It is characterized by a hard, nontender swelling on the upper or lower lid with redness and swelling of the adjacent conjunctiva. Initial treatment is with warm compresses. If resolution has not occurred by 2–3 weeks, incision and curettage is indicated. Corticosteroid injection may also be effective.

3. Blepharitis

Blepharitis is a common chronic bilateral inflammatory condition of the lid margins.

1. Anterior blepharitis—This involves the lid skin, eyelashes, and associated glands. It may be ulcerative because of infection by staphylococci, or seborrheic in association with seborrhea of the scalp, brows, and ears.

2. Posterior blepharitis—This results from inflammation of the meibomian glands. There may be bacterial infection, particularly with staphylococci, or primary glandular dysfunction, which is strongly associated with acne rosacea.

Clinical Findings

Symptoms are irritation, burning, and itching.

1. Anterior blepharitis—The eyes are "red-rimmed" and scales or collarettes can be seen clinging to the lashes.

2. Posterior blepharitis—The lid margins are hyperemic with telangiectasias, and the meibomian glands and their orifices are inflamed. The lid margin is frequently rolled inward to produce a mild entropion, and the tear film may be frothy or abnormally greasy.

Blepharitis is a common cause of recurrent conjunctivitis. Both anterior and, especially, posterior blepharitis may be complicated by hordeola or chalazia; abnormal lid or lash positions, producing trichiasis; epithelial keratitis of the lower third of the cornea; marginal corneal infiltrates; and inferior corneal vascularization and thinning.

Treatment

1. Anterior blepharitis—Eyelid hygiene is usually sufficient to control anterior blepharitis. Warm compresses help soften the scales and warm the meibomian gland secretions. Eyelid cleansing can be achieved by gentle eyelid massage and lid scrubs with baby shampoo or 0.01% hypochlorous acid. In acute exacerbations, an antibiotic eye ointment, such as bacitracin or erythromycin, is applied daily to the lid margins (Table 7–2).

2. Posterior blepharitis—Regular meibomian gland expression and warm compresses may be used to control mild posterior blepharitis. Inflammation of the conjunctiva and cornea is treated with long-term low-dose oral antibiotic therapy, eg, tetracycline (250 mg twice daily for 2–4 weeks), doxycycline (100 mg daily for 2–4 weeks), minocycline (50–100 mg daily for 2–4 weeks) erythromycin (250 mg three times daily for 2–4 weeks), or azithromycin (500 mg daily for 3 days in three cycles with 7-day intervals). Short-term (5–7 days) topical corticosteroids, eg, prednisolone, 0.125% twice daily, may also be indicated. Topical therapy with antibiotics, such as ciprofloxacin 0.3% ophthalmic solution twice daily, may be helpful but should be restricted to short courses of 5–7 days.

Amescua G et al; American Academy of Ophthalmology Preferred Practice Pattern Cornea and External Disease Panel. Blepharitis Preferred Practice Pattern®. Ophthalmology. 2019;126:P56. [PMID: 30366800]

4. Entropion & Ectropion

Entropion (inward turning of usually the lower lid) occurs occasionally in older people from degeneration of the lid fascia or may follow extensive scarring of the conjunctiva and tarsus. Surgery is indicated if the lashes rub on the cornea. Botulinum toxin injections may also be used for temporary correction of the involutional lower lid entropion of older people.

Ectropion (outward turning of the lower lid) is common with advanced age. Surgery is indicated if there is excessive tearing, exposure keratitis, or a cosmetic problem.

5. Tumors of the Lids

Lid tumors are usually benign. Basal cell carcinoma is the most common malignant tumor. Squamous cell carcinoma, meibomian gland carcinoma, and malignant melanoma also occur. Surgery for any lesion involving the lid margin should be performed by an ophthalmologist or suitably trained plastic surgeon to avoid deformity of the lid. Histopathologic examination of eyelid tumors should be routine, since 2% of lesions thought to be benign clinically are found to be malignant. Medications such as vismodegib, imiquimod, and 5-fluorouracil occasionally are used instead of or as an adjunct to surgery for some basal and squamous cell carcinomas.

6. Dacryocystitis

Dacryocystitis is infection of the lacrimal sac usually due to congenital or acquired obstruction of the nasolacrimal system. It may be acute or chronic and occurs most often in infants and in persons over 40 years. It is usually unilateral. Infection is typically with *S aureus* and streptococci in acute dacryocystitis and *Staphylococcus epidermidis*, streptococci, or gram-negative bacilli in chronic dacryocystitis.

Acute dacryocystitis is characterized by pain, swelling, tenderness, and redness in the tear sac area; purulent material may be expressed. In chronic dacryocystitis, tearing and discharge are the principal signs, and mucus or pus may also be expressed.

Acute dacryocystitis responds well to systemic oral antibiotics with gram-positive coverage, such as amoxicillin-clavulanate, cephalexin, ciprofloxacin, clindamycin, or trimethoprim-sulfamethoxazole; microbiologic culture is usually not necessary. To relieve the underlying obstruction, surgery is usually done electively but may be performed urgently in acute cases. The chronic form may be kept latent with systemic antibiotics, but relief of the obstruction is the only cure. In adults, the standard procedure is dacryocystorhinostomy, which involves surgical exploration of the lacrimal sac and formation of a fistula into the nasal cavity and, if necessary, supplemented by nasolacrimal intubation.

Congenital nasolacrimal duct obstruction is common and often resolves spontaneously. It can be treated by probing the nasolacrimal system, supplemented by nasolacrimal intubation or balloon catheter dilation, if necessary; dacryocystorhinostomy is rarely required.

CONJUNCTIVITIS

Conjunctivitis may be acute or chronic. Most cases are due to viral or bacterial (including gonococcal and chlamydial) infection. Other causes include keratoconjunctivitis sicca, allergy, chemical irritants, and trauma. The mode of transmission of infectious conjunctivitis is usually via direct contact of contaminated fingers or objects to the eye or to other persons. It may also be spread through respiratory secretions or contaminated eye drops.

Conjunctivitis must be differentiated from acute uveitis, acute glaucoma, and corneal disorders (Table 7–1).

Varu DM et al; American Academy of Ophthalmology Preferred Practice Pattern Cornea and External Disease Panel. Conjunctivitis Preferred Practice Pattern®. Ophthalmology. 2019;126:P94. [PMID: 30366797]

1. Viral Conjunctivitis

Viral conjunctivitis is a clinical diagnosis with etiology varying by location and rarely confirmed. Adenovirus is one common etiology. Often, there is sequential bilateral disease with copious watery discharge and a follicular conjunctivitis. Infection spreads easily. Epidemic keratoconjunctivitis, which may result in decreased vision from corneal subepithelial infiltrates, is usually caused by adenovirus types 8, 19, and 37. The active viral conjunctivitis lasts up to 2 weeks, with the immune-mediated keratitis occurring later. Infection with adenovirus types 3, 4, 7, and 11 is typically associated with pharyngitis, fever, malaise, and preauricular adenopathy (pharyngoconjunctival fever). The disease usually lasts 10 days. Contagious acute hemorrhagic conjunctivitis (see Chapter 37) may be caused by enterovirus 70 or coxsackievirus A24, though etiologies vary globally. Herpes simplex virus (HSV) conjunctivitis is typically unilateral and may be associated with lid vesicles. SARS-CoV-2 may present with conjunctivitis only. There are no clinical differentiating features between SARS-CoV-2 conjunctivitis and any other viral etiologies of conjunctivitis.

Except for HSV infection for which treatment with ophthalmic (eg, ganciclovir 0.15% gel) and/or systemic (eg, oral acyclovir, valacyclovir) antivirals is recommended (Table 37–1), there is no specific treatment for contagious viral conjunctivitis. Artificial tears and cold compresses may reduce discomfort. The use of ophthalmic antibiotics and corticosteroids in the acute viral infection is discouraged. Frequent hand and linen hygiene is encouraged to minimize spread. A single low-concentration ocular betadine wash commonly preceded by a drop of ophthalmic anesthesia (administered by an eye care specialist) may expedite recovery.

2. Bacterial Conjunctivitis

Common bacterial conjunctivitis pathogens are staphylococci, including methicillin-resistant *S aureus* (MRSA); streptococci, particularly *Streptococcus pneumoniae*; *Haemophilus* species; *Pseudomonas;* and *Moraxella*. All may produce purulent discharge and eyelid matting. Blurring of vision and discomfort are mild. In severe (hyperpurulent) cases, culture is recommended, particularly to identify

Table 7–1. The inflamed eye: differential diagnosis of common causes.

	Acute Conjunctivitis	Acute Anterior Uveitis (Iritis)	Acute Angle-Closure Glaucoma	Corneal Trauma or Infection
Incidence	Extremely common	Common	Uncommon	Common
Discharge	Moderate to copious	None	None	Watery or purulent
Vision	No effect on vision	Often blurred	Markedly blurred	Usually blurred
Pain	Mild	Moderate	Severe	Moderate to severe
Conjunctival injection	Diffuse	Mainly circumcorneal	Mainly circumcorneal	Mainly circumcorneal
Cornea	Clear	Usually clear	Cloudy	Clarity change related to cause
Pupil size	Normal	Small	Moderately dilated	Normal or small
Pupillary light response	Normal	Poor	None	Normal
Intraocular pressure	Normal	Usually normal but may be elevated	Markedly elevated	Normal
Infectious	Commonly	Occasionally	No	Commonly

gonococcal infection that requires emergent and systemic treatment.

The infection is usually self-limited, lasting about 10–14 days if untreated. Most ophthalmic antibiotics hasten clinical remission, and no ophthalmic antibiotic has proven superiority over another (Table 7–2).

A. Gonococcal Conjunctivitis

Gonococcal conjunctivitis, usually acquired through contact with infected genital secretions, typically causes copious purulent discharge. It is an ophthalmologic emergency because the cornea may perforate. The diagnosis should be confirmed by Gram stain and culture of the discharge. Systemic treatment is required with a single 500-mg dose of intramuscular ceftriaxone for patients < 150 kg or 1-g dose for patients > 150 kg (see Chapter 38). Fluoroquinolone resistance is common. Eye irrigation with saline may promote resolution. Ophthalmic antibiotics such as erythromycin and bacitracin may be added. Other STIs, including chlamydiosis, syphilis, and HIV infection, should be considered. Standard treatment for chlamydial infection is recommended.

Alsoudi AF … Seitzman GD. Purulent conjunctivitis and progressive corneal stromal necrosis. JAMA Ophthalmol. 2021;139:908. [PMID: 34081098]

B. Chlamydial Keratoconjunctivitis

Inclusion conjunctivitis—The eye becomes infected after contact with secretions infected with chlamydia. The disease starts with acute redness, discharge, and irritation. Examination shows follicular conjunctivitis with mild keratitis. A nontender preauricular lymph node can often be palpated. Healing usually leaves no sequelae. Diagnosis can be rapidly confirmed by immunologic tests or PCR on conjunctival samples. Treatment is doxycycline, 100 mg orally twice daily for 7 days. All cases should be assessed for genital tract infection and other STIs.

3. Dry Eye

Dry eye is an umbrella term describing tear film instability and associated ocular and visual complaints. Dry eye is more common in women than men and increases with age. Hypofunction of the lacrimal glands, causing loss of the aqueous component of tears (keratoconjunctivitis sicca), may be due to aging, hereditary disorders, systemic disease (eg, Sjögren syndrome), or systemic drugs. Excessive evaporation of tears may be due to environmental factors (eg, excessive screen time, windy climate) or abnormalities of the lipid component of the tear film, as in blepharitis and ocular rosacea. Mucin deficiency may be due to vitamin A deficiency or conjunctival scarring, Stevens-Johnson syndrome, mucous membrane pemphigoid, graft-versus-host disease, chemical burns, or ophthalmic drug toxicity.

Clinical Findings

The patient complains of dryness, redness, foreign body sensation, and variable vision. In severe cases, there is persistent marked discomfort, with photophobia, difficulty moving the lids, and excessive mucus secretion. Gross inspection often reveals no abnormality, but on slit-lamp examination there are abnormalities of tear film stability and reduced tear volume. In more severe cases, damaged corneal and conjunctival cells stain with fluorescein and lissamine green. In the most severe cases, there is marked conjunctival injection, mucoid discharge, loss of the normal conjunctival and corneal luster, and epithelial keratopathy that stains with fluorescein and may progress to frank ulceration. The Schirmer test, which measures the rate of production of the aqueous component of tears, may be helpful.

Treatment

Aqueous deficiency can be treated with artificial tears drops or ointments. Drop preparations containing a mucomimetic such as hydroxypropyl methylcellulose (HPMC) or carboxymethylcelluose (carmellose) provide more prolonged duration. Warm compresses to the eyelid can help unclog meibomian glands.

Artificial tear preparations are generally safe and, in most cases, are used three or four times a day. However, preservatives included in some preparations to maintain sterility are potentially toxic and allergenic and may cause ocular surface toxicity in frequent users. Such reactions may be misinterpreted as a worsening of the dry eye state requiring more frequent use of the artificial tears, leading to further deterioration, rather than being recognized as a need to change to a preservative-free preparation. Preservative-free preparations are recommended if use is more than four times a day. Eye drops claiming to "get the red out" are not recommended as they cause toxicity and rebound hyperemia with prolonged use.

Dry eye is considered an inflammatory ocular surface disease. Accordingly, disease modification may require episodic treatment with low potency corticosteroid drops. Ophthalmic corticosteroids should only be prescribed by eye specialists to monitor intraocular pressure for steroid induced glaucoma and for cataracts. Corticosteroid-sparing anti-inflammatory drops such as cyclosporine 0.05% ophthalmic emulsion (Restasis) and lifitegrast 5% are commonly used with no universal consensus of efficacy. Lacrimal punctal occlusion by canalicular plugs or cautery is useful in severe cases.

McCann P et al. Interventions for dry eye: an overview of systematic reviews. JAMA Ophthalmol. 2024;142:58. [PMID: 38127364]

4. Blepharitis

Blepharitis is an anterior or posterior eyelid inflammation. Anterior blepharitis is characterized by inflammatory debris on the eyelid skin and around the eyelashes and includes staphylococcal, seborrheic, and *Demodex* mite forms. Posterior blepharitis occurs with meibomian gland inflammation, which alters lipid secretion into the tear film and is a common etiology of dry eye syndrome. Clogged meibomian glands can lead to chalazia (swollen lumps in the eyelid).

Table 7–2. Topical ophthalmic agents (selected list).

Agent	Recommended Regimen	Indications
Antibiotic Agents (ophthalmic)		
Azithromycin (AzaSite)	One drop two times daily for 2 days, then once daily for 5 days	Bacterial conjunctivitis
Bacitracin 500 U/g ointment (various)[1]	Apply 0.5 inch into lower conjunctival sac or to eyelids three to four times daily for 7–10 days	Bacterial conjunctivitis, blepharitis, stye
Bacitracin/Polymyxin ointment (Polysporin, AK-Poly)	Apply 0.5 inch into lower conjunctival sac or to eyelids three to four times daily for 7–10 days	Corneal abrasion Following corneal foreign body removal
Besifloxacin ophthalmic suspension, 0.6% (Besivance)	For bacterial conjunctivitis, typically one drop four times a day for 1 week For bacterial keratitis, depends on severity, often one drop every hour during the day and every 2 hours during the night for 48 hours, then gradually reduce	Bacterial conjunctivitis Bacterial keratitis
Ciprofloxacin HCl 0.3% solution (Ciloxan)	For bacterial conjunctivitis, typically one drop four times a day for 1 week For bacterial keratitis, depends on severity, often one drop every hour during the day and every 2 hours during the night for 48 hours, then gradually reduce	Bacterial conjunctivitis Bacterial keratitis
Ciprofloxacin HCl 0.3% ointment	Apply 0.5 inch into lower conjunctival sac or to eyelids three to four times daily for 7–10 days	Bacterial conjunctivitis
Erythromycin 0.5% ointment (various)	Apply 0.5 inch into lower conjunctival sac or to eyelids three to four times daily for 7–10 days	Bacterial infection of the conjunctiva or lid margin
Fusidic acid 1% gel (Fucithalmic) Not available in United States	One drop two times daily	Bacterial conjunctivitis, blepharitis, stye, keratitis
Gatifloxacin 0.5% solution (Zymaxid)	For bacterial conjunctivitis, typically one drop four times a day for 1 week For bacterial keratitis, depends on severity, often one drops every hour during the day and every 2 hours during the night for 48 hours, then gradually reduce	Bacterial conjunctivitis Bacterial keratitis
Gentamicin sulfate 0.3% solution (various)	One drop four times a day for bacterial conjunctivitis	Ocular surface infection
Gentamicin sulfate 0.3% ointment (various)	Apply 0.5 inch into lower conjunctival sac two to three times daily	Ocular surface infection
Gentamicin sulfate 1.5% (fortified preparation)	One drop every hour for 48 hours, then gradually reduce	Bacterial keratitis
Levofloxacin 0.5% solution (various)	For bacterial conjunctivitis, typically one drop four times a day for 1 week For bacterial keratitis, depends on severity, often one drop every hour during the day and every 2 hours during the night for 48 hours, then gradually reduce	Bacterial conjunctivitis Bacterial keratitis
Moxifloxacin 0.5% solution (Vigamox)	For bacterial conjunctivitis, typically one drop three times a day for 1 week For bacterial keratitis, depends on severity, often one drop every hour during the day and every 2 hours during the night for 48 hours, then gradually reduce	Bacterial conjunctivitis Bacterial keratitis
Neomycin/Polymyxin B/Gramicidin (Neosporin)	One drop three to four times a day for 1 week	Ocular surface infection
Norfloxacin 0.3% solution Not available in United States	For bacterial conjunctivitis, typically one drop four times a day for 1 week For bacterial keratitis, depends on severity, often one drop every hour during the day and every 2 hours during the night for 48 hours, then gradually reduce	Ocular surface infection Bacterial keratitis

(*continued*)

Table 7–2. Topical ophthalmic agents (selected list). (continued)

Agent	Recommended Regimen	Indications
Ofloxacin 0.3% solution (Ocuflox)	For bacterial conjunctivitis, typically one drop four times a day for 1 week For bacterial keratitis, depends on severity, often one drop every hour during the day and every 2 hours during the night for 48 hours, then gradually reduce	Bacterial conjunctivitis Bacterial keratitis
Polymyxin B 10,000 U/mL/Trimethoprim sulfate 1 mg/mL (Polytrim)[2]	For bacterial conjunctivitis, typically one drop four times a day for 1 week	Ocular surface infection
Sulfacetamide sodium 10% solution (various)	For bacterial conjunctivitis, typically one drop four times a day for 1 week	Bacterial infection of the conjunctiva or lid margin
Tobramycin 0.3% solution (various)	For bacterial conjunctivitis, typically one drop four times a day for 1 week For bacterial keratitis, depends on severity, often one drop every hour during the day and every 2 hours during the night for 48 hours, then gradually reduce	Bacterial conjunctivitis Bacterial keratitis
Tobramycin 1.5% (fortified) solution	One drop every hour during the day and every 2 hours during the night for 48 hours, then gradually reduce	Bacterial keratitis
Tobramycin 0.3% ointment (Tobrex)	Apply 0.5 inch into lower conjunctival sac or to eyelids three to four times daily for 7–10 days	Bacterial conjunctivitis
Antifungal Agents		
Amphotericin 0.1–0.5% solution	One drop every 1–2 hours initially, then reduce as dictated by the severity of the infection	Fungal blepharitis, conjunctivitis, keratitis
Natamycin 5% suspension (Natacyn)	One drop every 1–2 hours initially, then reduce as dictated by the severity of the infection	
Voriconazole 1% solution	One drop every 1–2 hours initially, then reduce as dictated by the severity of the infection	
Antiviral Agents		
Acyclovir 3% ointment (Zovirax) Not available in United States	Five times daily	Herpes simplex keratitis
Ganciclovir 0.15% gel (Zirgan)	Five times daily	
Trifluridine 1% solution (Viroptic)	One drop onto cornea every 2 hours while awake for a maximum daily dose of nine drops until resolution occurs; then an additional 7 days of one drop every 4 hours while awake (minimum five times daily)	
Antiparasitic Agents		
Lotilaner 0.25% solution	One drop applied twice daily for 6 weeks	*Demodex* mite blepharitis
Polyhexamethylene biguanide (PHMB) (0.02–0.8%)	One drop every 1–2 hours initially, then reduce as dictated by the severity of the infection	Acanthamoeba keratitis
Chlorhexidine (0.02–0.06%)	One drop every 1–2 hours initially, then reduce as dictated by the severity of the infection	Acanthamoeba keratitis
Anti-Inflammatory Agents		
Antihistamines[3] (ophthalmic)		
Emedastine difumarate 0.05% solution (Emadine) Not available in United States	One drop four times daily	Allergic eye disease
Levocabastine (Livostin) Not available in United States	One drop twice daily	
Mast cell stabilizers		
Cromolyn sodium 4% solution (Crolom)	One drop four times daily	
Lodoxamide tromethamine 0.1% solution (Alomide)	One or two drops twice a day	

(*continued*)

Table 7–2. Topical ophthalmic agents (selected list). (continued)

Agent	Recommended Regimen	Indications
Nedocromil sodium 2% solution (Alocril)	One drop twice daily	
Pemirolast potassium 0.1% solution (Alamast) Not available in United States	One drop four times daily	
Combined antihistamines and mast cell stabilizers		
Alcaftadine 0.25% ophthalmic solution (Lastacaft)	One drop once daily	
Azelastine HCl 0.05% ophthalmic solution (Optivar)	One drop two to four times daily	
Bepotastine besilate 1.5% solution (Bepreve)	One drop twice daily	
Epinastine hydrochloride 0.05% ophthalmic solution (Elestat)	One drop twice daily	
Ketotifen fumarate 0.025% solution (Zaditor)	One drop twice daily	
Ketotifen 0.025% preservative-free solution (Alaway)	One drop twice daily	
Olopatadine hydrochloride 0.1% solution (Patanol)	One drop twice daily	
Olopatadine hydrochloride 0.2% or 0.77% solution	One drop daily	
Nonsteroidal anti-inflammatory agents (ophthalmic)		
Bromfenac 0.09% solution (Xibrom)	One drop to operated eye twice daily beginning 24 hours after cataract surgery and continuing through 2 postoperative weeks	Treatment of postoperative inflammation following cataract extraction
Diclofenac sodium 0.1% solution (Voltaren)	One drop to operated eye four times daily beginning 24 hours after surgery and continuing through 2 postoperative weeks	Treatment of postoperative inflammation following cataract extraction and laser corneal surgery
Flurbiprofen sodium 0.03% solution (various)	One drop to operated eye four times daily beginning 24 hours after cataract surgery	Inhibition of intraoperative miosis; treatment of cystoid macular edema and inflammation after cataract extraction
Indomethacin 1% solution (Indocid) Not available in United States	One drop four times daily	Treatment of allergic eye disease, postoperative inflammation following cataract extraction and laser corneal surgery
Ketorolac tromethamine 0.5% solution (Acular)	One drop four times daily tapered with decreasing inflammation, not to be used long term	
Nepafenac 0.1% suspension (Nevanac)	One drop to operated eye three times daily beginning 24 hours after cataract surgery and continuing through 2 postoperative weeks	Treatment of postoperative inflammation following cataract extraction
Corticosteroids[4]		
Dexamethasone sodium phosphate 0.1% solution (various)	One drop as often as indicated by severity; use every hour during the day and every 2 hours during the night in severe inflammation; taper off as inflammation decreases	Treatment of steroid-responsive inflammatory conditions
Difluprednate 0.05% suspension[5]	One drop four times daily beginning 24 hours after surgery and continuing throughout 2 postoperative weeks; then one drop twice daily for a week and then taper based on the response One drop four times daily for 2 weeks and then taper as clinically indicated	Treatment after ocular surgery and for non-infectious uveitis

(*continued*)

Table 7–2. Topical ophthalmic agents (selected list). (continued)

Agent	Recommended Regimen	Indications
Fluorometholone 0.1% suspension (various)[6]	One drop four times a day and tapered off as inflammation decreases	Treatment of ocular surface inflammatory conditions
Fluorometholone 0.25% suspension (FML Forte)[6]	One drop two to four times daily	
Fluorometholone 0.1% ointment (FML S.O.P.) Not available in United States	Apply thin coating on lower conjunctival sac three or four times daily	
Loteprednol etabonate 0.5% (Lotemax)	One drop twice daily for severe allergies. More frequently for intraocular inflammation, tapered off as inflammation decreases	Treatment of steroid-responsive ocular inflammatory conditions
Prednisolone acetate 0.12% suspension (Pred Mild)	One drop four times a day and tapered as inflammation decreases	
Prednisolone acetate 1% suspension (various)	One drop as often as indicated by severity of inflammation; use every hour during the day and every 2 hours during the night in severe inflammation; taper off as inflammation decreases	
Prednisolone sodium phosphate 1% solution (various)	One drop as often as indicated by severity of inflammation; use every hour during the day and every 2 hours during the night in severe inflammation; taper off as inflammation decreases	
Immunomodulators		
Cyclosporine emulsion 0.05% (Restasis), 0.09%, 0.1% (commercial); 1%, 2% (compounded)	One drop twice daily	Dry eyes and severe allergic eye disease
Tacrolimus 0.03%, 0.1% ointment	Apply to lower conjunctival sac twice daily	Severe allergic eye disease (off-label)
Glaucoma and Ocular Hypertension Agents		
Sympathomimetics (ophthalmic)		
Apraclonidine HCl 0.5% solution (Iopidine)	One drop three times daily	Reduction of intraocular pressure; expensive; reserve for treatment of resistant cases
Apraclonidine HCl 1% solution (Iopidine)	One drop 1 hour before and immediately after anterior segment laser surgery	To control or prevent elevations of intraocular pressure after laser trabeculoplasty or iridotomy
Brimonidine tartrate 0.2% solution (Alphagan, Alphagan P [benzalkonium chloride-free])	One drop two or three times daily	Reduction of intraocular pressure
β-Adrenergic blocking agents (ophthalmic)		
Betaxolol HCl 0.5% solution (Betoptic) and 0.25% suspension (Betoptic S)[7]	One drop twice daily	Reduction of intraocular pressure
Carteolol HCl 1% and 2% solution (various, Teoptic)[8]	One drop twice daily	
Levobunolol HCl 0.25% and 0.5% solution (Betagan)[9]	One drop once or twice daily	
Metipranolol HCl 0.3% solution (OptiPranolol)[9]	One drop twice daily	
Timolol 0.25% and 0.5% solution (Betimol)[9]	One drop once or twice daily	
Timolol maleate 0.25% and 0.5% solution (Istalol, Ocudose [preservative-free], Timoptic) and 0.1%, 0.25%, and 0.5% gel (Timoptic-XE, Timoptic GFS)[9]	One drop once or twice daily	

(*continued*)

Table 7–2. Topical ophthalmic agents (selected list). (continued)

Agent	Recommended Regimen	Indications
Miotics (ophthalmic)		
Pilocarpine HCl 1–4% solution[10]	One drop up to four times daily for elevated intraocular pressure	Reduction of intraocular pressure, treatment of acute or chronic angle-closure glaucoma, and pupillary constriction
Carbonic anhydrase inhibitors (ophthalmic)		
Brinzolamide 1% suspension (Azopt)	One drop two to three times daily	Reduction of intraocular pressure
Dorzolamide HCl 2% solution (Trusopt)	One drop two to three times daily	
Prostaglandin analogs		
Bimatoprost 0.03% solution (Lumigan)	One drop once daily at night	Reduction of intraocular pressure
Latanoprost 0.005% solution (Xalatan, Monopost [preservative-free]) (Monopost not available in United States)	One drop once or twice daily at night	
Latanoprostene bunod 0.024% solution (Vyzulta)	One drop daily at night	
Tafluprost 0.0015% solution (Saflutan [preservative-free], Taflotan, Zioptan [preservative-free]) (Saflutan not available in United States)	One drop once daily at night	
Travoprost 0.004% solution (Travatan, Travatan Z [benzalkonium chloride-free])	One drop once daily at night	
Rho kinase inhibitor (ophthalmic)		
Netarsudil ophthalmic solution 0.02% (Rhopressa)	One drop daily in the evening	Reduction of intraocular pressure
Combined preparations (ophthalmic)		
Bimatoprost 0.03% and timolol 0.5% (Ganfort) Not available in United States	One drop daily in the morning	Reduction of intraocular pressure
Brimonidine 0.2% and timolol 0.5% (Combigan)	One drop twice daily	
Brimonidine 0.2% and brinzolamide 1% (Simbrinza)	One drop three times a day	
Brinzolamide 1% and timolol 0.5% (Azarga) Not available in United States	One drop twice daily	
Dorzolamide 2% and timolol 0.5% (Cosopt, Cosopt PF [preservative-free])	One drop twice daily	
Latanoprost 0.005% and timolol 0.5% (Xalacom) Not available in United States	One drop daily in the morning	
Tafluprost 0.0015% and timolol 0.5% (Taptiqom [preservative-free]) Not available in United States	One drop daily	
Travoprost 0.004% and timolol 0.5% (DuoTrav) Not available in United States	One drop daily	

(*continued*)

Table 7–2. Topical ophthalmic agents (selected list). (continued)

Agent	Recommended Regimen	Indications
Mydriatic Agents for Pupillary Dilation (ophthalmic)		
Tropicamide 1% and phenylephrine 2.5%	One drop	Shorter-acting mydriatic for eye examination
Cyclopentolate 1% and homatropine 5%	One drop twice daily	Long-acting cycloplegic for treatment of uveitis to prevent iris synechiae and relieve pain from ciliary spasm
Atropine 1%	One drop daily	

[1] Little efficacy against gram-negative organisms (except *Neisseria*).
[2] No gram-positive coverage.
[3] May produce rebound hyperemia and local reactions.
[4] Frequency of corticosteroid use is determined by the severity of the inflammation and is tapered as inflammation decreases. Long-term use may increase intraocular pressure (eye pressure should be monitored), may contribute to cataract development, and predisposes to bacterial, herpes simplex virus, and fungal keratitis.
[5] Because of its high potency, this is the corticosteroid most likely to cause increased intraocular pressure.
[6] Less likely to elevate intraocular pressure.
[7] Cardioselective (β-1) β-blocker.
[8] Teoptic is not available in the United States.
[9] Nonselective (β-1 and β-2) β-blocker. Monitor all patients for systemic side effects, particularly exacerbation of asthma.
[10] Decreased night vision and headaches possible.

Ocular rosacea results in inflammation of meibomian glands and is a common cause of posterior blepharitis. Anterior and posterior blepharitis may appear singularly or together. Typical symptoms of blepharitis include red and itchy eyelids and burning or foreign body sensations.

Initial treatment for anterior blepharitis commonly includes medicated or nonmedicated eyelash scrubs. Topical antimicrobials (Table 7–2) targeting staphylococcal or *Demodex* mite overgrowth can be helpful. Posterior blepharitis can be treated with warm compresses. Oral antibiotics (tetracyclines and macrolides) may be helpful in patients with rosacea.

5. Allergic Eye Disease

Allergic eye disease is common, takes a number of different forms, and is an expression of atopy, which may also manifest as atopic asthma, atopic dermatitis, or allergic rhinitis.

Clinical Findings

Symptoms include itching, tearing, redness, stringy discharge, and occasionally, photophobia and visual loss.

Allergic conjunctivitis is common. It may be seasonal (hay fever), often flaring during the spring, or perennial. Clinical signs include conjunctival hyperemia and edema (chemosis), the latter at times being marked and sudden in onset.

Vernal keratoconjunctivitis tends to occur in late childhood and early adulthood. It is usually seasonal, with a predilection for the spring. Large "cobblestone" papillae are noted on the upper tarsal conjunctiva.

Atopic keratoconjunctivitis is a more chronic disorder of adulthood. Both the upper and the lower tarsal conjunctivas exhibit a papillary conjunctivitis. Severe cases demonstrate conjunctival fibrosis, resulting in eyelid scarring, entropion, and trichiasis. Corneal involvement, including refractory ulceration, is frequent during exacerbations of both vernal and severe atopic keratoconjunctivitis. The latter may be complicated by herpes simplex keratitis.

Treatment

A. Mild and Moderately Severe Allergic Eye Disease

Ophthalmic anti-inflammatory agents include mast cell stabilizers and antihistamines (see Anti-Inflammatory Agents in Table 7–2). Mast cell stabilization takes longer to act than antihistamines but can be useful for prophylaxis. Ophthalmic vasoconstrictors, such as ephedrine, naphazoline, tetrahydrozoline, and phenylephrine, alone or in combination with antihistamines, are available as over-the-counter medications and not typically used because of limited efficacy, rebound hyperemia, and follicular conjunctivitis. Systemic antihistamines (eg, loratadine 10 mg orally daily) may be useful in prolonged atopic keratoconjunctivitis. In allergic conjunctivitis, specific allergens may be avoidable.

B. Acute Exacerbations and Severe Allergic Eye Disease

Ophthalmic corticosteroids (Table 7–2) are commonly required to control acute exacerbations of both vernal and atopic keratoconjunctivitis. The lowest-potency corticosteroid that controls ocular inflammation should be used. Corticosteroid-induced side effects should be monitored by eye care professionals and include cataracts, glaucoma, and exacerbation of herpes simplex keratitis. Ophthalmic cyclosporine or tacrolimus may be effective. Systemic corticosteroid or other immunosuppressant therapy may be required in severe atopic keratoconjunctivitis.

PINGUECULA & PTERYGIUM

Pinguecula is a yellowish, elevated conjunctival nodule adjacent to the cornea and in the palpebral fissure. It is common in persons over age 35 years. **Pterygium** is a fleshy, triangular encroachment of the conjunctiva onto the cornea and is usually associated with prolonged exposure to wind, sun, sand, and dust. Pinguecula and pterygium are often bilateral and occur more frequently on the nasal side of the conjunctiva.

Pingueculae rarely grow but may become inflamed (pingueculitis). Pterygia become inflamed and may grow. Treatment is rarely required for inflammation of pinguecula or pterygium, and artificial tears are often beneficial.

The indications for excision of pterygium are growth that threatens vision by encroaching on the cornea, marked induced astigmatism, or severe ocular irritation.

CORNEAL ULCER

Corneal ulcers are most commonly due to infection by bacteria, viruses, fungi, or amoebas. All persons wearing contact lenses should be counseled not to sleep, swim, or shower before removing them. Noninfectious causes—all of which may be complicated by infection—include neurotrophic keratitis (resulting from loss of corneal sensation), exposure keratitis (due to inadequate lid closure), severe dry eye, severe allergic eye disease, and inflammatory disorders that may be purely ocular or part of a systemic vasculitis. Delayed or ineffective treatment of corneal ulceration may lead to devastating consequences and vision loss. Prompt referral is essential.

Patients complain of pain, photophobia, tearing, and reduced vision. The conjunctiva is injected, and there may be purulent or watery discharge. The corneal appearance varies according to the underlying cause.

▶ When to Refer

Any patient with an acute painful red eye and corneal abnormality should be referred emergently to an ophthalmologist. Contact lens wearers with acute eye pain, redness, and decreased vision should be referred immediately.

Ting DSJ … Seitzman GD et al. Diagnostic armamentarium of infectious keratitis: a comprehensive review. Ocul Surf. 2022;23:27. [PMID: 34781020]

INFECTIOUS KERATITIS

1. Bacterial Keratitis

Risk factors for bacterial keratitis include contact lens wear—especially overnight wear—and corneal trauma, including surgery. The most common pathogens are staphylococci, including MRSA; streptococci; and *Pseudomonas aeruginosa*, *Moraxella* species, and other gram-negative bacilli. The cornea has an epithelial defect and an underlying opacity on slit-lamp examination, or may have a "white spot" on direct visualization. Hypopyon may be present. Ophthalmic fluoroquinolones, such as levofloxacin 0.5%, ofloxacin 0.3%, norfloxacin 0.3%, or ciprofloxacin 0.3%, are commonly used as first-line agents when the local prevalence of resistant organisms is low (Table 7–2). For severe central ulcers, diagnostic scrapings can be sent for Gram stain and culture. Treatment may include compounded high-concentration ophthalmic antibiotic drops applied hourly day and night for at least the first 48 hours. Fourth-generation ophthalmic fluoroquinolones (moxifloxacin 0.5% and gatifloxacin 0.3%) are also frequently used in this setting. Although early adjunctive ophthalmic corticosteroid therapy may improve visual outcome, it should be prescribed only by an ophthalmologist.

▶ When to Refer

Any patient with suspected bacterial keratitis must be referred emergently to an ophthalmologist.

Lin A et al; American Academy of Ophthalmology Preferred Practice Pattern Cornea and External Disease Panel. Bacterial keratitis: Preferred Practice Pattern®. Ophthalmology. 2019;126:P1. [PMID: 30366799]

2. Herpes Simplex Keratitis

Primary ocular herpes simplex virus infection may manifest as lid, conjunctival, or corneal ulceration. Virus colonization of the trigeminal ganglion leads to recurrences that may be precipitated by fever, excessive exposure to sunlight, or immunodeficiency. Herpetic corneal disease is typically unilateral but can be bilateral with atopy or immunocompromise. The dendritic (branching) corneal ulcer is the most characteristic manifestation of herpetic corneal disease. More extensive "geographic" ulcers also occur, particularly if ophthalmic corticosteroids have been used. The corneal ulcers are most easily seen with a slit lamp after instillation of fluorescein and examination with a cobalt blue light. Treatment of corneal herpetic disease is with ophthalmic antiviral agents (eg, ganciclovir 0.15% gel, one drop five times daily until healing has occurred and then one drop three times daily for 1 more week, trifluoride drops, or acyclovir ointment) or oral antiviral agents (eg, acyclovir, 400–800 mg five times daily or valacyclovir 500–1000 mg three times daily for 7–14 days). Ophthalmic antiviral agents may cause corneal toxicity after approximately 10–14 days of therapy and are not commonly used for long-term suppressive therapy.

Stromal herpes simplex keratitis produces increasingly severe corneal opacity with each recurrence. Antiviral agents alone are insufficient to control stromal disease; thus ophthalmic corticosteroids are also used, but they may enhance viral replication and steroid dependence frequently occurs. **Caution:** *For patients with known or possible herpetic disease, ophthalmic corticosteroids should be prescribed only with ophthalmologic consultation.* Severe stromal scarring may require corneal transplantation; recurrence in the new cornea is common and long-term oral antiviral agents are required.

The rate of recurrent corneal herpetic disease is reduced by using long-term oral acyclovir, 400 mg twice daily; famciclovir, 250 mg once daily; or valacyclovir, 500 mg once daily. Long-term oral antiviral dosing may be adjusted if the disease breaks through suppressive dosing or if kidney dysfunction is present.

When to Refer

Any patient with a history of herpes simplex keratitis and an acute red eye should be referred urgently to an ophthalmologist.

3. Herpes Zoster Ophthalmicus

Herpes zoster frequently involves the ophthalmic division of the trigeminal nerve. It presents with malaise, fever, headache, and periorbital burning and itching. These symptoms may precede the eruption by a day or more. The rash is initially vesicular, quickly becoming pustular and then crusting. Involvement of the tip of the nose or the lid margin predicts involvement of the eye. Ocular signs include conjunctivitis, keratitis, episcleritis, and anterior uveitis, often with elevated intraocular pressure. If needed, PCR from aqueous or corneal pseudodendrites can confirm the clinical diagnosis. Recurrent anterior segment inflammation, neurotrophic keratitis, and posterior subcapsular cataract are long-term complications. Optic neuropathy, cranial nerve palsies, acute retinal necrosis, and cerebral angiitis occur infrequently. HIV infection is an important risk factor for herpes zoster ophthalmicus and increases the likelihood of complications.

High-dose oral acyclovir (800 mg five times a day), valacyclovir (1 g three times a day), or famciclovir (500 mg three times a day) for 7–10 days started within 72 hours after the appearance of the rash reduces the incidence of ocular complications but not of postherpetic neuralgia. Treatment of keratitis is discussed above. Anterior uveitis requires additional treatment with ophthalmic corticosteroids and cycloplegic agents (eg, cyclopentolate). Ophthalmic corticosteroids, which promote viral replication, may have to be delayed until the keratitis has resolved. Neurotrophic keratitis is an important cause of long-term morbidity. Extending oral antiviral therapy for 12 months is recommended to reduce recurrence rates and duration of pain.

When to Refer

Any patient with herpes zoster ophthalmicus and ocular symptoms or signs should be referred urgently to an ophthalmologist.

4. Fungal Keratitis

Fungal keratitis tends to occur after corneal injury involving plant material or in agricultural settings, in eyes with chronic ocular surface disease, and in contact lens wearers. It may be an indolent process. The corneal infiltrate may have feathery edges and multiple “satellite” lesions. A hypopyon may be present. Unlike bacterial keratitis, an epithelial defect may or may not be present. Corneal scrapings should be cultured on media suitable for fungi. Diagnosis is often delayed, and treatment frequently requires 6 months or longer for severe disease. Natamycin 5%, amphotericin 0.1–0.5%, and voriconazole 0.2–1% are commonly used ophthalmic agents (Table 7–2). Systemic azoles are probably not helpful unless there is scleritis or intraocular infection. Corneal grafting is often required.

Donovan C et al. Fungal keratitis: mechanisms of infection and management strategies. Surv Ophthalmol. 2022;67:758. [PMID: 34425126]

5. Amoebic Keratitis

Amoebic infection from *Acanthamoeba* is an important cause of keratitis. The two greatest risk factors in developed countries are contact lens wear and fresh-water or hot-tub exposure. Although severe pain with perineural and ring infiltrates in the corneal stroma is characteristic, it is not specific and earlier forms with changes confined to the corneal epithelium are identifiable. Diagnosis is facilitated by confocal microscopy and Giemsa staining of cornea smears. Culture requires specialized media. Intensive ophthalmic compounded biguanide (polyhexamethylene or chlorhexidine) is initiated immediately, and long-term treatment is required. Ophthalmic diamidine (propamidine or hexamidine) may be added. Oral miltefosine is FDA approved for the treatment of *Acanthamoeba* keratitis, but indications and efficacy have yet to be established. There should be close monitoring for systemic toxicity (vomiting, diarrhea, elevation of transaminases, and kidney function tests) during its use. Delayed diagnosis and prior treatment with ophthalmic corticosteroids adversely affect the visual outcome. Corneal grafting may be required after resolution of infection to restore vision.

ACUTE ANGLE-CLOSURE GLAUCOMA

ESSENTIALS OF DIAGNOSIS

- Older age group, particularly farsighted individuals.
- Rapid onset of severe pain and profound visual loss with “halos around lights.”
- Red eye, cloudy cornea, dilated pupil.
- Hard eye on palpation.

General Considerations

Primary acute angle-closure glaucoma (acute angle-closure crisis) results from closure of a preexisting narrow anterior chamber angle. The predisposing factors are shallow anterior chamber, which may be associated with farsightedness or a small eye (short axial length); enlargement of the crystalline lens with age; and inheritance, such as among persons of Inuit and Asian ancestry. Closure of the angle is precipitated by pupillary dilation and thus can occur from sitting in a darkened theater, during times of stress, following nonocular administration of anticholinergic or sympathomimetic agents (eg, nebulized bronchodilators, atropine, antidepressants, bowel or bladder antispasmodics, nasal decongestants, or tocolytics), or, rarely, from pharmacologic mydriasis (see Precautions in Management of Ocular Disorders, below). Subacute primary angle-closure glaucoma may present as recurrent headache.

Secondary acute angle-closure glaucoma does not require a preexisting narrow angle and the mechanism may differ between cases. It may occur in anterior uveitis, with dislocation of the lens, with hemodialysis, or due to various drugs (see Adverse Ocular Effects of Systemic Drugs, below). The reduction in serum osmolarity that occurs with hemodialysis causes an osmotic gradient between the plasma and aqueous fluid, leading to a buildup of fluid in the aqueous compartment. Patients with a compromised outflow system (as with narrow angle) cannot accommodate the buildup and the intraocular pressure rises. Symptoms are the same as in primary acute angle-closure glaucoma, but differentiation is important for management.

Clinical Findings

Patients with acute glaucoma usually seek treatment immediately because of extreme pain and blurred vision, though there are subacute cases. Typically, the blurred vision is associated with halos around lights. Nausea and abdominal pain may occur. The eye is red, the cornea cloudy, and the pupil moderately dilated and nonreactive to light. Intraocular pressure is usually over 50 mm Hg, producing a hard eye on palpation.

Differential Diagnosis

Acute glaucoma must be differentiated from conjunctivitis, acute uveitis, and corneal disorders (Table 7–1).

Treatment

Initial treatment, regardless of mechanism, is reduction of intraocular pressure. A single 500-mg intravenous dose of acetazolamide, followed by 250 mg orally four times a day, together with topical medications such as timolol maleate (a β-blocker) that lower intraocular pressure (Table 7–2), is usually sufficient. Osmotic diuretics, such as oral glycerin and intravenous urea or mannitol—the dosage of all three being 1–2 g/kg—may be necessary if there is no response to acetazolamide. Definitive treatment depends on the mechanism.

A. Primary Angle-Closure Glaucoma

In primary acute angle-closure glaucoma, once the intraocular pressure has started to fall, topical 4% pilocarpine, 1 drop every 15 minutes for 1 hour and then four times a day, is used to reverse the underlying angle closure. The definitive treatment is cataract extraction. Laser peripheral iridotomy is also a first-line treatment.

All patients with primary acute angle closure should undergo prophylactic laser peripheral iridotomy to the unaffected eye, or early cataract extraction should be considered, unless that eye has already undergone cataract or glaucoma surgery.

B. Secondary Angle-Closure Glaucoma

In secondary acute angle-closure glaucoma, additional treatment is determined by the cause.

Prognosis

Untreated acute angle-closure glaucoma results in severe and permanent visual loss within 2–5 days after onset of symptoms. Affected patients need to be monitored for development of chronic glaucoma.

When to Refer

Any patient with suspected acute angle-closure glaucoma must be referred emergently to an ophthalmologist.

Gedde SJ et al. American Academy of Ophthalmology Preferred Practice Pattern Glaucoma Panel. Primary Angle-Closure Disease Preferred Practice Pattern®. Ophthalmology. 2021;128:30. [PMID: 34933744]

CHRONIC GLAUCOMA

ESSENTIALS OF DIAGNOSIS

- Three types of chronic glaucoma: open-angle glaucoma, angle-closure glaucoma, and normal-tension glaucoma.
- No symptoms in early stages.
- Insidious progressive bilateral loss of peripheral vision resulting in tunnel vision; visual acuities preserved until advanced disease.
- Pathologic cupping of the optic disks.
- Intraocular pressure is usually elevated.

General Considerations

Chronic glaucoma is characterized by gradually progressive excavation ("cupping") of the optic disk with loss of vision progressing from slight visual field loss to complete blindness.

Chronic open-angle glaucoma—intraocular pressure is elevated in either primary or secondary glaucoma due to reduced drainage of aqueous fluid through the trabecular meshwork.

Chronic angle-closure glaucoma—the flow of aqueous fluid into the anterior chamber angle is obstructed in this disorder, which is particularly common in persons of Inuit and eastern Asian ancestry.

Normal-tension glaucoma—intraocular pressure is not elevated in this form of glaucoma, but the same pattern of optic nerve damage occurs.

Primary chronic open-angle glaucoma is usually bilateral. There is an increased prevalence in first-degree relatives of affected individuals and in patients with diabetes. In Afro-Caribbean and African persons, and probably in Latino persons, it is more frequent, occurs at an earlier age, and results in more severe optic nerve damage. Secondary chronic open-angle glaucoma may result from ocular disease, eg, pigment dispersion, pseudoexfoliation, uveitis, or trauma; or corticosteroid therapy, whether it is intraocular, topical, inhaled, intranasal, or systemic.

It is estimated that 2% of Americans > 40 years of age have chronic glaucoma, affecting > 2.5 million individuals. At least 25% of cases are undetected. More than 90% of cases are of the open-angle type. The incidence of normal-tension glaucoma (a type of open-angle glaucoma) ranges from 10% to 50%. Worldwide, about 45 million people have open-angle glaucoma, of whom about 4.5 million are bilaterally blind. About 4 million people, of whom approximately 50% live in China, are bilaterally blind from chronic angle-closure glaucoma.

Clinical Findings

Because initially there are no symptoms, chronic glaucoma is often first suspected at a routine eye test. Diagnosis requires consistent and reproducible abnormalities in at least two of three parameters—optic disk or retinal nerve fiber layer (or both), visual field, and intraocular pressure.

1. Optic disk cupping—Optic disk cupping is identified as an absolute increase or an asymmetry between the two eyes of the ratio of the diameter of the optic cup to the diameter of the whole optic disk (cup-disk ratio). (Cup-disk ratio > 0.5 or asymmetry between eyes of ≥ 0.2 is suggestive.) Detection of optic disk cupping and associated abnormalities of the retinal nerve fiber layer is facilitated by optical coherence tomography scans.

2. Visual field abnormalities—Visual field abnormalities initially develop in the paracentral region, followed by constriction of the peripheral visual field. Central vision remains good until late in the disease.

3. Intraocular pressure—The normal range of intraocular pressure is 10–21 mm Hg. In many individuals, elevated intraocular pressure is not associated with optic disk or visual field abnormalities (ocular hypertension). Monitoring for the development of glaucoma is required in all such cases; a significant proportion of eyes with primary open-angle glaucoma have initial normal intraocular pressure, and only repeated measurements identify the abnormally high pressure. In normal-tension glaucoma, intraocular pressure is always within the normal range.

Prevention

There are many causes of optic disk abnormalities or visual field changes that mimic glaucoma, and visual field testing may prove unreliable in some patients, particularly in the older age group. Although all persons over age 50 years may benefit from intraocular pressure measurement and optic disk examination every 3–5 years, screening for chronic open-angle glaucoma should be targeted at individuals with an affected first-degree relative, at persons who have diabetes mellitus, and at older individuals with African or Hispanic ancestry. Screening may also be warranted in patients taking long-term oral or combined intranasal and inhaled corticosteroid therapy. Screening for chronic angle-closure glaucoma should be targeted at persons with Inuit or Asian ancestry.

Treatment

A. Medications

Medical treatment is directed toward lowering intraocular pressure, even with normal-tension glaucoma. Prostaglandin analog eye drops are commonly used as first-line therapy because of their efficacy, lack of systemic side effects, and convenient once-daily dose (except unoprostone) (see Table 7–2). All may produce conjunctival hyperemia, permanent darkening of the iris and eyebrow color, increased eyelash growth, and reduction of periorbital fat (prostaglandin-associated periorbitopathy). Latanoprostene bunod is metabolized into latanoprost and another component that releases nitric oxide, which increases trabecular outflow. Topical β-adrenergic blockers may be used alone or in combination with a prostaglandin analog. The use of topical β-adrenergic blockers may be contraindicated in patients with reactive airway disease or HF. Cardioselective betaxolol is theoretically safer in reactive airway disease but less effective at reducing intraocular pressure. Brimonidine 0.2%, a selective α_2-adrenoceptor agonist, and topical carbonic anhydrase inhibitors can be used in addition to a prostaglandin analog or a β-blocker or as initial therapy when prostaglandin analogs and β-blockers are contraindicated. All three are associated with allergic reactions. Brimonidine may cause uveitis. Apraclonidine, 0.5–1%, another α_2-adrenoceptor agonist, can be used to defer surgery in patients receiving maximal medical therapy, but long-term use is limited by adverse reactions. It is more commonly used to control acute rise in intraocular pressure, such as after laser therapy. The topical agent netarsudil ophthalmic solution 0.02% (a Rho kinase inhibitor) increases aqueous fluid outflow through the trabecular meshwork. Pilocarpine 1–4% is rarely used because of adverse effects. Oral carbonic anhydrase inhibitors (such as acetazolamide) may be used long-term if topical therapy is inadequate and surgical or laser therapy is inappropriate.

Various eye drop preparations combining two agents (eg, prostaglandin analogs, β-adrenergic blocking agents, brimonidine, and topical carbonic anhydrase inhibitors) are available to improve compliance when multiple medications are required. Formulations of one or two agents without preservative or not including benzalkonium chloride as the preservative are preferred to reduce adverse ocular effects for patients with allergies or severe dry eyes.

B. Laser Therapy and Surgery

1. Open-angle glaucoma—Laser trabeculoplasty is used as an adjunct to topical therapy to defer surgery for open-angle glaucoma; it is also advocated as primary treatment, especially when compliance with medications is an issue. Surgical trabeculectomy is generally undertaken when intraocular pressure is inadequately controlled by medical and laser therapy, but it may also be used as primary treatment in advanced cases. Trabeculectomy remains the standard procedure. Adjunctive treatment with subconjunctival mitomycin or fluorouracil is used perioperatively or postoperatively in worse prognosis cases. A variety of less invasive procedures that avoid a full-thickness incision into the eye, called microinvasive glaucoma surgery, are appropriate for moderate glaucoma and are associated with fewer complications but can be more difficult to perform.

2. Angle-closure glaucoma—In chronic angle-closure glaucoma, laser peripheral iridotomy, surgical peripheral iridectomy, or cataract extraction may be helpful. In patients with asymptomatic narrow anterior chamber angles, which includes about 10% of Chinese adults, prophylactic laser peripheral iridotomy can reduce the risk of acute and chronic angle-closure glaucoma. However, there are concerns about the efficacy of such treatment and the risk of cataract progression and corneal decompensation. In the United States, about 1% of people over age 35 years have narrow anterior chamber angles, but acute and chronic angle closure are sufficiently uncommon that prophylactic therapy is not generally advised.

3. Normal-tension glaucoma—The goal of treatment for normal-tension glaucoma is reduction in intraocular pressure by 30% (even if it is in the normal range) to prevent progression. As with open-angle glaucoma, if intraocular pressure is not lowered with medical therapy alone, laser trabeculoplasty is used as an adjunct. Trabeculectomy is the standard surgical procedure if medical and laser therapy are inadequate.

Prognosis

Untreated chronic glaucoma that begins at age 40–45 years will probably cause complete blindness by age 60–65. Early diagnosis and treatment can preserve useful vision throughout life. In primary open-angle glaucoma and if treatment is required in ocular hypertension, the aim is to reduce intraocular pressure to a level that will adequately reduce progression of visual field loss. In eyes with marked visual field or optic disk changes, intraocular pressure must be reduced to < 16 mm Hg. In normal-tension glaucoma with progressive visual field loss, it is necessary to achieve even lower intraocular pressure such that surgery is often required.

When to Refer

All patients with suspected chronic glaucoma should be referred to an ophthalmologist or optometrist.

UVEITIS

ESSENTIALS OF DIAGNOSIS

- Usually immunologic but possibly infectious or neoplastic.
- Inflammation may be confined to the eye or may be systemic.
- **Acute anterior uveitis:** sudden redness and blurry vision, often with photophobia.
- **Posterior uveitis:** gradual loss of vision, commonly with floaters, in a variably inflamed eye.

General Considerations

Intraocular inflammation (uveitis) is clinically classified as acute or chronic and also classified by which ocular anatomic locations are involved (anterior, intermediate, posterior, or all [panuveitis]).

In most cases the pathogenesis of uveitis is primarily immunologic, but infection may be the cause, particularly in immunodeficiency states. Most causes of uveitis can present in a variety of ocular anatomic locations.

1. Anterior uveitis—Systemic disorders associated with anterior uveitis include HLA-B27–related conditions (ankylosing spondylitis, reactive arthritis, psoriasis, ulcerative colitis, and Crohn disease). Sarcoidosis, toxoplasmosis, tuberculosis, syphilis, and Vogt-Koyanagi-Harada disease (bilateral uveitis associated with alopecia, poliosis [depigmented eyelashes, eyebrows, or hair], vitiligo, and hearing loss) can present as acute, chronic, anterior, and posterior uveitis. Behçet syndrome may present with chronic recurrent anterior uveitis, recurrent hypopyon, and posterior uveitis, characteristically with branch retinal vein occlusions. Sympathetic ophthalmia may present as anterior or posterior uveitis and occurs after penetrating ocular trauma. Chronic anterior uveitis occurs in juvenile idiopathic arthritis. Both herpes simplex and herpes zoster infections may cause acute anterior uveitis as well as retinitis (acute retinal necrosis).

2. Intermediate, posterior, and panuveitis—Intermediate uveitis generally manifests as far peripheral retinal abnormalities (pars planitis). It is often idiopathic but can be due to multiple sclerosis or sarcoidosis. Retinal vasculitis predominantly manifests as posterior uveitis with central or peripheral retinal abnormalities. It can be caused by many infectious agents and noninfectious systemic conditions, including vasculitis, but may be idiopathic. With toxoplasmosis, there may be evidence of previous episodes of retinochoroiditis. Syphilis may induce a “salt and pepper” fundus but may present with a wide variety of clinical manifestations. Common pathogens resulting in ocular inflammation during HIV infection are cytomegalovirus (CMV), herpes simplex and herpes zoster viruses, mycobacteria, *Cryptococcus*, *Toxoplasma*, and *Candida*. Any etiology of uveitis that presents with anterior and posterior or intermediate and posterior uveitis is labeled panuveitis.

Clinical Findings

Anterior uveitis is characterized by inflammatory cells and flare, best visualized with a slit lamp within the aqueous humor. In severe cases, there may be hypopyon (layered collection of white cells) and fibrin within the anterior chamber. Cells may also be seen on the corneal endothelium as keratic precipitates. In granulomatous uveitis, there are large "mutton-fat" keratic precipitates, and sometimes iris nodules. In nongranulomatous uveitis, the keratic precipitates are smaller or absent with no iris nodules. The pupil is usually small, and with the development of posterior synechiae (adhesions between the iris and anterior lens capsule), it also becomes irregularly shaped and poorly reactive.

Anterior uveitis tends to present acutely with unilateral pain, redness, photophobia, and visual loss. However, the ocular inflammation associated with juvenile idiopathic arthritis is frequently indolent, commonly asymptomatic initially, and carries a high risk of sight-threatening complications. Chronic recurrent anterior uveitis may cause blurred vision in a variably inflamed eye. **Intermediate uveitis** presents with vitreous inflammation.

Posterior uveitis can occur with retinitis or choroiditis, with or without vasculitis or vitreous inflammation. New retinal lesions are yellow with indistinct margins, and there may be retinal hemorrhages. Older lesions have more defined margins and are commonly pigmented. Retinal vessel sheathing may occur adjacent to such lesions or more diffusely. In severe cases, vitreous opacity precludes visualization of retinal details.

Posterior uveitis can be unilateral or bilateral with symptoms of floaters and visual loss. Symptoms are commonly slower in onset, though acute presentations can occur. Visual loss may be due to vitreous haze and opacities, inflammatory lesions involving the macula, macular edema, retinal vein occlusion, or rarely, optic neuropathy.

Differential Diagnosis

Retinal detachment, intraocular tumors, and CNS lymphoma may all masquerade as uveitis.

Treatment

Anterior uveitis usually responds to ophthalmic corticosteroids (Table 7–2). Occasionally, periocular or intraocular corticosteroid injections or even systemic corticosteroids are required. Dilation of the pupil with a cycloplegic agent (eg, cyclopentolate, homatropine, atropine) (Table 7–2) is important to relieve discomfort and prevent permanent posterior synechiae. **Intermediate, posterior, and panuveitis** more commonly require systemic, periocular, or intravitreal corticosteroid therapy. In chronic cases, systemic corticosteroid-sparing immunomodulatory therapy with agents such as azathioprine, cyclosporine, mycophenolate, methotrexate, tacrolimus, or sirolimus is commonly required. Biologic therapies also are often used. Pupillary dilation is not usually necessary.

If an infectious cause is identified, specific antimicrobial therapy is often needed. In general, the prognosis for anterior uveitis is better than that for posterior uveitis.

When to Refer

- Any patient with suspected acute uveitis should be referred urgently to an ophthalmologist or emergently if there is visual loss or severe pain.
- Any patient with suspected chronic uveitis should be referred to an ophthalmologist, urgently if there is more than mild visual loss.

Al-Janabi A et al. Long-term outcomes of treatment with biological agents in eyes with refractory, active, noninfectious intermediate uveitis, posterior uveitis, or panuveitis. Ophthalmology. 2020;127:410. [PMID: 31607412]

CATARACT

ESSENTIALS OF DIAGNOSIS

- Gradually progressive blurred vision.
- No pain or redness.
- Lens opacities (may be grossly visible).

General Considerations

Cataracts are opacities of the crystalline lens and are usually bilateral. They are the leading cause of blindness worldwide. Age-related cataract is by far the most common cause. Other causes include (1) congenital (from intrauterine infections, such as rubella and CMV, or inborn errors of metabolism, such as galactosemia); (2) traumatic; (3) secondary to systemic disease (diabetes mellitus, myotonic dystrophy, atopic dermatitis); (4) topical, systemic, or inhaled corticosteroid treatment; (5) uveitis; or (6) radiation exposure. Most persons over age 60 have some degree of lens opacity. Cigarette smoking increases the risk of cataract formation. Multivitamin/mineral supplements and high dietary antioxidants may prevent the development of age-related cataract.

Clinical Findings

The predominant symptom is progressive blurring of vision. Glare, especially in bright light or with night driving; change of focusing, particularly development of nearsightedness; and monocular double vision may occur.

Even in its early stages, a cataract can be seen through a dilated pupil with an ophthalmoscope or slit lamp. As the cataract matures, the retina will become increasingly difficult to visualize, until finally the fundus reflection is absent and the pupil is white.

Treatment

Functional visual impairment, specifically its effect on daily activities and increased risk of falls, is the prime criterion for surgery. The cataract is usually removed by one of the techniques in which the posterior lens capsule remains (extracapsular), thus providing support for a prosthetic intraocular lens. Ultrasonic fragmentation (phacoemulsification) of the lens nucleus and foldable intraocular lenses allow cataract surgery to be performed through a small incision without the need for sutures, thus reducing the postoperative complication rate and accelerating visual rehabilitation. The standard monofocal prosthetic intraocular lens can correct near or far vision. Premium intraocular lenses (multifocal, extended depth of focus, and accommodative) reduce the need for both distance and near vision correction. The light-adjustable lens is a type of intraocular lens that can be adjusted to improve vision after cataract surgery. In the developing world, manual small-incision surgery, in which the lens nucleus is removed intact, is popular because less equipment is required. Additional laser treatment may be required subsequently (months to years after the initial cataract surgery) if the posterior capsule opacifies. The use of topical eye drops to dissolve or prevent cataracts has shown promising results in experimental models; surgery, however, is currently the only treatment option for a visually significant cataract.

Prognosis

Cataract surgery is cost-effective in improving survival and quality of life. In the developed world, it improves visual acuity in 95% of cases. In the other 5%, there is preexisting retinal damage or operative or postoperative complications. In less developed areas, the improvement in visual acuity is not as high, in part due to uncorrected refractive error postoperatively. Nasolacrimal duct obstruction increases the risk of intraocular infection (endophthalmitis).

A large number of drugs, such as α-adrenoreceptor antagonists for benign prostatic hyperplasia and antipsychotics, increase the risk of complications during surgery (floppy iris syndrome) and in the early postoperative period. The α-blocker tamsulosin has the greatest risk of floppy iris syndrome. There is no consensus about whether to stop α-blockers before surgery because the effects of the drug on the iris can persist for months to years. The surgeon must know if the patient is taking an α-blocker to prepare for iris issues during surgery. If the patient has not yet started an α-blocker and is planning to have cataract surgery shortly, it is best to wait until after surgery to begin the medication, if possible.

When to Refer

Patients with cataracts should be referred to an ophthalmologist when their visual impairment adversely affects their everyday activities.

Miller KM et al. American Academy of Ophthalmology Preferred Practice Pattern Cataract/Anterior Segment Panel. Cataract in the Adult Eye Preferred Practice Pattern®. Ophthalmology. 2022;129:1. [PMID: 34780842]

RETINAL DETACHMENT

ESSENTIALS OF DIAGNOSIS

- Loss of vision in one eye that is usually rapid, possibly with "curtain" spreading across field of vision.
- No pain or redness.
- Detachment seen by ophthalmoscopy.

General Considerations

Most cases of retinal detachment are due to development of one or more peripheral retinal tears or holes (rhegmatogenous retinal detachment). This usually results from posterior vitreous detachment, related to degenerative changes in the vitreous, and often occurs in persons over 50 years of age. Nearsightedness and cataract extraction are the two most common predisposing causes. It may also be caused by penetrating or blunt ocular trauma, sometimes years earlier.

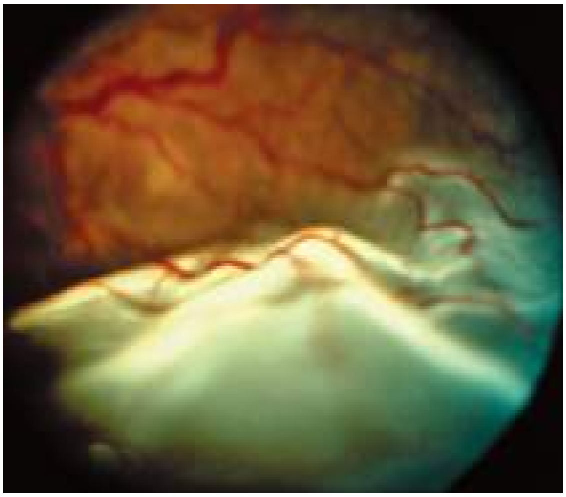
Tractional retinal detachment occurs when there is preretinal fibrosis, such as in proliferative retinopathy due to diabetic retinopathy or retinal vein occlusion, or as a complication of rhegmatogenous retinal detachment. Exudative retinal detachment results from accumulation of subretinal fluid, such as in neovascular age-related macular degeneration or secondary to choroidal tumor.

Clinical Findings

Rhegmatogenous retinal detachment usually starts in the peripheral retina, spreading rapidly to cause visual field loss. Symptoms of the predisposing posterior vitreous detachment with vitreoretinal traction include recent onset of or increase in floaters and photopsias (flashes of light). Central vision remains intact until the central macula becomes detached. On ophthalmoscopic examination, the retina may be seen elevated in the vitreous cavity with an irregular surface (Figure 7–1). In tractional retinal detachment, there is irregular retinal elevation adherent to scar tissue on the retinal surface, sometimes extending into the vitreous. Exudative retinal detachments are dome-shaped and the subretinal fluid shifts position with changes in posture. Ocular ultrasonography assists in the detection and characterization of retinal detachment, especially if blood accompanies the retinal detachment.

Treatment

Treatment of rhegmatogenous retinal detachments requires closing all the retinal tears and holes by forming a permanent adhesion with laser photocoagulation to the retinal pigment epithelium or cryotherapy to the sclera. Certain types of uncomplicated retinal detachment may be treated



▲ **Figure 7–1.** Inferior retinal detachment as seen on direct or indirect ophthalmoscopy.

by pneumatic retinopexy, in which an expansile gas is injected into the vitreous cavity and the patient's head is positioned to facilitate apposition between the gas and the hole, which permits reattachment of the retina. Once the retina is reattached, the retinal defects are surrounded by laser photocoagulation or cryotherapy scars; these two methods are also used to seal retinal defects without associated detachment.

In complicated retinal detachments, particularly tractional retinal detachments, retinal reattachment can be accomplished only by vitrectomy, direct manipulation of the retina, and internal tamponade of the retina with air, expansile gas, or silicone oil. The presence of an expansile gas within the eye is a contraindication to air travel, mountaineering at high altitude, and nitrous oxide anesthesia, all of which can cause the gas to expand with severe increases in intraocular pressure. Such gases persist in the globe for weeks after surgery (see Chapter 42). Treatment of exudative retinal detachments is determined by the underlying cause.

Prognosis

About 90% of uncomplicated rhegmatogenous retinal detachments can be cured with one operation. The visual prognosis is worse if the macula is detached or if the detachment is of long duration.

When to Refer

All cases of retinal detachment must be referred urgently to an ophthalmologist, and emergently if central vision is good because this indicates that the macula has not yet detached. During transportation, the patient's head is positioned so that the retinal tear is placed at the lowest point of the eye to minimize extension of the detached retina. If the inferior retina is detached with superior visual field loss, the patient should keep the head upright so that the tear is located at the lowest point, whereas if the temporal retina is detached (visual field loss on the side by the nose), the patient should keep the temporal side of the head (ear side) down to reduce the chances that the fluid will extend beneath the central retina, causing the macula to detach. If vision is good and the macula is attached, patients should minimize eye motion; in some patients, patching both eyes can be helpful in preventing the eyes from moving until surgery can be performed to repair the retinal detachment.

Starr MR et al. Primary retinal detachment outcomes study: summary of reports number 1 to number 18. Curr Opin Ophthalmol 2023;34:211. [PMID: 36866845]

VITREOUS HEMORRHAGE

Patients with vitreous hemorrhage complain of sudden visual loss, abrupt onset of floaters that may progressively increase in severity, or occasionally, "bleeding within the eye." Visual acuity ranges from 20/20 (6/6) to light perception. The eye is not inflamed, red, or painful, and clues to diagnosis are inability to see fundus details or localized blood in the vitreous, in front of the retina. Causes of vitreous hemorrhage include retinal tear (with or without detachment), diabetic or sickle cell retinopathy, retinal vein occlusion, retinal vasculitis, neovascular age-related macular degeneration, retinal arterial macroaneurysm, blood dyscrasia, anticoagulation, trauma, subarachnoid hemorrhage, and severe straining (Valsalva retinopathy).

When to Refer

All patients with suspected vitreous hemorrhage must be referred urgently to an ophthalmologist to determine the etiology. If the vitreous hemorrhage is caused by a retinal tear or detachment, it must be repaired urgently to prevent permanent vision loss.

Shaikh N et al. Vitreous hemorrhage–causes, diagnosis, and management. Indian J Ophthalmol 2023;71:28. [PMID: 36588205]

AGE-RELATED MACULAR DEGENERATION

ESSENTIALS OF DIAGNOSIS

- Older age group.
- In one or both eyes; acute or chronic deterioration of central vision; distortion or abnormal size of images, sometimes developing acutely.
- No pain or redness.
- Classified as dry ("atrophic," "geographic") or wet ("neovascular," "exudative") macular degeneration.
- Macular abnormalities seen by ophthalmoscopy.

General Considerations

Age-related macular degeneration is the leading cause of permanent visual loss in the older population. Its prevalence progressively increases over age 50 years (to almost 30% by age 75). Its occurrence and response to treatment are likely influenced by genetically determined variations, many of which involve the complement pathway. Other associated factors include a slight female predominance, family history, hypertension, hypercholesterolemia, CVD, farsightedness, light iris color, and cigarette smoking (the most readily modifiable risk factor).

Although both dry and wet age-related macular degeneration are progressive and usually bilateral, a patient’s eyes are often affected asymmetrically and manifestations, prognosis, and management may differ between the eyes of an individual.

Clinical Findings

Drusen are the hallmark of age-related macular degeneration. The macula can be visualized with the use of a direct ophthalmoscope, by fundus photographs, or with cross-sectional optical coherence tomography scans. Hard drusen appear as discrete yellow subretinal deposits. Soft drusen are paler and less distinct. Large, confluent soft drusen are risk factors for neovascular (wet) age-related macular degeneration. Vision loss in age-related macular degeneration involves the central vision or pericentral vision in most patients. Peripheral fields, and hence navigational vision, are maintained, except in patients with severe neovascular age-related macular degeneration or in patients with coincident optic nerve disease such as glaucoma. Although “dry” age-related macular degeneration is more common, untreated “wet” age-related macular degeneration accounts for about 90% of all cases of legal blindness due to age-related macular degeneration.

1. “Dry” age-related macular degeneration—There is gradual progressive bilateral visual loss due to geographic atrophy of the outer retina, the retinal pigment epithelium, and the choriocapillaris, which supplies blood to both the outer retina and the retinal pigment epithelium.

2. “Wet” age-related macular degeneration—Choroidal new vessels grow under either the retina or the retinal pigment epithelial cells, leading to accumulation of exudative fluid, hemorrhage, and fibrosis. The onset of visual loss is more rapid and more severe than in atrophic degeneration. The two eyes are frequently affected sequentially over a period of a few years.

Treatment

No dietary modification has been shown to prevent the development of age-related macular degeneration, but its progression may be reduced by oral treatment with antioxidants (vitamins C and E), zinc, copper, and carotenoids (lutein and zeaxanthin, rather than vitamin A [β-carotene]). Oral omega-3 fatty acids do not provide additional benefit.

1. Dry age-related macular degeneration—Pegcetacoplan and avacincaptad pegol are FDA-approved agents for treatment of dry age-related macular degeneration with geographic atrophy of the outer retina extending toward the fovea. Both agents inhibit the complement pathway, are delivered by monthly or every-other-monthly injection into the vitreous, and slow the rate of growth of geographic atrophy lesions. However, both agents are associated with mildly increased risk of choroidal neovascularization, and intravitreal injection is associated with risks of infection (1/2000), retinal detachment (1/10,000), vitreous hemorrhage, and cataract. As with wet degeneration, rehabilitation including low-vision aids is important. Patients should be advised to stop smoking cigarettes and to take vitamin supplements as described above, which are similarly effective to the complement inhibitor therapies in reducing rates of progression.

2. “Wet” age-related macular degeneration—Inhibitors of vascular endothelial growth factors (VEGF), such as ranibizumab, bevacizumab, aflibercept, faricimab, and brolucizumab, and biosimilar medications, such as ranibizumab-nuna and ranibizumab-eqrn, can cause regression of choroidal neovascularization with resorption of subretinal fluid and improvement or stabilization of vision. Long-term repeated intraocular injections are often required and must be administered in the eye clinic several times a year, if not monthly. Treatment is well tolerated with minimal adverse effects, but there is a risk of infection, retinal detachment, vitreous hemorrhage, and cataract with each injection. Brolucizumab has been associated with intraocular inflammation and occlusive retinal vasculitis resulting in irreversible vision loss. Some patients do not respond to anti-VEGF injections, and up to one-third of eyes lose vision despite regular treatment.

When to Refer

Older patients with sudden visual loss, particularly paracentral or central distortion or scotoma with preserved central acuity, should be referred urgently to an ophthalmologist.

CENTRAL & BRANCH RETINAL VEIN OCCLUSIONS

ESSENTIALS OF DIAGNOSIS

- Sudden monocular loss of vision.
- No pain or redness.
- Widespread or sectoral retinal hemorrhages.

General Considerations

Central and branch retinal vein occlusion are common causes of acute vision loss, with branch vein occlusions being four times more common. The major predisposing factors are the etiologic factors associated with arteriosclerosis, but glaucoma is also a major risk factor.

Clinical Findings

A. Symptoms and Signs

1. Central retinal vein occlusion—Ophthalmoscopic signs include widespread retinal hemorrhages, retinal venous dilation and tortuosity, retinal cotton-wool spots, and optic disk swelling. Rarely, central retinal vein occlusion presents with severe vision loss and pain when neovascularization of the iris develops, usually about 90 days after a central retinal vein occlusion has caused severe retinal nonperfusion, release of vascular endothelial growth factor (VEGF), and growth of new blood vessels that block aqueous fluid from leaving the eye.

2. Branch retinal vein occlusion—Sudden loss of vision may occur at the time of occlusion if the fovea is involved, or some time afterward from vitreous hemorrhage due to retinal new vessels. More gradual visual loss may occur with development of macular edema. In acute branch retinal vein occlusion, the retinal abnormalities (hemorrhages, microaneurysms, venous dilation and tortuosity, and cotton-wool spots) are confined to the area drained by the obstructed vein.

To assess for possible reversible risk factors, check blood pressure and ask about tobacco smoking in all patients, and ask women about estrogen therapy (including combined oral contraceptives). Patients should be asked about a history of glaucoma and should undergo a comprehensive eye examination to check intraocular pressure. A sleep study to assess for obstructive sleep apnea may be recommended.

B. Laboratory Findings

Obtain screening laboratory studies for diabetes mellitus, hyperlipidemia, and hyperviscosity (especially in simultaneous bilateral disease), including serum protein electrophoresis for paraproteinemia. Particularly in younger patients, consider obtaining antiphospholipid antibodies, lupus anticoagulant, tests for inherited thrombophilia, and plasma homocysteine levels.

Complications

If central retinal vein occlusion is associated with widespread retinal ischemia, manifesting as poor visual acuity (20/200 [6/60] or worse), extensive retinal hemorrhages, an afferent pupillary defect, and widespread capillary closure on fluorescein angiography, there is a high risk of development of neovascular (rubeotic) glaucoma, typically within the first 3 months after the occlusion. Branch retinal vein occlusion may be complicated by peripheral retinal neovascularization or chronic macular edema.

Treatment

A. Macular Edema

Intravitreal injection of VEGF inhibitors, including ranibizumab, bevacizumab, or aflibercept and biosimilar medications, is beneficial in patients with macular edema due to either branch or central retinal vein occlusion.

B. Neovascularization

Eyes at risk for neovascular glaucoma following ischemic central retinal vein occlusion should be treated with panretinal laser photocoagulation prophylactically or as soon as there is evidence of neovascularization, with the latter approach necessitating frequent monitoring. Regression of retinal and iris neovascularization can be achieved with intravitreal injections of bevacizumab or other anti-VEGF agents, but panretinal laser photocoagulation is the definitive treatment and cannot be substituted by anti-VEGF agents. In branch retinal vein occlusion complicated by retinal neovascularization, the ischemic retina should be treated with laser photocoagulation.

Prognosis

In central retinal vein occlusion, severity of visual loss initially is a good guide to visual outcome. Initial visual acuity of 20/60 (6/18) or better indicates a good prognosis. Visual prognosis is poor for eyes with neovascular glaucoma. In branch retinal vein occlusion, visual outcome is determined by the severity of glaucoma and macular damage from hemorrhage, ischemia, or edema.

When to Refer

All patients with retinal vein occlusion should be referred urgently to an ophthalmologist.

Romano F et al. Update on retinal vein occlusion. Asia Pac J Ophthalmol (Phila). 2023;12:196. [PMID: 36912792]

CENTRAL & BRANCH RETINAL ARTERY OCCLUSIONS

ESSENTIALS OF DIAGNOSIS

- Sudden monocular loss of vision.
- No pain or redness.
- Widespread or sectoral pale retinal swelling.

General Considerations

Acute retinal arterial ischemia, including central and branch retinal artery occlusion, is a true ocular and medical emergency. In patients 50 years of age or older with central retinal artery occlusion, giant cell arteritis must be considered (see Ischemic Optic Neuropathy and Chapter 23). Otherwise, even if no retinal emboli are identified on ophthalmoscopy, urgent investigation for carotid and cardiac sources of emboli must be undertaken in central and branch retinal artery occlusion for timely treatment to reduce the risk of stroke (see Chapters 14, 16, and 27). Diabetes mellitus, hyperlipidemia, and systemic hypertension are common etiologic factors. Migraine, oral contraceptives, systemic vasculitis, congenital or acquired thrombophilia, and hyperhomocysteinemia are also causes, particularly in young patients. Internal carotid artery dissection should be considered, especially when there is neck pain or a recent history of neck trauma.

Clinical Findings

A. Symptoms and Signs

1. Central retinal artery occlusion—This occlusion presents as sudden profound monocular visual loss. Visual acuity is usually reduced to counting fingers or worse, and visual field may be restricted to an island of vision in the temporal field. Ophthalmoscopy reveals pale swelling of the retina with a cherry-red spot at the fovea (Figure 7–2). Occasionally, emboli are seen in the central retinal artery or its branches. The retinal swelling subsides over a period of 4–6 weeks, leaving a pale optic disk with thinning of the inner retina on optical coherence tomography scans; these findings can help diagnose unexplained vision loss if the patient is examined after the acute occlusive event has resolved.

2. Branch retinal artery occlusion—This occlusion also may present with sudden loss of vision if the fovea is involved, but it more commonly presents with sudden loss of a discrete area in the visual field in one eye. Fundus signs of retinal swelling and sometimes adjacent cotton-wool spots are limited to the area of retina supplied by the occluded artery.

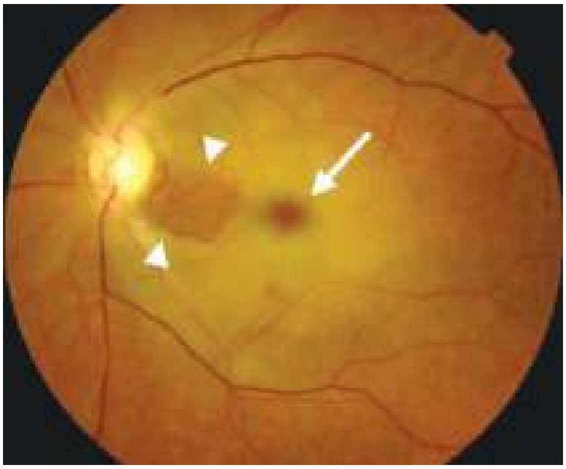

Figure 7–2. Acute central retinal artery occlusion with cherry-red spot (arrow) seen at the fovea centered in macular loss of retinal transparency, and preserved retinal perfusion (arrowheads) adjacent to the optic disk due to macular cilioretinal artery supply. (Reproduced, with permission, from Riordan-Eva P, Augsburger JJ. *Vaughan & Asbury's General Ophthalmology,* 19th ed. McGraw Hill, 2018.)

The clinician should identify risk factors for cardiac sources of emboli including arrhythmia, particularly atrial fibrillation, and cardiac valvular disease, and check the blood pressure. Clinical features of giant cell arteritis are age 50 years or older, headache, scalp tenderness, jaw claudication, general malaise, weight loss, symptoms of polymyalgia rheumatica, and tenderness, thickening, or absence of pulse of the superficial temporal arteries. Table 23–12 lists the clinical manifestations of vasculitis.

B. Laboratory Findings

Giant cell arteritis should be considered in cases of central retinal artery occlusion without visible emboli. ESR and CRP are usually elevated in giant cell arteritis, but one or both may be normal (see Chapter 23). Consider screening for other types of vasculitis (see Table 23–11). Screen for diabetes mellitus and hyperlipidemia in all patients. Particularly in younger patients, consider testing for antiphospholipid antibodies, lupus anticoagulant, inherited thrombophilia, and elevated plasma homocysteine.

C. Imaging

A brain MRI with diffusion-weighted imaging sequences should be obtained urgently to look for cerebral infarction, which is present in up to 31% of patients with branch or central retinal artery occlusion. Obtain duplex ultrasonography of the carotid arteries, ECG, echocardiography with transesophageal studies to identify carotid and cardiac sources of emboli, and CT or MR studies for internal carotid artery dissection, if necessary.

Treatment

Retinal artery occlusions are a true emergency and require urgent referral to an emergency department, ideally with a stroke center, for imaging and clinical assessment to prevent subsequent stroke. If the patient is seen within a few hours after onset, emergency treatment, comprising laying the patient flat, ocular massage, high concentrations of inhaled oxygen, intravenous acetazolamide, and anterior chamber paracentesis, may influence the visual outcome. Early thrombolysis, particularly by local intra-arterial injection but also intravenously, has shown good results in central retinal artery occlusion not due to giant cell arteritis. However, local intra-arterial injection of thrombolytic agents has a high incidence of adverse effects and may be difficult to accomplish quickly enough to prevent permanent vision loss due to inner retinal ischemia, which nonhuman primate studies suggest occurs within 90 minutes of occlusion.

In giant cell arteritis, there is risk of involvement of the other eye without prompt treatment. Once giant cell arteritis is suspected, initial treatment with intravenous methylprednisolone 1 g/day is recommended for 3 days. All patients require subsequent long-term corticosteroid therapy; concomitant administration of long-term low-dose aspirin therapy is controversial. Tocilizumab, a monoclonal antibody against the receptor for interleukin-6, is also approved to treat giant cell arteritis. (See Polymyalgia

Rheumatica & Giant Cell Arteritis, Chapter 23, for further discussion of treatment.)

Patients with embolic retinal artery occlusion with 70–99% ipsilateral carotid artery stenosis, and possibly those with 50–69% stenosis, should be considered for carotid endarterectomy or possibly angioplasty within 2 weeks of the occlusion (see Chapters 14 and 27). Retinal embolization due to cardiac disease such as atrial fibrillation or a hypercoagulable state usually requires anticoagulation. Cardiac valvular disease and patent foramen ovale may require surgical treatment.

When to Refer

- Patients with retinal artery occlusions should be referred immediately to an emergency department, ideally with a stroke center, to evaluate for stroke manifestations.
- Patients with central retinal artery occlusion should be referred emergently to an ophthalmologist.
- Patients with branch retinal artery occlusion should be referred urgently for examination by an ophthalmologist.
- Patients with suspected giant cell arteritis should be referred to a rheumatologist to guide management.

When to Admit

Patients with visual loss due to giant cell arteritis may require emergency admission for high-dose corticosteroid therapy and close monitoring to ensure adequate treatment.

TRANSIENT MONOCULAR VISUAL LOSS

ESSENTIALS OF DIAGNOSIS

- ▶ Sudden-onset, monocular loss of vision usually lasting a few minutes with complete recovery.

Clinical Findings

A. Symptoms and Signs

Transient monocular visual loss (“ocular transient ischemic attack [TIA]”) is usually caused by a retinal embolus from ipsilateral carotid disease or the heart. The visual loss is characteristically described as a curtain passing vertically across the visual field with complete monocular visual loss lasting a few minutes and a similar curtain effect as the episode passes (amaurosis fugax; also called “fleeting blindness”). An embolus is rarely seen on ophthalmoscopy. Other causes of transient, often recurrent, visual loss due to ocular ischemia are giant cell arteritis, hypercoagulable state (such as antiphospholipid syndrome), hyperviscosity, and severe occlusive carotid disease. More transient visual loss affecting one or both eyes, termed transient visual obscurations, lasts only a few seconds to 1 minute, usually is recurrent, and occurs in patients with optic disk swelling, such as in those with raised intracranial pressure.

B. Diagnostic Studies

In most cases, clinical assessment and investigations are much the same as for retinal artery occlusion with emphasis on urgent neuroimaging to assess for cerebral infarction, and identification of a source of emboli, since patients with embolic transient vision loss are at increased risk for stroke, MI, and other vascular events. Optic disk swelling requires different investigations (see Optic Disk Swelling, below).

Treatment

All patients with possible embolic transient visual loss should be treated immediately with oral aspirin (at least 81 mg daily), or another antiplatelet drug, until the cause has been determined. Affected patients with 70–99% (and possibly those with 50–69%) ipsilateral carotid artery stenosis should be considered for urgent carotid endarterectomy or possibly angioplasty with stenting (see Chapters 14 and 27). In all patients, vascular risk factors (eg, hypertension) need to be controlled. Retinal embolization due to cardiac arrhythmia, such as atrial fibrillation, or a hypercoagulable state usually requires anticoagulation. Cardiac valvular disease and patent foramen ovale may require surgical treatment.

When to Refer

In all cases of episodic visual loss, early ophthalmologic consultation is advisable.

When to Admit

Referral to a stroke center or hospital admission is recommended in embolic transient visual loss if there have been two or more episodes in the preceding week (“crescendo TIA”) or the underlying cause is cardiac or a hypercoagulable state.

RETINAL DISORDERS ASSOCIATED WITH SYSTEMIC DISEASES

1. Diabetic Retinopathy

ESSENTIALS OF DIAGNOSIS

- By 20 years after diagnosis of diabetes, 99% of patients with type 1 diabetes and 60% of patients with type 2 diabetes will have diabetic retinopathy.
- **Nonproliferative diabetic retinopathy:** can be mild, moderate, or severe. Microvascular changes are limited to the retina.
- **Proliferative diabetic retinopathy:** new blood vessels grow on the surface of the retina, optic nerve, or iris.
- **Diabetic macular edema:** central retinal swelling; can occur with any severity level of diabetic retinopathy; can reduce visual acuity if the foveal center is involved.

General Considerations

Diabetic retinopathy is present in about one-third of patients in whom diabetes has been diagnosed, and about one-third of those have sight-threatening disease. In the United States, it affects about 4 million people; it is the leading cause of vision loss worldwide among adults aged 25–74 years; and the number of affected individuals aged 65 years or older is increasing. Retinopathy increases in prevalence and severity with increasing duration and poorer control of diabetes. In type 1 diabetes, retinopathy is not detectable for the first 5 years after diagnosis. In type 2 diabetes, about 20% of patients have retinopathy at diagnosis, likely because they had diabetes for many years before diagnosis. Macular involvement is the most common cause of legal blindness in type 2 diabetes.

There are two main categories of diabetic retinopathy: nonproliferative and proliferative. Diabetic macular edema can occur at any stage in both nonproliferative and proliferative retinopathy and is the most common reason for ophthalmic diabetic treatment.

Nonproliferative retinopathy (previously known as "background" retinopathy) is subclassified as mild, moderate, or severe. It represents the earliest stage of retinal involvement by diabetes. During this stage, the retinal capillaries leak proteins, lipids, or red cells into the retina. When this process occurs in the macula and causes clinically significant macular edema, visual acuity is affected; this is the most common cause of visual impairment in patients with type 2 diabetes.

Proliferative retinopathy is less common than nonproliferative retinopathy but causes more severe visual loss. It involves the growth of new vessels and fibrous tissue on the surface of the retina, extending into the vitreous chamber. It is a consequence of severe capillary occlusion, which causes retinal ischemia and release of VEGF; this, in turn, stimulates new vessel growth with vision loss from preretinal hemorrhage, fibrosis, and retinal traction.

Clinical Findings

Clinical assessment comprises visual acuity testing, stereoscopic examination of the retina, retinal imaging with optical coherence tomography, and sometimes fluorescein angiography.

Nonproliferative retinopathy manifests as microaneurysms, retinal hemorrhages, venous beading, retinal edema, and hard exudates. In mild nonproliferative diabetic retinopathy, there are mild retinal abnormalities without visual loss. Reduction of vision is most commonly due to diabetic macular edema, which may be focal or diffuse, but it can also be due to macular ischemia. Severe nonproliferative retinopathy is defined as having any one of the following: severe intraretinal hemorrhages and microaneurysms in four quadrants, venous beading in two or more quadrants, or intraretinal microvascular abnormalities in at least one quadrant.

Proliferative retinopathy is characterized by neovascularization, arising from either the optic disk or the retinal vascular arcades. Prior to proliferation of new capillaries, a preproliferative phase often occurs in which arteriolar ischemia is manifest as cotton-wool spots (small infarcted areas of retina). Vision is usually normal until macular edema, vitreous hemorrhage, or retinal detachment occurs. Proliferation into the vitreous of blood vessels, with associated fibrosis, may lead to vitreous hemorrhage and tractional retinal detachment.

Diabetic retinopathy may worsen after bariatric surgery or in patients with long-standing hyperglycemia that is rapidly brought under tight control, such as after receiving an insulin pump or being treated with GLP-1 receptor agonists, SGLT-2 inhibitors, or dipeptidyl peptidase-4 inhibitors. It is believed that capillary endothelial cells retain "metabolic memory" of hyperglycemia and that epigenetic changes persist for several months after the hyperglycemia is corrected, sometimes causing retinopathy progression after intensive glycemic control is initiated; however, after the first 18–24 months, rates of progression are significantly lower in patients treated with intensive control compared to conventional regimens.

Screening

Visual symptoms and visual acuity are poor guides to the presence of diabetic retinopathy. Patients with diabetes mellitus should undergo regular fundus photography, which can be performed using telemedicine with computer detection software programs, or dilated examination of the retina. Ultrawide-field fluorescein angiography can identify peripheral retinal vascular lesions that predict disease worsening in eyes with nonproliferative diabetic retinopathy. Patients with type 1 diabetes mellitus should be screened 5 years after the diabetes is diagnosed. Patients with type 2 diabetes mellitus should be screened at or shortly after diagnosis of diabetes. More frequent monitoring is required in women with type 1 or 2 diabetes during pregnancy and in those planning pregnancy, and for the first 2 years after intensive glycemic control is initiated.

Treatment

Treatment includes optimizing blood glucose, blood pressure, kidney function, and serum lipids. When patients are initially brought into intensive glycemic control, they should have an ophthalmologic examination every 3–4 months so they can be treated if retinopathy progresses. Glycemic control is the most important modifiable factor for diabetic retinopathy, but intensive blood pressure control and avoiding tobacco use also slow retinopathy progression.

1. Nonproliferative retinopathy—VEGF inhibitor therapy improves diabetic retinopathy severity in eyes at all levels of nonproliferative diabetic retinopathy. In severe nonproliferative retinopathy, fluorescein angiography can demonstrate the extent of retinal ischemia, which can help determine whether panretinal laser photocoagulation should be performed prophylactically.

2. Proliferative retinopathy—This is usually treated by intravitreal injection of a VEGF inhibitor or panretinal laser photocoagulation, preferably before vitreous hemorrhage or tractional detachment has occurred. Proliferative diabetic retinopathy, especially after successful laser treatment, is not a contraindication to treatment with thrombolytic agents, aspirin, or warfarin unless there has been recent intraocular hemorrhage. Vitrectomy is necessary to remove persistent vitreous hemorrhage, improve vision, allow panretinal laser photocoagulation, treat tractional retinal detachment involving the macula, and manage rapidly progressive proliferative disease.

3. Macular edema—Intravitreal injection of a VEGF inhibitor (ranibizumab, bevacizumab, aflibercept, faricimab, or brolucizumab) is the mainstay of treatment for diabetic macular edema. Macular edema and exudates, but not macular ischemia, may also respond to laser photocoagulation; to corticosteroid treatment (triamcinolone, dexamethasone implant, or fluocinolone implant); or to vitrectomy if there is traction from scarring on the retinal surface.

When to Refer

- All patients with sudden loss of vision or retinal detachment should be referred emergently to an ophthalmologist.
- Proliferative retinopathy or macular involvement requires urgent referral to an ophthalmologist.
- Severe nonproliferative retinopathy or unexplained reduction of visual acuity requires early referral to an ophthalmologist.

2. Hypertensive Retinochoroidopathy

Systemic hypertension affects both the retinal and choroidal circulations. The clinical manifestations vary according to the degree and rapidity of rise in blood pressure and the state of the ocular circulation. The most florid ocular changes occur in young patients with abrupt elevations of blood pressure, such as may occur in pheochromocytoma, hypertensive crisis with advanced bilateral retinopathy (malignant hypertension), or preeclampsia-eclampsia. Hypertensive retinopathy has been associated with increased risk of stroke; patients with hypertension should have routine retinal examinations for retinopathy.

Chronic hypertension accelerates the development of atherosclerosis. The retinal arterioles become more tortuous and narrower and develop abnormal light reflexes ("silver-wiring" and "copper-wiring") (Figure 13–2). There is increased venous compression at the retinal arteriovenous crossings ("arteriovenous nicking"), predisposing to branch retinal vein occlusions. Flame-shaped hemorrhages occur in the nerve fiber layer of the retina. Detection is aided by nonmydriatic fundus photography.

Acute elevations of blood pressure result in loss of autoregulation in the retinal circulation, leading to breakdown of endothelial integrity and occlusion of precapillary arterioles and capillaries that manifest as cotton-wool spots, retinal hemorrhages, retinal edema, and retinal exudates, often in a stellate appearance at the macula. Vasoconstriction and ischemia in the choroid result in exudative retinal detachments and retinal pigment epithelial infarcts that later develop into pigmented lesions that may be focal, linear, or wedge-shaped. The abnormalities in the choroidal circulation may also affect the optic nerve head, producing ischemic optic neuropathy with optic disk swelling. *Fundus abnormalities are the hallmark of hypertensive crisis with retinopathy (previously known as malignant hypertension) that requires emergency treatment* (see Chapter 13). Marked fundus abnormalities are likely to be associated with permanent retinal, choroidal, or optic nerve damage. Precipitous reduction of blood pressure may exacerbate such damage.

Di Marco E et al. A literature review of hypertensive retinopathy: systemic correlations and new technologies. Eur Rev Med Pharmacol Sci. 2022;26:6424. [PMID: 36196693]

Wang Z et al. Hypertensive retinopathy can predict stroke: a systematic review and meta-analysis based on observational studies. J Stroke Cerebrovasc Dis. 2024;33:107953. [PMID: 39227002].

3. Blood Dyscrasias

Severe thrombocytopenia or anemia may result in retinal or choroidal hemorrhages, including white-centered retinal hemorrhages (Roth spots) that occur in leukemia and other situations (eg, bacterial endocarditis). Involvement of the macula may result in permanent visual loss.

Sickle cell retinopathy is particularly common in hemoglobin SC disease but may also occur with other hemoglobin S variants. Manifestations include "salmon-patch" preretinal/intraretinal hemorrhages, "black sunbursts" resulting from intraretinal hemorrhage, and new vessels. Severe visual loss is rare with sickle cell retinopathy but more common in patients with pulmonary hypertension. Retinal laser photocoagulation reduces the frequency of vitreous hemorrhage from new vessels. Surgery is occasionally needed for persistent vitreous hemorrhage or tractional retinal detachment.

Nelson M et al. The clinical spectrum of HbSC sickle cell disease – not a benign condition. Br J Haematol. 2024;205:653. [PMID: 38898714]

4. HIV Infection/AIDS

See Chapter 36. **HIV retinopathy** causes cotton-wool spots, retinal hemorrhages, and microaneurysms but may also lead to reduced contrast sensitivity and retinal nerve fiber layer and outer retinal damage (HIV neuroretinal disorder).

CMV retinitis is less common since the availability of antiretroviral therapy (ART) but continues to be prevalent where resources are limited. It usually occurs when CD4 counts are < 50/mcL (0.05×10^9/L) and is characterized by progressively enlarging yellowish-white patches of retinal opacification and retinal hemorrhages, usually beginning adjacent to the major retinal vascular arcades. Patients are often asymptomatic until there is involvement of the fovea or optic nerve, or until retinal detachment develops. See Table 36–3 for initial therapeutic recommendations. Maintenance therapy can be achieved with lower-dose systemic therapy. Systemic therapy has a greater risk of nonocular adverse effects but reduces the incidence of retinitis in the other eye and avoids intraocular complications of intravitreal administration. In all patients with CMV retinitis, ART needs to be instituted or adjusted. This may lead to the immune reconstitution inflammatory syndrome (IRIS), which may lead to visual loss, predominantly due to cystoid macular edema. The likelihood of IRIS may be reduced by using immunomodulatory therapy to suppress the immune response causing the inflammation. If the CD4 count is maintained > 100/mcL (0.1×10^9/L), it may be possible to discontinue maintenance anti-CMV therapy.

Other ophthalmic manifestations of opportunistic infections occurring in patients with AIDS include herpes simplex retinitis, which usually manifests as acute retinal necrosis; toxoplasmic and candidal chorioretinitis possibly progressing to endophthalmitis; herpes zoster ophthalmicus and herpes zoster retinitis, which can manifest as acute retinal necrosis or progressive outer retinal necrosis; and various entities due to syphilis, tuberculosis, or cryptococcosis. Kaposi sarcoma of the conjunctiva (see Chapter 36) and orbital lymphoma may also be seen on rare occasions.

ISCHEMIC OPTIC NEUROPATHY

ESSENTIALS OF DIAGNOSIS

- Sudden painless visual loss with signs of optic nerve dysfunction.
- Optic disk swelling in anterior ischemic optic neuropathy.

Anterior ischemic optic neuropathy—due to inadequate perfusion of the posterior ciliary arteries that supply the anterior portion of the optic nerve. In older patients, it may be caused by giant cell arteritis (arteritic anterior ischemic optic neuropathy). The predominant factor predisposing to nonarteritic anterior ischemic optic neuropathy, which subsequently affects the other eye in around 15% of cases, is a congenitally crowded optic disk, compromising optic disk circulation. Other predisposing factors are systemic hypertension, diabetes mellitus, hyperlipidemia, systemic vasculitis, inherited or acquired thrombophilia, interferon-α therapy, and obstructive sleep apnea; hypotension and anemia during dialysis may cause bilateral anterior ischemic optic neuropathy.

Posterior ischemic optic neuropathy, involving the retrobulbar optic nerve and thus not causing any optic disk swelling, may occur with severe blood loss; nonocular surgery, particularly prolonged lumbar spine surgery in the prone position with increased orbital pressure; severe burns; or in association with dialysis, from profound hypotension and anemia. In all such situations, there may be contributory factors and visual loss may be severe and irreversible.

Clinical Findings

Anterior ischemic optic neuropathy presents with sudden visual loss, usually with an altitudinal field defect and optic disk swelling with pallor.

Posterior ischemic optic neuropathy does not cause any optic disk swelling as the damage occurs behind the optic disc, but patients experience rapid-onset, severe vision loss with initially normal-appearing optic discs. Both anterior and posterior ischemic optic neuropathy that affect only one eye are associated with a relative afferent pupillary defect on the affected eye. Vision loss in patients with posterior ischemic optic neuropathy is more commonly bilateral and severe than in patients with anterior ischemic optic neuropathy.

Treatment

Arteritic anterior ischemic optic neuropathy necessitates emergency high-dose systemic corticosteroid treatment to prevent visual loss in the other eye. (See Central & Branch Retinal Artery Occlusions, above, and Polymyalgia Rheumatica & Giant Cell Arteritis, Chapter 23.) It is uncertain whether systemic or intravitreal therapy influences the outcome in nonarteritic anterior ischemic optic neuropathy or whether oral low-dose aspirin (~81 mg daily) reduces the risk of involvement of the other eye. A systematic review of 32 studies found no evidence that treatment affects visual outcome in nonarteritic anterior ischemic optic neuropathy. In ischemic optic neuropathy after nonocular surgery or dialysis, treatment of marked anemia by blood transfusion may be beneficial.

When to Refer

Patients with ischemic optic neuropathy should be referred urgently to an ophthalmologist.

When to Admit

Patients with ischemic optic neuropathy due to giant cell arteritis or other vasculitis may require emergency admission for high-dose corticosteroid therapy and close monitoring to ensure that treatment is adequate.

OPTIC NEURITIS

ESSENTIALS OF DIAGNOSIS

- Subacute, usually unilateral, visual loss.
- Pain exacerbated by eye movements.
- Optic disk is usually normal in acute stage but subsequently develops pallor.

General Considerations

Inflammatory optic neuropathy is strongly associated with demyelinating disease (typical optic neuritis), particularly multiple sclerosis, but it also occurs in acute disseminated encephalomyelitis; sarcoidosis; neuromyelitis optica spectrum disorder, which is characterized by serum antibodies to aquaporin-4; in association with serum antibodies to myelin oligodendrocyte glycoprotein; following viral infection (usually in children); in varicella zoster virus infection; in autoimmune disorders, particularly SLE and Sjögren syndrome; during treatment with a biologic agent; and by spread of inflammation from the meninges, orbital tissues, or paranasal sinuses.

Clinical Findings

Optic neuritis in demyelinating disease is characterized by unilateral loss of vision developing over a few days. Visual acuity ranges from 20/30 (6/9) to no perception of light, with more severe visual loss being associated with low serum vitamin D. In almost all cases, there is pain behind the eye, exacerbated by eye movements, central visual field loss, color vision loss, and a relative afferent pupillary defect. In about two-thirds of cases, the optic nerve is normal during the acute stage (retrobulbar optic neuritis). In the remainder, the optic disk is swollen (papillitis) with occasional flame-shaped peripapillary hemorrhages. Visual acuity usually improves within 2–3 weeks and returns to 20/40 (6/12) or better in 95% of previously unaffected eyes. Optic atrophy subsequently develops if there has been extensive optic nerve fiber damage. Patients without a diagnosis of multiple sclerosis in whom visual recovery does not occur, or if there is continuing deterioration of vision, or pain persisting after 2 weeks, should undergo MRI of the head and orbits to look for periventricular white matter demyelination or a lesion compressing the optic nerve.

Treatment

In acute demyelinating optic neuritis, intravenous methylprednisolone (1 g daily for 3 days followed by a tapering course of oral prednisolone) has been shown to accelerate visual recovery, but not to improve final vision. However, in clinical practice, the oral taper is not often prescribed. Use in an individual patient is determined by the degree of visual loss, the state of the other eye, and the patient's visual requirements. Other therapies include monoclonal antibodies against immune cells and cell-based therapies to deplete or modulate T and B cell responses. Vitamin D may play immunoregulatory roles in cytokine production, immune cell development and differentiation, and antibody production and is often prescribed for optic neuritis.

Atypical optic neuritis due to sarcoidosis, neuromyelitis optica, herpes zoster, or SLE generally has a poorer prognosis, requires immediate and more prolonged corticosteroid therapy, may require plasma exchange, and may necessitate long-term immunosuppression.

Prognosis

Among patients with a first episode of clinically isolated optic neuritis, multiple sclerosis will develop in 50% within 15 years; however, the likelihood of developing multiple sclerosis ranges from 25% for patients without demyelinating lesions on brain MRI to 72% in patients with one or more demyelinating lesions. The major risk factors are female sex and multiple white matter lesions on brain MRI. Retinal nerve fiber layer optical coherence tomography quantifies axonal damage that can be used to monitor disease progression.

When to Refer

All patients with optic neuritis should be referred urgently for ophthalmologic or neurologic assessment.

OPTIC DISK SWELLING

Optic disk swelling may result from elevated intracranial pressure, orbital lesions, or intraocular lesions, including retinal and optic nerve lesions. Raised intracranial pressure usually causes bilateral disk swelling without reduced visual acuity and requires urgent imaging to exclude an intracranial mass, hemorrhage, infection, or cerebral venous sinus occlusion. Orbital lesions can cause optic nerve compression resulting in optic disk swelling. Intraocular causes of optic disk swelling include central retinal vein occlusion, posterior uveitis, and posterior scleritis. Optic nerve lesions causing disk swelling include anterior ischemic optic neuropathy; optic neuritis; optic nerve sheath meningioma; and infiltration by sarcoidosis, leukemia, or lymphoma.

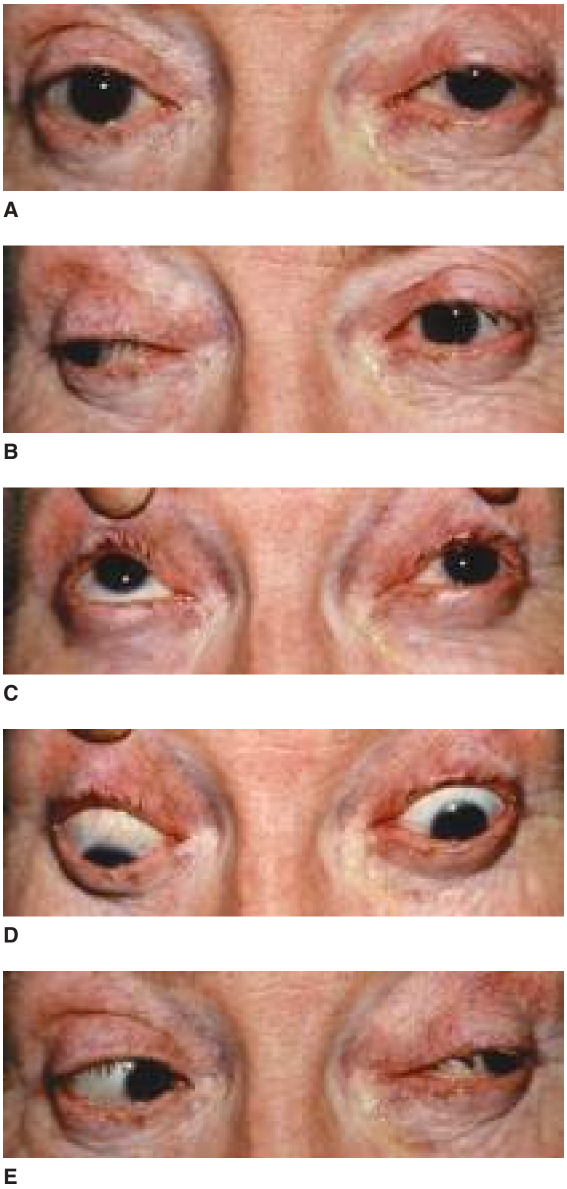
Papilledema (optic disk swelling due to raised intracranial pressure) is usually bilateral and most commonly produces enlargement of the blind spot without loss of acuity. Severe acute papilledema or chronic papilledema, as in idiopathic intracranial hypertension and cerebral venous sinus occlusion, may be associated with visual field and occasionally with profound visual acuity loss. All patients with chronic papilledema must be monitored carefully—especially their visual fields—and CSF shunt or optic nerve sheath fenestration should be considered in those with progressive visual loss not controlled by medical therapy (weight loss where appropriate and usually acetazolamide in patients with idiopathic intracranial hypertension). In idiopathic intracranial hypertension, transverse venous sinus stenting is also an option for patients with progressive vision loss.

Bouthour W et al. Diagnosis of optic disc oedema: fundus features, ocular imaging findings, and artificial intelligence. Neuroophthalmology. 2023;47:177. [PMID: 37434667]

CRANIAL NERVE PALSIES

A cranial nerve palsy of any of the three cranial nerves that supply the extraocular muscles can cause double vision.

In a complete **third nerve palsy**, there is ptosis with a divergent and slightly depressed eye (Figure 7–3). Extraocular movements are restricted in all directions except laterally (preserved lateral rectus function) (Figure 7–3E). Intact fourth nerve (superior oblique) function is detected by inward rotation on attempted depression of the eye. Pupillary involvement, manifesting as a relatively dilated pupil that does not constrict normally to light, usually means compression, which may be due to aneurysm of the posterior communicating artery or uncal herniation due to a supratentorial mass lesion. In acute painful isolated third nerve palsy with pupillary involvement, posterior communicating artery aneurysm must be excluded. Pituitary apoplexy is a rarer cause. Causes of isolated third nerve palsy without pupillary involvement include diabetes mellitus, hypertension, giant cell arteritis, and herpes zoster.



▲ **Figure 7–3.** Left partial third nerve palsy with ptosis **(A)**, reduced adduction **(B)**, reduced elevation **(C)**, and reduced depression **(D)** but normal abduction **(E)** of the left eye.

Fourth nerve palsy causes upward deviation of the eye with failure of depression on adduction. In acquired cases, there is vertical and torsional diplopia that is most apparent on looking down. Trauma is a major cause of acquired—particularly bilateral—fourth nerve palsy, but posterior fossa tumor and medical causes, such as in third nerve palsy, should also be considered. Similar clinical features are seen in congenital cases due to developmental anomaly of the nerve, muscle, or tendon.

Sixth nerve palsy causes convergent squint in the primary position with failure of abduction of the affected eye, producing horizontal diplopia that increases on gaze to the affected side and on looking into the distance. It is an important sign of raised intracranial pressure and may also be due to trauma, neoplasms, brainstem lesions, petrous apex lesions, or medical causes (such as diabetes mellitus, hypertension, giant cell arteritis, and herpes zoster).

In an isolated cranial nerve palsy presumed to be due a medical cause, brain MRI is not always required initially, but it is necessary if recovery has not begun within 3 months.

A cranial nerve palsy accompanied by other neurologic signs may be due to lesions in the brainstem, cavernous sinus, or orbit. Lesions around the cavernous sinus involve the first and second divisions of the trigeminal nerve, the third, fourth, and sixth cranial nerves, and occasionally the optic chiasm. Orbital apex lesions involve the optic nerve and the three cranial nerves supplying the extraocular muscles.

Myasthenia gravis and thyroid eye disease (see Graves Ophthalmopathy) should be considered in the differential diagnosis of disordered extraocular movements.

▶ When to Refer

- In recent-onset isolated third nerve palsy, especially if there is pupillary involvement or pain, immediate referral is required for neurologic assessment and possibly CT, MRI, or catheter angiography for intracranial aneurysm.
- All patients with recent-onset double vision should be referred urgently to a neurologist or ophthalmologist, particularly if there are multiple cranial nerve dysfunctions or other neurologic abnormalities.

▶ When to Admit

Patients with double vision due to giant cell arteritis may require emergency admission for high-dose corticosteroid therapy and close monitoring to ensure that treatment is adequate. (See Central & Branch Retinal Artery Occlusions and Chapter 23.)

Jain S. Diplopia: diagnosis and management. Clin Med (Lond). 2022;22:104. [PMID: 35304368]

THYROID EYE DISEASE (Graves Ophthalmopathy)

See Hyperthyroidism (Thyrotoxicosis) in Chapter 29.

ORBITAL CELLULITIS

Orbital cellulitis is characterized by fever, proptosis, restriction of extraocular movements, and swelling with redness of the lids. Immediate treatment with intravenous antibiotics is necessary to prevent optic nerve damage and spread of infection to the cavernous sinuses, meninges, and brain. Infection of the paranasal sinuses is the usual underlying cause; infecting organisms include *S pneumoniae*, the incidence of which has been reduced by the administration of pneumococcal vaccine; other streptococci, such as the anginosus group; *H influenzae*; and, less commonly, *S aureus* including MRSA. Penicillinase-resistant penicillin, such as nafcillin, is recommended, possibly together with metronidazole or clindamycin to treat anaerobic infections. If trauma is the underlying cause, a cephalosporin, such as cefazolin or ceftriaxone, should be added to ensure coverage for *S aureus* and group A β-hemolytic streptococci. If MRSA infection is a concern, vancomycin or clindamycin may be required. For patients with penicillin hypersensitivity, vancomycin, levofloxacin, and metronidazole are recommended. The response to antibiotics is usually excellent, but surgery may be required to drain the paranasal sinuses or orbital abscess. In immunocompromised patients, mucormycosis must be considered.

▶ When to Refer

Orbital cellulitis requires admission to the hospital and initiation of broad-spectrum intravenous antibiotics.

Tsirouki T et al. Orbital cellulitis. Surv Ophthalmol. 2018;63:534. [PMID: 29248536]

OCULAR TRAUMA

Ocular trauma is an important cause of avoidable severe visual impairment at all ages, and it is the leading cause of monocular blindness in young adult men in the United States. Thorough but safe clinical assessment, supplemented when necessary by imaging, is crucial to effective management. Ocular damage and the possible need for early assessment by an ophthalmologist need to be borne in mind in the assessment of any patient with mid-facial injury.

Heath Jeffery RC et al. Eye injuries: understanding ocular trauma. Aust J Gen Pract. 2022;51:476. [PMID: 35773155]
Rho JY et al. Management of eye trauma for the primary care physician. J Am Board Fam Med. 2021;34:1018. [PMID: 34535529]

1. Conjunctival & Corneal Foreign Bodies

If a patient complains of “something in my eye” and gives a consistent history, a foreign body is usually present on the cornea or under the upper lid even though it may not be visible. Visual acuity should be tested before treatment is instituted to assess the severity of the injury and as a basis for comparison in the event of complications.

After a local anesthetic (eg, proparacaine, 0.5%) is instilled, the eye is examined with a slit lamp or with a hand flashlight, using oblique illumination, and loupe. The instillation of sterile fluorescein may make corneal foreign bodies more apparent, which are then removed with a sterile wet cotton-tipped applicator or hypodermic needle.

Bacitracin-polymyxin ophthalmic ointment should be instilled. It is not necessary to patch the eye. All patients need to be advised to return promptly for reassessment if there is any increase in pain, redness, or impairment of vision.

Iron foreign bodies usually leave a diffuse rust ring. This requires excision and is best done under local anesthesia using a slit lamp. **Caution:** *Anesthetic drops should not be given to the patient for self-administration.*

If there is no infection, a layer of corneal epithelial cells will line the crater within 24 hours. While the epithelium is defective, the cornea is extremely susceptible to infection. Early infection is manifested by a white necrotic area around the crater and a small amount of gray exudate.

In the case of a foreign body under the upper lid, a local anesthetic is instilled and the lid is everted by grasping the lashes gently and exerting pressure on the mid portion of the outer surface of the upper lid with an applicator. If a foreign body is present, it can easily be removed by passing a wet sterile cotton-tipped applicator across the conjunctival surface.

▶ When to Refer

Refer urgently to an ophthalmologist if a corneal foreign body cannot be removed or if there is suspicion of corneal infection.

Fraenkel A et al. Managing corneal foreign bodies in office-based general practice. Aust Fam Physician. 2017;46:89. [PMID: 28260265]

2. Intraocular Foreign Body

An intraocular foreign body requires emergency treatment by an ophthalmologist. Patients giving a history of "something hitting the eye"—particularly while hammering on metal or using grinding equipment—must be assessed for this possibility, especially when no corneal foreign body is seen, a corneal or scleral wound is apparent, or there is marked visual loss or media opacity. Such patients must be treated as for open globe injury and referred without delay. Intraocular foreign bodies significantly increase the risk of intraocular infection.

▶ When to Refer

Patients with suspected intraocular foreign body must be referred emergently to an ophthalmologist.

3. Corneal Abrasions

A patient with a corneal abrasion complains of severe pain and photophobia. There is often a history of trauma to the eye, commonly involving a fingernail, piece of paper, or contact lens. Visual acuity is recorded, and the cornea and conjunctiva are examined with a light and loupe to rule out a foreign body. If an abrasion is suspected but cannot be seen, sterile fluorescein is instilled into the conjunctival sac: the area of corneal abrasion will stain because fluorescein stains areas that are devoid of epithelium.

Treatment includes bacitracin-polymyxin ophthalmic ointment or drops, or a fluoroquinolone topical antibiotic in contact lens wearers, as prophylaxis against infection. A mydriatic (cyclopentolate 1%) and either topical or oral NSAIDs can be used for pain control. Patching the eye is probably not helpful for small abrasions. Corneal abrasions heal more slowly in persons who smoke cigarettes. Recurrent corneal erosion may follow corneal abrasions.

Although treatment of pain from a corneal abrasion with topical tetracaine for 24 hours has been reported, there is a risk of delayed healing and severe corneal disease from misuse of topical anesthetics, so it is not recommended.

4. Contusions

Contusion injury of the eye (closed globe injury) and surrounding structures may cause ecchymosis ("black eye"), subconjunctival hemorrhage, edema of the cornea, hemorrhage into the anterior chamber (hyphema), rupture of the root of the iris (iridodialysis), paralysis of the pupillary sphincter, paralysis of the muscles of accommodation, cataract, dislocation of the lens, vitreous hemorrhage, retinal hemorrhage and edema (most common in the macular area), detachment of the retina, rupture of the choroid, fracture of the orbital floor ("blowout fracture"), or optic nerve injury. Many of these injuries are immediately obvious; others may not become apparent for days or weeks. The possibility of globe injury must always be considered in patients with facial injury, particularly if there is an orbital fracture. Patients with moderate to severe contusions should be seen by an ophthalmologist.

Any injury causing hyphema involves the danger of secondary hemorrhage, which may cause intractable glaucoma with permanent visual loss. The patient should be advised to rest until complete resolution has occurred. Frequent ophthalmologic assessment is essential. Aspirin and any drugs inhibiting coagulation increase the risk of secondary hemorrhage and are to be avoided. Sickle cell anemia or trait adversely affects outcome.

▶ When to Refer

Patients with moderate or severe ocular contusion should be referred to an ophthalmologist, emergently if there is hyphema.

5. Lacerations

A. Lids

If the lid margin is lacerated, the patient should be referred for specialized care, since permanent notching may result. Lacerations of the lower eyelid near the inner canthus often sever the lower canaliculus, for which canalicular intubation is likely to be required. Lid lacerations not involving the margin may be sutured like any skin laceration.

B. Conjunctiva

In lacerations of the conjunctiva, sutures are not necessary. To prevent infection, topical sulfonamide or other antibiotic is used until the laceration is healed.

C. Cornea or Sclera

Patients with suspected corneal or scleral laceration or rupture (open globe injury) must be seen emergently by an ophthalmologist. Manipulation is kept to a minimum, since pressure may result in extrusion of intraocular contents. The eye is bandaged lightly and covered with a shield that rests on the orbital bones above and below. The patient should be instructed not to squeeze the eye shut and to remain still. If there may be a metallic intraocular foreign body, a radiograph or CT scan is obtained to identify and localize it. *MRI is contraindicated because of the risk of movement of any metallic foreign body but may be useful for non-metallic foreign body.* Endophthalmitis occurs in over 5% of open globe injuries.

▶ When to Refer

Patients with suspected open globe injury must be referred emergently to an ophthalmologist.

CHEMICAL CONJUNCTIVITIS & KERATITIS

Chemical burns are treated by copious irrigation of the eyes as soon as possible after exposure. Saline solution or sterile eye wash solution is preferred. If not available, tap water can be used. Alkali injuries are more serious and require prolonged irrigation. It is important to remove any retained particulate matter, commonly present in injuries involving cement and building plaster. This often requires eversion of the upper lid. The pupil should be dilated with 1% cyclopentolate, 1 drop twice a day, to relieve discomfort, and prophylactic ophthalmic antibiotics should be started (Table 7–2). In moderate to severe injuries, intensive ophthalmic corticosteroids and systemic vitamin C are also necessary. Amniotic membrane transplants can promote corneal epithelial healing. Complications include mucus deficiency, scarring of the cornea and conjunctiva, symblepharon (adhesions between the tarsal and bulbar conjunctiva), tear duct obstruction, and secondary infection. A slit lamp examination is required to assess the severity of ocular surface chemical burns.

PRECAUTIONS IN MANAGEMENT OF OCULAR DISORDERS

1. Use of Local Anesthetics

Unsupervised self-administration of local anesthetics is dangerous because they are toxic to the corneal epithelium, delay healing, and the patient may further injure an anesthetized eye without realizing it.

Lee MD … Seitzman GD. Cornea specialists do not recommend routine usage of ophthalmic anesthetics for corneal abrasions. Ann Emerg Med. 2019;74:463. [PMID: 31445551]

2. Corticosteroid Therapy

Co-management with eye specialists is strongly recommended to monitor for ocular complications of corticosteroid therapy. Long-term use of local corticosteroids may be complicated by ocular hypertension leading to open-angle glaucoma; cataract formation; and exacerbation of ocular infections, such as herpes simplex (dendritic) and fungal keratitis. Furthermore, perforation of the cornea may occur when ophthalmic corticosteroids are used indiscriminately for infectious keratitis. The potential for causing or exacerbating systemic hypertension, diabetes mellitus, gastritis, osteoporosis, or glaucoma must always be borne in mind when systemic corticosteroids are prescribed.

3. Contaminated Eye Medications

Ophthalmic solutions are prepared with the same degree of care as fluids intended for intravenous administration. Once ophthalmic solution bottles are opened, there is a risk of contamination, particularly with tetracaine, proparacaine, fluorescein, and any preservative-free preparations.

Four weeks after opening is the usual maximum time for use of an eye solution containing preservatives before discarding. Preservative-free preparations should be kept refrigerated and usually discarded within 1 week after opening. Single-use products should not be reused.

If the eye has been injured by accident or by surgical trauma, it is important to use freshly opened bottles of sterile medications or single-use products.

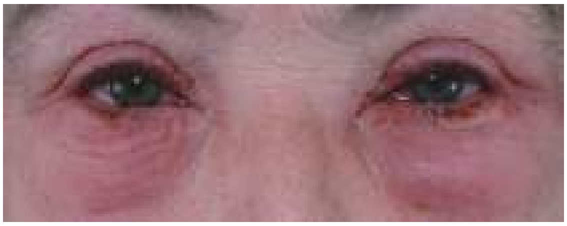
4. Toxic & Hypersensitivity Reactions to Ophthalmic Therapy

In patients receiving long-term ophthalmic therapy, local toxic or hypersensitivity reactions to the active agent or preservatives may develop (Figure 7–4), especially if there is inadequate tear secretion. Preservatives in contact lens cleaning solutions may produce similar problems. Burning and soreness are exacerbated by drop instillation or contact lens insertion; occasionally, fibrosis and scarring of the conjunctiva and cornea may occur. Preservative-free ophthalmic medications and contact lens solutions are available.

An antibiotic instilled into the eye can sensitize the patient to that drug and cause an allergic reaction upon subsequent systemic administration. Potentially fatal anaphylaxis can occur in up to 0.3% of patients after intravenous fluorescein for fluorescein angiography. Anaphylaxis also has been reported after ophthalmic-only administration of fluorescein dye.

5. Systemic Effects of Ocular Drugs

The systemic absorption of certain ophthalmic drugs must be considered when there is a systemic medical



▲ **Figure 7–4.** Periocular contact dermatitis due to eye drop preservative.

contraindication to the use of the drug. Ophthalmic solutions of the nonselective β-blockers, eg, timolol, may worsen bradycardia, HF, or asthma. Phenylephrine eye drops may precipitate hypertensive crises and angina. Adverse interactions between systemically administered and ocular drugs should also be considered. Using only 1 or 2 drops at a time and a few minutes of nasolacrimal occlusion or eyelid closure ensures maximum ocular efficacy and decreases systemic side effects of ophthalmic agents.

ADVERSE OCULAR EFFECTS OF SYSTEMIC DRUGS

Systemically administered drugs produce a wide variety of adverse effects on the visual system (Table 7–3). The likelihood of most complications is rare, but if visual changes develop during treatment with these medications, the patient should be referred to an eye care professional for an eye examination. Screening for toxic retinopathy is recommended in patients receiving long-term chloroquine or hydroxychloroquine therapy. If no baseline abnormalities are present, screening should be repeated annually beginning after 5 years. More frequent screening, with visual fields and optical coherence tomography scans as often as every 3–6 months, is necessary in patients treated with doses > 5.0 mg per kg measured body weight per day of hydroxychloroquine or > 2.3 mg/kg/day of chloroquine, in patients with kidney or macular disease or in those taking tamoxifen.

Patients receiving long-term systemic corticosteroids are at increased risk for several ocular complications, including glaucoma, cataract, and central serous retinopathy. They should be referred to an eye care professional for an eye examination at baseline before starting corticosteroids and at any time if reduced or blurry vision develops.

An ophthalmologist should be informed whether a patient is taking or has ever taken α-adrenoreceptor

Table 7–3. Adverse ophthalmic effects of systemic drugs (selected list).

Medications	Possible Ophthalmic Side Effects
Amebicides	
Diiodohydroxyquinoline	Optic neuropathy
Antibiotics	
Chloramphenicol	Optic neuropathy
Clofazimine	Crystalline deposits (conjunctiva, cornea, iris)
Ethambutol	Optic neuropathy
Fluoroquinolones	Diplopia, retinal detachment
Isoniazid	Optic neuropathy
Linezolid	Optic neuropathy
Rifabutin	Uveitis
Streptomycin	Optic neuropathy, epidermal necrolysis
Sulfonamides	Nearsightedness, angle-closure glaucoma due to ciliary body swelling
Tetracycline, doxycycline, minocycline	Papilledema
Antimalarial agents	
Chloroquine, hydroxychloroquine	Retinal degeneration principally involving the macula, vortex keratopathy
Quinine	Retinal toxicity, pupillary abnormalities
Antivirals	
Cidofovir	Uveitis
Bisphosphonates	
Alendronate, pamidronate	Scleritis, episcleritis, uveitis
Cardiovascular medications	
Amiodarone	Corneal deposits (vortex keratopathy), optic neuropathy, thyroid eye disease
Amlodipine	Chemosis (conjunctival edema)
Anticoagulants	Conjunctival, retinal, and vitreous hemorrhage
Carbonic anhydrase inhibitors (eg, acetazolamide, methazolamide)	Nearsightedness, angle-closure glaucoma due to ciliary body swelling

(*continued*)

Table 7–3. Adverse ophthalmic effects of systemic drugs (selected list). (continued)

Medications	Possible Ophthalmic Side Effects
Chlorthalidone	Angle-closure glaucoma due to ciliary body swelling
Digoxin	Disturbance of color vision, photopsia, optic neuropathy
Furosemide	Angle-closure glaucoma due to ciliary body swelling
Phosphodiesterase type 5 inhibitors (eg, sildenafil, tadalafil, vardenafil)	Color vision changes, nonarteritic anterior ischemic optic neuropathy
Statins	Extraocular muscle palsy (myasthenic syndrome)
Thiazides (eg, indapamide)	Angle-closure glaucoma, nearsightedness, xanthopsia (yellow vision), band keratopathy due to hypercalcemia, macular edema
Chelating agents	
Deferoxamine, deferasirox	Retinopathy, optic neuropathy, lens opacity
Penicillamine	Ocular pemphigoid, optic neuropathy, extraocular muscle palsy (myasthenic syndrome)
Chemotherapeutic agents	
Antibody–drug conjugates	Corneal pseudomicrocysts, conjunctivitis
Bortezomib	Chalazia
Chlorambucil	Optic neuropathy
Cisplatin	Optic neuropathy
Docetaxel	Lacrimal (canalicular) obstruction
Fluorouracil	Lacrimal (canalicular) obstruction
MEK inhibitors: trametinib, selumetinib, cobimetinib, pimasertib	Multifocal serous retinal detachment, retinal vein occlusion, cystoid macular edema
Vincristine	Optic neuropathy
CNS medications	
Amphetamines	Widening of palpebral fissure, blurring of vision due to mydriasis, elevated intraocular pressure
Anticholinergic agents including preoperative medications	Angle-closure glaucoma due to mydriasis, blurring of vision due to cycloplegia, dry eyes
Aripiprazole	Nearsightedness
Diazepam	Nystagmus
Haloperidol	Capsular cataract
Lithium carbonate	Proptosis, oculogyric crisis, nystagmus
MAO inhibitors	Nystagmus, visual hallucinations, diplopia, myasthenia gravis
Morphine/opioids	Miosis, visual hallucinations, diplopia, dry eye
Neostigmine	Nystagmus, miosis
Olanzapine	Angle-closure glaucoma due to mydriasis
Phenothiazines (eg, chlorpromazine)	Pigmentary deposits in conjunctiva, cornea, lens, and retina; oculogyric crisis Chlorpromazine causes floppy iris syndrome during intraocular surgery
Phenytoin	Nystagmus
Quetiapine	Floppy iris syndrome during intraocular surgery
Retigabine	Ocular pigmentation and retinopathy
Risperidone, paliperidone	Floppy iris syndrome during intraocular surgery
SNRIs (eg, venlafaxine)	Angle-closure glaucoma, mydriasis, dry eye
SSRIs (eg, paroxetine, sertraline)	Angle-closure glaucoma, ischemic optic neuropathy, cataract
Thioridazine	Corneal and lens deposits, retinopathy, oculogyric crisis

(*continued*)

Table 7–3. Adverse ophthalmic effects of systemic drugs (selected list). (continued)

Medications	Possible Ophthalmic Side Effects
Topiramate	Angle-closure glaucoma due to ciliary body swelling, nearsightedness, macular folds, anterior uveitis, corneal edema
Tricyclic agents (eg, imipramine)	Angle-closure glaucoma due to mydriasis, blurring of vision due to cycloplegia, dry eye
Triptans (eg, sumatriptan, zolmitriptan)	Angle-closure glaucoma due to ciliary body swelling, nearsightedness
Vigabatrin	Visual field constriction, cone dystrophy
Zonisamide	Angle-closure glaucoma due to ciliary body swelling, nearsightedness
Dermatologic agents	
Dupilumab	Conjunctivitis
Retinoids (eg, isotretinoin, tretinoin, acitretin, and etretinate)	Papilledema, blepharoconjunctivitis, corneal opacities, decreased contact lens tolerance, decreased dark adaptation, teratogenic ocular abnormalities, idiopathic intracranial hypertension, optic neuritis
Gastrointestinal medications	
Anticholinergic agents	Angle-closure glaucoma due to mydriasis, blurring of vision due to cycloplegia, dry eyes
H_2-blockers	Retinal vascular occlusion, optic neuropathy, retrobulbar optic neuritis
Hormonal agents	
Aromatase inhibitors (eg, anastrozole)	Dry eye, vitreoretinal traction, retinal hemorrhages
Cabergoline	Angle-closure glaucoma
Female sex hormones	Retinal artery occlusion, retinal vein occlusion, papilledema, cranial nerve palsies, ischemic optic neuropathy
Tamoxifen	Crystalline retinal and corneal deposits, altered color perception, cataract, optic neuropathy, macular edema, retinal pigmentary change
Hypoglycemic agents (oral)	
Chlorpropamide	Refractive error, epidermal necrolysis, optic neuropathy
Thiazolidinediones (glitazones)	Increase in diabetic macular edema
Immunomodulators	
Corticosteroids	Cataract (posterior subcapsular); susceptibility to viral (herpes simplex), bacterial, and fungal infections; steroid-induced glaucoma; idiopathic intracranial hypertension; central serous retinopathy
Cyclosporine	Posterior reversible leukoencephalopathy
Fingolimod	Macular edema, retinal vein occlusion
Interferon-α	Retinopathy, keratoconjunctivitis, dry eyes, optic neuropathy
NSAIDs	Corneal opacity, vortex keratopathy, periorbital edema, dry eye
Tacrolimus	Optic neuropathy, posterior reversible leukoencephalopathy
Obstetric drugs	
Sympathomimetic tocolytics	Angle-closure glaucoma due to mydriasis
Respiratory medications	
Anticholinergic bronchodilators (eg, ipratropium)	Angle-closure glaucoma due to mydriasis, blurring of vision due to cycloplegia, dry eyes
Sympathomimetic bronchodilators (eg, salbutamol) and decongestants (eg, ephedrine)	Angle-closure glaucoma due to mydriasis
Rheumatologic agents	
Chloroquine, hydroxychloroquine	Retinal degeneration principally involving the macula, vortex keratopathy
Gold salts	Deposits in the cornea, conjunctiva, and lens

(*continued*)

Table 7–3. Adverse ophthalmic effects of systemic drugs (selected list). (continued)

Medications	Possible Ophthalmic Side Effects
NSAIDs (eg, ibuprofen, naproxen, indomethacin)	Vortex keratopathy (ibuprofen, naproxen), corneal deposits (indomethacin), retinal degeneration principally involving the macula (indomethacin)
Penicillamine	Ocular pemphigoid, optic neuropathy, extraocular muscle palsy (myasthenic syndrome)
Salicylates	Subconjunctival and retinal hemorrhages, nystagmus
Urinary tract medications	
α-Adrenoceptor antagonists (eg, doxazosin, prazosin, tamsulosin, terazosin)	Intraoperative floppy iris syndrome
Anticholinergic agents	Angle-closure glaucoma due to mydriasis, blurring of vision due to cycloplegia, dry eyes
Finasteride	Floppy iris syndrome during intraocular surgery
Pentosan polysulfate sodium	Maculopathy
Phosphodiesterase type 5 inhibitors (eg, sildenafil, tadalafil, vardenafil)	Color vision changes, nonarteritic anterior ischemic optic neuropathy
Vitamins	
Vitamin A	Papilledema
Vitamin D	Band-shaped keratopathy

antagonists (such as tamsulosin) before cataract surgery because these medications increase the risk of intraoperative floppy iris syndrome, which can make cataract surgery more challenging. Cataract surgery should be completed before α-adrenoreceptor antagonist treatment is started, if possible.

The chemotherapeutic MEK inhibitors are associated with ocular complications including serous retinal detachment, cystoid macular edema, and retinal vein occlusion. Patients receiving MEK inhibitors should have a complete eye examination at baseline before the initiation of these medications and should be referred for an eye examination if blurred or reduced vision develops while taking MEK inhibitors.

DISEASES OF THE EAR

HEARING LOSS

ESSENTIALS OF DIAGNOSIS

- Hearing loss is generally categorized as either conductive or sensorineural.
- Diagnostic evaluation routinely includes audiologic testing.

Classification & Epidemiology

Table 8–1 categorizes hearing loss as normal, mild, moderate, severe, or profound and outlines the vocal equivalent as well as the decibel range.

A. Conductive Hearing Loss

Conductive hearing loss results from a mechanical disruption of the external auditory canal or middle ear. Several mechanisms may result in impairment of the passage of sound vibrations to the inner ear, such as obstruction (eg, cerumen impaction), mass loading (eg, middle ear effusion), stiffness (eg, otosclerosis), and discontinuity (eg, ossicular disruption). Conductive losses in adults are most commonly due to cerumen impaction or transient eustachian tube dysfunction from upper respiratory tract infection. Persistent conductive losses usually result from chronic ear infection, trauma, or otosclerosis. Perforations of the tympanic membrane may also result in a conductive hearing loss. Conductive hearing loss is often correctable with medical (eg, use of a hearing aid) or surgical (eg, repair of tympanic membrane and ossicular chain) therapy, or both. CT of the temporal bone may be used as an adjunct to physical examination to determine the potential cause of conductive hearing loss.

B. Sensorineural Hearing Loss

Sensorineural hearing losses are common in adults and generally result from deficits of the inner ear or central (brain) auditory pathway. Sensory hearing loss results from deterioration of the cochlea, usually due to loss of sensory hair cells within the organ of Corti. The most common form of sensorineural hearing loss is **age-related hearing loss** that manifests as a gradually progressive, predominantly high-frequency hearing loss. Other causes of sensorineural hearing loss include excessive noise exposure; head trauma; ototoxic medications, such as cisplatin-based chemotherapy; and systemic diseases.

While most types of sensorineural hearing loss are gradual, sensorineural hearing loss may be sudden. ***Sudden*** **sensorineural hearing loss, often called idiopathic sudden sensorineural hearing loss, is considered an otologic emergency and may be treatable with oral or intratympanic corticosteroids if delivered within several weeks of onset.** Long-term severe to profound sensorineural hearing loss due to deficits at the level of the inner ear may be correctable with surgery, such as cochlear implantation. Sensorineural hearing loss may also be due to deficits at the level of the central auditory pathway, including lesions involving the eighth cranial nerve, auditory nuclei, ascending tracts, or auditory cortex. Examples of central causes of hearing loss include acoustic neuroma, multiple sclerosis, and auditory neuropathy. Treatment of hearing loss due to central causes are usually aimed at addressing the underlying pathology.

US Preventive Services Task Force; Krist AH et al. Screening for hearing loss in older adults: US Preventive Services Task Force recommendation statement. JAMA. 2021;325:1196. [PMID: 33755083]

Table 8–1. Hearing loss classification.

Classification	Vocal Equivalent	Decibel (dB) Range
Normal	Soft whisper	0–20 dB
Mild	Soft spoken voice	20–40 dB
Moderate	Normal spoken voice	40–60 dB
Severe	Loud spoken voice	60–80 dB
Profound	Shout	> 80 dB

Evaluation of Hearing (Audiology)

In a quiet room, the hearing level may be estimated by having the patient repeat aloud words presented in a soft whisper, a normal spoken voice, or a shout. Normal spoken voice is about 60 decibels. A 512-Hz tuning fork is useful in differentiating conductive from sensorineural hearing loss. In the **Weber test**, the tuning fork is placed directly on the forehead or front teeth. In conductive losses, the sound is heard as louder in the ear with *poorer hearing;* however, in sensorineural losses, the sound radiates to the ear that *hears better* than the other ear. In the **Rinne test**, the tuning fork is placed alternately on the mastoid bone (bone conduction) and in front of the ear canal (air conduction). In conductive losses > 25 dB, bone conduction sounds louder than air conduction.

Formal audiometric studies are performed in a soundproofed room. Pure-tone thresholds in decibels (dB) are obtained over the range of 250–8000 Hz. Conductive losses create a "gap" between the air and bone thresholds, whereas in sensorineural losses, both air and bone thresholds are equally diminished. Speech discrimination measures the clarity of hearing, reported as percentage correct (90–100% is normal). MRI scanning is the most sensitive and specific test to determine the possible location of a defect resulting in sensorineural hearing loss.

Every patient who reports hearing loss should be referred for audiologic evaluation unless the cause is easily remediable (eg, cerumen impaction, otitis media). Immediate audiometric referral is indicated for patients with idiopathic sudden sensorineural hearing loss because it requires treatment (corticosteroids) within a limited several-week time period.

Hearing Amplification

Patients with hearing loss not correctable by medical therapy may benefit from hearing amplification. Contemporary hearing aids are comparatively free of distortion and have been miniaturized to the point where they often may be contained entirely within the ear canal or lie inconspicuously behind the ear.

For patients with conductive loss or unilateral profound sensorineural loss, bone-conducting hearing aids directly stimulate the ipsilateral cochlea (for conductive losses) or contralateral ear (profound unilateral sensorineural loss). In most adults with severe to profound sensory hearing loss, the **cochlear implant**—an electronic device that is surgically implanted into the cochlea to stimulate the auditory nerve—offers socially beneficial auditory rehabilitation.

DISEASES OF THE AURICLE

Disorders of the auricle include skin cancers due to sun exposure. Traumatic auricular hematoma must be drained to prevent significant cosmetic deformity "cauliflower ear" or canal blockage resulting from dissolution of supporting cartilage. Similarly, cellulitis of the auricle must be treated promptly to prevent perichondritis and resultant deformity. **Relapsing polychondritis** is characterized by recurrent, frequently bilateral, painful episodes of auricular erythema and edema and sometimes progressive involvement of the cartilaginous tracheobronchial tree. Treatment with corticosteroids may help forestall cartilage dissolution. Polychondritis and perichondritis may be differentiated from cellulitis by sparing of involvement of the lobule, which does not contain cartilage.

DISEASES OF THE EAR CANAL

1. Cerumen Impaction

Cerumen is a protective secretion produced by the outer portion of the ear canal. *In most persons, the ear canal is self-cleansing and no hygiene measures are recommended.* Cerumen impaction is most often self-induced through ill-advised cleansing attempts by entering the canal itself, eg, digital trauma or use of a cotton-tip applicator. It may be relieved by the patient using detergent ear drops (eg, 3% hydrogen peroxide; 6.5% carbamide peroxide) and irrigation, or by the clinician using mechanical removal, suction, or irrigation. Irrigation is performed with water at body temperature to avoid a vestibular caloric response. The stream should be directed at the posterior ear canal wall adjacent to the cerumen plug. Irrigation should be performed only when the tympanic membrane is known to be intact.

Use of jet irrigators (eg, WaterPik) should be avoided since they may result in tympanic membrane perforations. Following irrigation, the ear canal should be thoroughly dried (eg, by the patient using a hair blow-dryer on low-power setting or by the clinician instilling isopropyl alcohol) to reduce the likelihood of otitis externa. Specialty referral is indicated if impaction is frequently recurrent, if it has not responded to routine measures, or if there is tympanic membrane perforation or chronic otitis media.

Horton GA et al. Cerumen management: an updated clinical review and evidence-based approach for primary care physicians. J Prim Care Community Health. 2020;11:2150132720904181. [PMID: 31994443]

2. Foreign Bodies

Foreign bodies in the ear canal are more frequent in children than in adults. Firm materials may be removed with a loop or a hook, taking care not to displace the object medially toward the tympanic membrane; microscopic guidance is helpful. Aqueous irrigation should *not* be performed for organic foreign bodies (eg, beans, insects), because water may cause them to swell. Living insects are best immobilized before removal by filling the ear canal with lidocaine or mineral oil. Lidocaine should *never* be used in a patient with a possible tympanic membrane perforation as this may result in a profound vestibular response.

3. Otitis Externa

ESSENTIALS OF DIAGNOSIS

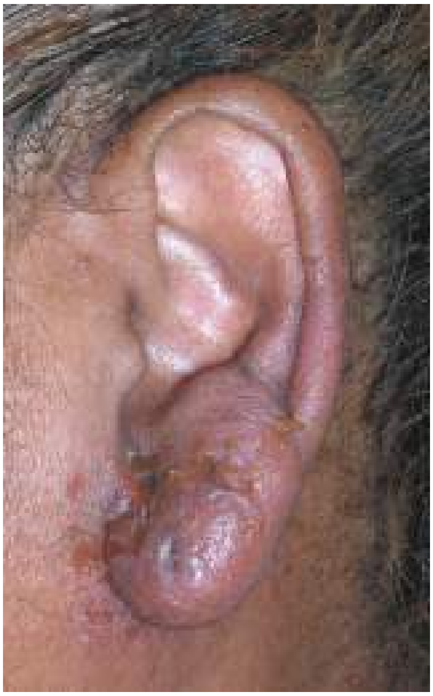
- Otalgia.
- Erythema, edema, and purulence of the external auditory canal skin.
- Patients who are immunocompromised or have diabetes are at risk for "malignant" otitis externa (osteomyelitis of the skull base).

General Considerations

Otitis externa, often called "swimmer's ear," presents with otalgia with associated external auditory canal edema and purulent discharge. There is often a history of recent water exposure or mechanical trauma (eg, scratching, cotton applicators). Otitis externa is usually caused by gram-negative rods (eg, *Pseudomonas, Proteus*) or fungi (eg, *Aspergillus*), which grow in the presence of excessive moisture. In patients who are immunocompromised or have diabetes, persistent otitis externa may evolve into osteomyelitis of the skull base (so-called **malignant otitis externa**). Usually caused by *Pseudomonas aeruginosa*, osteomyelitis begins in the floor of the ear canal and may extend into the middle fossa floor, the clivus, and even the contralateral skull base.

Clinical Findings

Examination reveals erythema and edema of the ear canal skin, often with a purulent exudate (Figure 8–1), as well as surrounding periauricular cellulitis. Manipulation of the auricle elicits pain. The lateral surface of the tympanic membrane is often erythematous. When the canal skin is very edematous, it may be impossible to visualize the tympanic membrane. In immunocompromised patients, such as those with diabetes, malignant otitis externa typically presents with persistent otorrhea; granulation tissue in the ear canal; deep otalgia; and in advanced cases, progressive palsies of cranial nerves, such as cranial nerve VI, VII, IX, X, XI, or XII. Diagnosis of malignant otitis externa is confirmed by the demonstration of osseous erosion on CT scanning and laboratory testing showing high inflammatory markers, such as ESR and CRP. MRI scanning is often important to rule out abscesses that may result from malignant otitis externa.



▲ **Figure 8–1.** Malignant otitis externa in a 40-year-old woman with diabetes mellitus, with typical swelling and honey-colored crusting of the pinna. Both the external auditory canal and temporal bone were involved in the pseudomonal infection. (Used, with permission, from E.J. Mayeaux Jr, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine,* 2nd ed. McGraw-Hill, 2013.)

Treatment

Treatment of otitis externa involves protection of the ear from additional moisture and avoidance of further mechanical injury by scratching. In cases of moisture in the ear (eg, swimmer's ear), acidification with a drying agent (ie, a 50/50 mixture of isopropyl alcohol/white vinegar) is often helpful. When infected, an otic antibiotic solution or suspension of an aminoglycoside (eg, neomycin/polymyxin B) or fluoroquinolone (eg, ciprofloxacin), with or without a corticosteroid (eg, hydrocortisone), is usually effective. Purulent debris filling the ear canal should be gently removed to permit entry of the topical medication.

Drops should be used abundantly (five or more drops three or four times a day) to penetrate the depths of the canal. When substantial edema of the canal wall prevents entry of drops into the ear canal, a wick is placed to facilitate their entry. In recalcitrant cases—particularly when cellulitis of the periauricular tissue has developed—oral fluoroquinolones (eg, ciprofloxacin, 500 mg twice daily for 1 week) are used because of their effectiveness against *Pseudomonas*. Newer medications that are ciprofloxacin suspensions hold promise to improve otitis externa outcomes. *Any case of persistent otitis externa in patients who are immunocompromised or have diabetes must be referred for specialty evaluation.*

Treatment of malignant otitis externa requires prolonged antipseudomonal antibiotic administration, often for several months. Although intravenous therapy is often required initially (eg, ciprofloxacin 200–400 mg every 12 hours), selected patients may be graduated to oral ciprofloxacin (500–1000 mg twice daily). To avoid relapse, antibiotic therapy should be continued, even in the asymptomatic patient, until gallium scanning indicates marked reduction or resolution of the inflammation. Surgical debridement of infected bone is reserved for cases of deterioration despite medical therapy.

4. Pruritus

Pruritus of the external auditory canal, particularly at the meatus, is common. While it may be associated with otitis externa or with seborrheic dermatitis or psoriasis, most cases are self-induced from excoriation or overly zealous ear cleaning. To permit regeneration of the protective cerumen blanket, patients should be instructed to avoid use of soap and water or cotton swabs in the ear canal and avoid any scratching. Patients with excessively dry canal skin may benefit from application of mineral oil, which helps counteract dryness and repel moisture. When an inflammatory component is present, topical application of a corticosteroid (eg, 0.1% triamcinolone) may be beneficial.

5. Exostoses & Osteomas

Bony overgrowths of the ear canal are a frequent incidental finding and rarely have clinical significance. They present as skin-covered bony mounds in the medial ear canal obscuring the tympanic membrane to a variable degree. Solitary osteomas are of no significance as long as they do not cause obstruction or infection. Multiple exostoses, which are generally acquired from repeated exposure to cold water (eg, “surfer’s ear”), may progress and require surgical removal if completely occluding the external auditory canal or resulting in frequent infections.

Wille AE et al. Prevention of external auditory canal exostosis in the Colorado whitewater community. J Osteopath Med. 2022;122:431. [PMID: 35355493]

6. Neoplasia

The most common neoplasm of the ear canal is squamous cell carcinoma. *When an apparent otitis externa does not resolve on therapy, a malignancy should be suspected and biopsy performed.* This disease carries a very high 5-year mortality rate because the tumor tends to invade the lymphatics of the cranial base and must be treated with wide surgical resection and radiation therapy. Adenomatous tumors, originating from the ceruminous glands, generally follow a more indolent course.

DISEASES OF THE EUSTACHIAN TUBE

1. Eustachian Tube Dysfunction

ESSENTIALS OF DIAGNOSIS

- Aural fullness.
- Discomfort with barometric pressure change.
- Retracted eardrum.

The tube that connects the middle ear to the nasopharynx—the eustachian tube—provides ventilation and drainage for the middle ear. It is normally closed, opening only during swallowing or yawning. When eustachian tube function is compromised, air trapped within the middle ear becomes absorbed and negative pressure results. The most common causes of eustachian tube dysfunction are diseases associated with edema of the tubal lining, such as viral upper respiratory tract infections and seasonal allergies. The patient usually reports a sense of fullness in the ear and mild to moderate impairment of hearing. When the tube is only partially blocked, swallowing or yawning may elicit a popping or crackling sound. Examination may reveal retraction of the tympanic membrane and decreased mobility on pneumatic otoscopy. Following a viral illness, this disorder is usually transient, lasting days to weeks. Treatment with systemic and intranasal decongestants (eg, pseudoephedrine, 60 mg orally every 4–6 hours; oxymetazoline, 0.05% spray every 8–12 hours), combined with **autoinsufflation** by forced exhalation against closed nostrils, may hasten relief. Autoinsufflation should not be recommended to patients with active intranasal infection since this maneuver may precipitate middle ear infection. Allergic patients may also benefit from intranasal corticosteroids (eg, beclomethasone dipropionate, two sprays in each nostril twice daily for 2–6 weeks). Air travel, rapid altitudinal change, and underwater diving should be avoided until resolution.

An overly patent eustachian tube (**"patulous eustachian tube"**) is a relatively uncommon, although quite distressing problem. Patients typically describe fullness in the ear and autophony (an exaggerated ability to hear oneself breathe and speak). A patulous eustachian tube may develop during rapid weight loss, such as following pregnancy, or it may be idiopathic. In contrast to eustachian tube dysfunction, the aural pressure is often made worse by exertion and may diminish during an upper respiratory tract infection. Although physical examination is usually normal, respiratory excursions of the tympanic membrane may occasionally be detected during vigorous breathing. Treatment includes avoidance of decongestant products and rarely surgery on the eustachian tube itself.

2. Serous Otitis Media

ESSENTIALS OF DIAGNOSIS

- Negative pressure from eustachian tube obstruction causes transudation of fluid into the middle ear and stasis.
- Dull and hypomobile tympanic membrane.

Prolonged eustachian tube dysfunction with resultant negative middle ear pressure may cause a transudation of fluid. In adults, serous otitis media usually occurs with an upper respiratory tract infection, with barotrauma, or with chronic allergic rhinitis, but when persistent and unilateral, nasopharyngeal carcinoma must be excluded. The tympanic membrane is dull and hypomobile, occasionally accompanied by air bubbles in the middle ear and conductive hearing loss. The treatment of serous otitis media is similar to that for eustachian tube dysfunction. A short course of oral corticosteroids (eg, prednisone, 40 mg/day for 7 days) has been advocated by some clinicians, as have oral antibiotics (eg, amoxicillin, 250 mg three times daily for 7 days)—or even a combination of the two. The role of these regimens remains controversial, but they are probably of little lasting benefit. When medication fails to bring relief after several months, a **ventilating tube** placed through the tympanic membrane may restore hearing and alleviate the sense of aural fullness.

Mulvaney CA et al. Antibiotics for otitis media with effusion (OME) in children. Cochrane Database Syst Rev. 2023;10:CD015254. [PMID: 37870130]

3. Barotrauma

Persons with poor eustachian tube function (eg, congenital narrowness or acquired mucosal edema) may be unable to equalize the barometric stress exerted on the middle ear by air travel, rapid altitudinal change, or underwater diving. The problem is generally most acute during airplane descent, since the negative middle ear pressure tends to collapse and block the eustachian tube, causing pain. Several measures are useful to enhance eustachian tube function and avoid otic barotrauma. The patient should be advised to swallow, yawn, and autoinsufflate frequently during descent. Oral decongestants (eg, pseudoephedrine, 60–120 mg) should be taken several hours before anticipated arrival time so that they will be maximally effective during descent. Topical decongestants, such as 1% phenylephrine or oxymetazoline nasal spray, should be administered 1 hour before arrival.

For acute negative middle ear pressure that persists on the ground, treatment includes decongestants and attempts at autoinsufflation. **Myringotomy** with or without placement of a **tympanostomy tube** provides immediate relief and is appropriate for severe otalgia and hearing loss.

Underwater diving may represent an even greater barometric stress to the ear than flying. Patients should be warned to avoid diving when they have an upper respiratory infection or episode of nasal allergy. During the descent phase of the dive, if inflation of the middle ear via the eustachian tube has not occurred, pain will develop within the first 15 feet; the dive must be aborted. In all cases, divers must descend slowly and equilibrate in stages to avoid the development of severely negative pressures in the tympanum that may result in hemorrhage (hemotympanum) or in perilymphatic fistula. In the latter, the oval or round window ruptures, resulting in sensory hearing loss and acute vertigo. During the ascent phase of a saturation dive, sensory hearing loss or vertigo may develop as the first (or only) symptom of decompression sickness. Immediate recompression will return intravascular gas bubbles to solution and restore the inner ear microcirculation.

Tympanic membrane perforation is an absolute contraindication to diving, as the patient will experience an unbalanced thermal stimulus to the semicircular canals and may experience vertigo, disorientation, and even emesis.

DISEASES OF THE MIDDLE EAR

1. Acute Otitis Media

ESSENTIALS OF DIAGNOSIS

- Otalgia.
- Purulent fluid of the middle ear.
- Erythema and hypomobility of tympanic membrane.

General Considerations

Acute otitis media is a bacterial infection of the mucosally lined, air-containing spaces of the middle ear. Purulent material may extend to pneumatized mastoid air cells and petrous apex of the lateral skull base. *Acute otitis media is usually precipitated by a viral upper respiratory tract infection that causes eustachian tube obstruction.* This results in accumulation of fluid and mucus, which becomes secondarily infected by bacteria. The most common pathogens are *Streptococcus pneumoniae, Haemophilus influenzae*, and *Streptococcus pyogenes.*

Clinical Findings

Acute otitis media may occur at any age. Presenting symptoms and signs include otalgia, aural pressure, decreased hearing, and often fever. The typical physical findings are erythema and decreased mobility of the tympanic membrane (Figure 8–2). Occasionally, bullae will appear on the tympanic membrane.

Rarely, when middle ear empyema is severe, the tympanic membrane bulges outward. In such cases, tympanic membrane rupture is imminent. Rupture is accompanied by a sudden decrease in pain, followed by the onset of otorrhea. With appropriate therapy, spontaneous healing of the tympanic membrane occurs in most cases. Acute mastoiditis results from an infection extending from the middle ear to the mastoid air cells. It is diagnosed by pain, postauricular erythema, and occasionally proptosis of the auricle. Frank swelling over the mastoid bone or the association of cranial neuropathies or central findings indicates severe disease requiring urgent care. Evaluation includes imaging, such as CT, to determine presence of "coalescence" of air cells and associated soft-tissue abscess.

Treatment

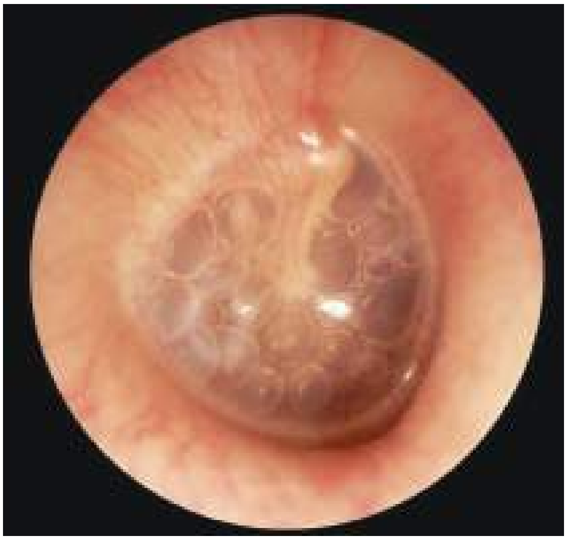

Figure 8–2. Acute otitis media with effusion of right ear, with multiple air-fluid levels visible through a translucent, slightly retracted, nonerythematous tympanic membrane. (Used, with permission, from Frank Miller, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine,* 2nd ed. McGraw-Hill, 2013.)

The treatment of acute otitis media is specific antibiotic therapy, often combined with nasal decongestants. The first-choice antibiotic is amoxicillin 1 g orally every 8 hours for 5–7 days. Alternatives (useful in resistant cases) are amoxicillin-clavulanate 875/125 mg or 2 g/125 mg ER every 12 hours for 5–10 days; or cefuroxime 500 mg or cefpodoxime 200 mg orally every 12 hours for 5–7 days. Recurrent acute otitis media may be managed with long-term antibiotic prophylaxis. Single daily oral doses of sulfamethoxazole (500 mg) or amoxicillin (250 or 500 mg) are given over a period of 1–3 months. Failure of this regimen to control infection is an indication for insertion of ventilating tubes.

Surgical drainage of the middle ear (myringotomy), debridement of the mastoid (mastoidectomy), or both are reserved for patients with severe otalgia or when complications of otitis (eg, mastoiditis, meningitis) have occurred.

Voigt A et al. Outcomes of in-office versus operating room insertion of tympanostomy tubes in children. Int J Pediatr Otorhinolaryngol. 2023;175:111772. [PMID: 37898011]

2. Chronic Otitis Media

ESSENTIALS OF DIAGNOSIS

- Chronic otorrhea with or without otalgia.
- Tympanic membrane perforation with conductive hearing loss.
- Often amenable to surgical correction.

General Considerations

Chronic infection of the middle ear and mastoid generally develops as a consequence of recurrent acute otitis media, although it may follow other diseases and trauma. Perforation or retraction of the tympanic membrane may be present. The bacteriology of chronic otitis media differs from that of acute otitis media. Common organisms include *P aeruginosa, Proteus* species, *Staphylococcus aureus*, and mixed anaerobic infections.

Clinical Findings

The clinical hallmark of chronic otitis media is purulent aural discharge. Drainage may be continuous or intermittent, with increased severity during upper respiratory tract infection or following water exposure. Pain is uncommon except during acute exacerbations. Conductive hearing loss results from destruction of the tympanic membrane or ossicular chain, or both.

Treatment

The medical treatment of chronic otitis media includes regular removal of infected debris, use of earplugs to protect against water exposure, and topical antibiotic drops (ofloxacin 0.3% or ciprofloxacin with dexamethasone) for exacerbations. Oral ciprofloxacin, active against *Pseudomonas*, 500 mg twice a day for 1–6 weeks, may help dry a chronically discharging ear.

In most cases, surgery is the definitive management of tympanic membrane perforations with or without association of ossicular disruption. Successful reconstruction of the tympanic membrane may be achieved with autologous tissue, such as temporalis fascia, in about 90% of cases, often with improvement in conductive hearing.

Complications of Otitis Media

A. Cholesteatoma

Cholesteatoma is a special variety of chronic otitis media (Figure 8–3). The most common cause is prolonged eustachian tube dysfunction, with inward migration of the upper flaccid portion of the tympanic membrane. This creates a squamous epithelium-lined sac, which—when its neck becomes obstructed—may fill with desquamated keratin and become chronically infected. Cholesteatomas typically erode bone, including the ossicular chain with extension into the mastoid. Over time, cholesteatoma may erode into the inner ear, involve the facial nerve and, on rare occasions, spread intracranially. Otoscopic examination may reveal a retraction pocket of the tympanic membrane or a marginal tympanic membrane perforation that exudes keratin debris or granulation tissue. The treatment of cholesteatoma is surgical, including marsupialization of the sac or its complete removal. This may require the creation of a "mastoid bowl" in which the ear canal and mastoid are joined into a large common cavity that must be periodically cleaned.

Tan D et al. Outcomes with management of cholesteatoma. Otolaryngol Clin North Am. 2025;58:141. [PMID: 39322451]

B. Mastoiditis

Acute suppurative mastoiditis usually evolves following several weeks of inadequately treated acute otitis media. It is characterized by pain and postauricular cellulitis accompanied by a spiking fever. CT scan reveals coalescence of the mastoid air cells due to destruction of their bony septa. Initial treatment consists of intravenous antibiotics (eg, cefazolin 0.5–1.5 g every 6–8 hours) directed against the most common offending organisms (*S pneumoniae, H influenzae*, and *S pyogenes*), and myringotomy for culture and drainage. Failure of medical therapy indicates the need for surgical drainage, such as a mastoidectomy.

C. Petrous Apicitis

The medial portion of the petrous bone between the inner ear and clivus may become a site of persistent infection when the drainage of its pneumatic cell tracts becomes blocked. This may cause foul discharge, deep ear and retro-orbital pain, and sixth nerve palsy (**Gradenigo syndrome**); meningitis may be a complication. Treatment is with prolonged antibiotic therapy (based on culture results) or surgical drainage via petrous apicectomy or both.

Isaac H et al. Transmastoid and transtemporal drainage of petrous apicitis with otitis media. Ann Otol Rhinol Laryngol. 2021;130:314. [PMID: 32772562]

D. Facial Paralysis

Facial palsy may be associated with either acute or chronic otitis media. In the acute setting, it results from inflammation of the seventh nerve in its middle ear segment. Treatment consists of myringotomy for drainage and culture, followed by intravenous antibiotics (based on culture results). The use of corticosteroids is controversial. The prognosis is excellent, with complete recovery in most cases.

Facial palsy associated with chronic otitis media usually evolves slowly due to chronic pressure on the seventh nerve in the middle ear or mastoid by cholesteatoma. Treatment requires surgical correction of the underlying disease. The prognosis is less favorable than for facial palsy associated with acute otitis media.

Mohan S et al. Considerations in management of acute otitis media in the COVID-19 era. Ann Otol Rhinol Laryngol. 2021;130:520. [PMID: 32911957]

E. Sigmoid Sinus Thrombosis

Trapped infection within the mastoid air cells adjacent to the sigmoid sinus may cause septic thrombophlebitis. This is heralded by signs of systemic sepsis (spiking fevers, chills), at times accompanied by signs of increased intracranial pressure (headache, lethargy, nausea and vomiting, papilledema). Diagnosis can be made noninvasively by magnetic resonance venography (MRV). Primary treatment is with intravenous antibiotics (based on culture results). Additional treatment, such as anticoagulation, surgical drainage, ligation of the internal jugular vein, or some combination thereof, may be indicated when embolization is suspected.

Ziv O et al. Post-operative clinical course in children undergoing mastoidectomy due to complicated acute mastoiditis. Eur Arch Otorhinolaryngol. 2022;279:3891. [PMID: 34714371]

F. Central Nervous System Infection

Otogenic meningitis is the most common intracranial complication of ear infection. In the setting of acute suppurative otitis media, it arises from hematogenous spread of bacteria, most commonly *H influenzae* and *S pneumoniae*. In chronic otitis media, it results either from passage of infection along preformed pathways, such as the petrosquamous suture line, or from direct extension of disease through the dural plates of the petrous pyramid.

Epidural abscesses arise from direct extension of disease in the setting of chronic infection. They are usually asymptomatic but may present with deep local pain, headache, and low-grade fever. They are often discovered as an incidental finding at surgery. **Brain abscess** may arise in the temporal lobe or cerebellum as a result of septic thrombophlebitis adjacent to an epidural abscess. The predominant causative organisms are *S aureus*, *S pyogenes*, and *S pneumoniae*. Rupture into the subarachnoid space results in meningitis and often death. (See Chapter 35.)

Botti C et al. Pneumolabyrinth: a systematic review. Eur Arch Otorhinolaryngol. 2021;278:4619. [PMID: 33881577]

3. Otosclerosis

Otosclerosis is a progressive disease with a marked familial tendency that affects the bony otic capsule. Lesions involving the footplate of the stapes result in increased impedance to the passage of sound through the ossicular chain, producing conductive hearing loss. This may be treated either through the use of a hearing aid or surgical replacement of the stapes with a prosthesis (stapedectomy). When otosclerotic lesions involve the cochlea ("cochlear otosclerosis"), permanent sensory hearing loss may occur.

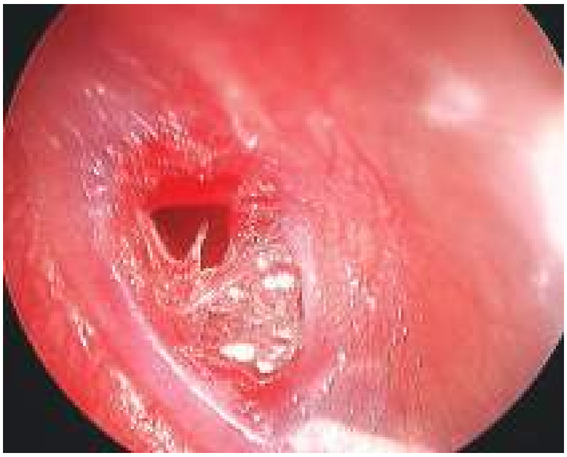
4. Trauma to the Middle Ear

Tympanic membrane perforation may result from impact injury or explosive acoustic trauma (Figure 8–4). Spontaneous healing occurs in most cases. Persistent perforation may result from secondary infection brought on by exposure to



▲ **Figure 8–4.** **Traumatic perforation of the left tympanic membrane.** (Used, with permission, from William Clark, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine*, 2nd ed. McGraw-Hill, 2013.)

water. During the healing period, patients should be advised to wear earplugs while swimming or bathing. Hemorrhage behind an intact tympanic membrane (**hemotympanum**) may follow blunt trauma or extreme barotrauma. Spontaneous resolution over several weeks is the usual course. When a conductive hearing loss > 30 dB persists for > 3 months following trauma, disruption of the ossicular chain should be suspected. Middle ear exploration with reconstruction of the ossicular chain, combined with repair of the tympanic membrane when required, will usually restore hearing.

Zhao X et al. The latest progress of tympanic membrane repair materials. Am J Otolaryngol. 2022;43:103408. [PMID: 36031699]

5. Middle Ear Neoplasia

Primary middle ear tumors are rare. **Glomus tumors** arise either in the middle ear (glomus tympanicum) or in the jugular bulb with upward erosion into the hypotympanum (glomus jugulare). They present clinically with pulsatile tinnitus and hearing loss. A vascular mass may be visible behind an intact tympanic membrane. Large glomus jugulare tumors are often associated with multiple cranial neuropathies, especially involving nerves VII, IX, X, XI, and XII. Treatment usually requires surgery, radiotherapy, or both. *Pulsatile tinnitus thus warrants magnetic resonance angiography (MRA) and MRV to rule out a vascular mass.*

EARACHE

Earache can be caused by a variety of otologic problems, but otitis externa and acute otitis media are the most common. Otitis externa and acute otitis media may be differentiated using history and physical examination, including pneumatic otoscopy. Pain out of proportion to the physical findings may be due to herpes zoster oticus, especially when vesicles appear in the ear canal or concha. Persistent pain and discharge from the ear suggest osteomyelitis of the skull base or cancer, and patients with these symptoms should be referred for specialty evaluation.

Nonotologic causes of otalgia are numerous. The sensory innervation of the ear is derived from the trigeminal, facial, glossopharyngeal, vagal, and upper cervical nerves. Because of this rich innervation, referred otalgia is quite frequent. Temporomandibular joint dysfunction is a common cause of referred ear pain. Pain is exacerbated by chewing or psychogenic grinding of the teeth (**bruxism**) and may be associated with dental malocclusion. Repeated episodes of severe lancinating otalgia may occur in glossopharyngeal neuralgia. Infections and neoplasia that involve the oropharynx, hypopharynx, and larynx frequently cause otalgia. Persistent earache demands specialty referral to exclude cancer of the upper aerodigestive tract.

DISEASES OF THE INNER EAR

1. Sensorineural Hearing Loss

Diseases of the cochlea and central auditory pathway result in hearing loss, a condition that is usually irreversible. The primary goals in the management of sensory hearing loss are prevention of further losses and functional improvement with auditory rehabilitation, such as with a hearing aid or cochlear implant.

A. Presbycusis

Presbycusis, or age-related hearing loss, is the most frequent cause of sensory hearing loss and is progressive, predominantly high-frequency, and symmetrical. Various etiologic factors (eg, prior noise trauma, drug exposure, genetic predisposition) may contribute to presbycusis. Most patients notice a loss of speech discrimination that is especially pronounced in noisy environments. *About 25% of people between the ages of 65 and 75 years and almost 50% of those over 75 experience hearing difficulties.* There is emerging evidence that conventional audiometry may not fully capture hearing loss (known as "hidden hearing loss"). Many patients may have subclinical hearing loss.

Zheng Z et al. Impact of hearing rehabilitation programs on presbycusis management: a systematic review and meta-analysis of randomized controlled trials. Front Aging. 2024;5:1299964. [PMID: 39497940]

B. Noise Trauma

Noise trauma is the second most common cause of sensorineural hearing loss. Sounds exceeding 85 dB for 8 hours or more are potentially injurious to the cochlea. The loss typically begins in the high frequencies (especially 4000 Hz) and, with continuing exposure, progresses to involve the speech frequencies. Among the more common sources of injurious noise are industrial machinery, weapons, and excessively loud music. Monitoring noise levels in the workplace by regulatory agencies has led to preventive programs that have reduced the frequency of occupational losses. Smartwatches have also recently gained capacity to measure environmental noise levels. Individuals of all ages, *especially those with existing hearing losses, should wear earplugs when exposed to moderately loud noises and specially designed earmuffs when exposed to explosive noises.*

Fischer T et al. Are smartwatches a suitable tool to monitor noise exposure for public health awareness and otoprotection? Front Neurol. 2022;13:856219. [PMID: 35432148]

Makaruse N et al. Early identification of potential occupational noise-induced hearing loss: a systematic review. Int J Audiol. 2024 Oct 28. [Epub ahead of print] [PMID: 39468424]

C. Physical Trauma

Concussive head trauma has effects on the inner ear similar to those of severe acoustic trauma. Some degree of sensory hearing loss may occur following concussion and is frequent after lateral skull base fracture.

D. Ototoxicity

Ototoxic substances may affect both the auditory and vestibular systems. The most commonly used ototoxic medications are aminoglycosides; loop diuretics; and several antineoplastic agents, notably cisplatin. *These medications may cause irreversible hearing loss even when administered in therapeutic doses.* When using these medications, it is important to identify high-risk patients, such as those with preexisting hearing losses or kidney disease. Patients simultaneously receiving multiple ototoxic agents are at particular risk owing to ototoxic synergy. Useful measures to reduce the risk of ototoxic injury include serial audiometry, monitoring of serum peak and trough levels, and substitution of equivalent nonototoxic medications whenever possible.

Tan WJT et al. Molecular characteristics of cisplatin-induced ototoxicity and therapeutic interventions. Int J Mol Sci. 2023;24:16545. [PMID: 38003734]

E. Idiopathic Sudden Sensory Hearing Loss

Idiopathic sudden loss of hearing in one ear may occur at any age, but typically it occurs in persons over age 20 years. In the setting a normal otologic physical examination, symptoms may include hearing loss, aural fullness, tinnitus, and dizziness. The cause is unknown; however, idiopathic sudden hearing loss may result from a viral infection or a sudden vascular occlusion of the internal auditory artery. Obtaining an MRI is essential after the diagnosis to rule out retrocochlear pathology (eg, tumors); however, this should not delay treatment. Prompt treatment with corticosteroids has been shown to improve the odds of recovery. Intratympanic administration of corticosteroids alone or in association with oral corticosteroids has been associated with an equal or more favorable prognosis. Because treatment appears to be most effective as close to the onset of the loss as possible, and appears not to be effective after 6 weeks, *a prompt audiogram should be obtained in all patients who present with sudden hearing loss without obvious middle ear pathology*. Prognosis is mixed, with many patients living with permanent deafness in the involved ear, while others have complete recovery.

Chaushu H et al. Spontaneous recovery rate of idiopathic sudden sensorineural hearing loss: a systematic review and meta-analysis. Clin Otolaryngol. 2023;48:395. [PMID: 36640119]

Chrysouli K et al. The effectiveness of intratympanic steroid injection in addition to systemic corticosteroids in the treatment of idiopathic sudden sensorineural hearing loss. Am J Otolaryngol. 2023;44:103872. [PMID: 37060782]

González-García M et al. Auditory prognosis of patients with sudden sensorineural hearing loss in relation to the presence of acute vestibular syndrome: a systematic literature review and meta-analysis. Ear Hear. 2025;46:8. [PMID: 39252156]

F. Autoimmune Hearing Loss

Sensorineural hearing loss that occurs in both ears simultaneously may be associated with a wide array of systemic autoimmune disorders, such as SLE, granulomatosis with polyangiitis, and Cogan syndrome (hearing loss, keratitis, aortitis). The loss is most often progressive. The hearing level often fluctuates, with periods of deterioration alternating with partial or even complete remission. Usually, there is the gradual evolution of permanent hearing loss, which often stabilizes with some remaining auditory function but occasionally proceeds to complete deafness. Vestibular dysfunction may accompany the auditory symptoms.

In many cases, the autoimmune pattern of audiovestibular dysfunction presents in the absence of recognized systemic autoimmune disease. Responsiveness to oral corticosteroid treatment is helpful in making the diagnosis and constitutes first-line therapy. If stabilization of hearing becomes dependent on long-term corticosteroid use, steroid-sparing immunosuppressive regimens may become necessary.

Gordis TM et al. Disease-modifying antirheumatic drugs in the treatment of autoimmune inner ear disease: a systematic review and meta-analysis of auditory and vestibular outcomes. Otol Neurotol. 2023;44:2. [PMID: 36509432]

Wang M et al. Investigating the process of autoimmune inner ear disease: unveiling the intricacies of pathogenesis and therapeutic strategies. Int J Med Sci. 2025;22:179. [PMID: 39744176]

2. Tinnitus

ESSENTIALS OF DIAGNOSIS

- Phantom noise or sounds.
- Persistent tinnitus often, although not always, indicates the presence of hearing loss.
- Intermittent periods of mild, high-pitched tinnitus lasting seconds to minutes are common in normal-hearing persons.

General Considerations

Tinnitus is defined as the sensation of sound in the absence of an exogenous sound source. Tinnitus can accompany any form of hearing loss, and its presence provides no diagnostic value in determining the cause of a hearing loss. Approximately 15% of the general population experiences some type of tinnitus, with prevalence beyond 20% in aging populations.

Clinical Findings

A. Symptoms and Signs

Though tinnitus is commonly associated with hearing loss, tinnitus severity correlates poorly with the degree of hearing loss. About one in seven tinnitus sufferers experiences severe annoyance, and 4% are severely disabled. When severe and persistent, tinnitus may interfere with sleep and ability to concentrate, resulting in considerable psychological distress.

Pulsatile tinnitus—often described by the patient as listening to one's own heartbeat—should be distinguished from **tonal tinnitus**. Although often ascribed to conductive hearing loss, pulsatile tinnitus may be far more serious and may indicate a vascular abnormality, such as glomus tumor, venous sinus stenosis, carotid vaso-occlusive disease, arteriovenous malformation, or aneurysm.

A staccato **"clicking" tinnitus** may result from middle ear muscle spasm (middle ear myoclonus) or sometimes palatal myoclonus. The patient typically perceives a rapid series of popping noises, lasting seconds to a few minutes, accompanied by a fluttering feeling in the ear. Specialized forms of tympanometry may formally diagnose this condition, and it is typically treated surgically.

B. Diagnostic Testing

For routine, nonpulsatile tinnitus, audiometry should be ordered to rule out an associated hearing loss. For unilateral tinnitus, particularly associated with hearing loss in the absence of an obvious causative factor (ie, noise trauma), an MRI should be obtained to rule out a retrocochlear lesion, such as vestibular schwannoma. MRA and MRV and temporal bone CT should be considered for patients who have pulsatile tinnitus to exclude a causative vascular lesion or sigmoid sinus abnormality.

Treatment

The most important treatment of tinnitus is avoidance of exposure to excessive noise, ototoxic agents, and other factors that may cause cochlear damage. Masking the tinnitus with music or through amplification of normal sounds with a hearing aid may also bring some relief. In addition to masking techniques, habituation techniques, such as tinnitus retraining therapy and cognitive behavioral therapy, may prove beneficial in those with refractory symptoms. Among patients who have emotional distress due to tinnitus, numerous antidepressant and antipsychotic medications have been tried to allow the patient to cope with it better.

Conlon B et al. Different bimodal neuromodulation settings reduce tinnitus symptoms in a large randomized trial. Sci Rep. 2022;12:10845. [PMID: 35773272]

Hoare DJ et al. Neuromodulation treatments targeting pathological synchrony for tinnitus in adults: a systematic review. Brain Sci. 2024;14:748. [PMID: 39199443]

Perrotta MV et al. Bimodal stimulation for the reduction of tinnitus using vibration on the skin. Int Tinnitus J. 2023;27:1. [PMID: 38050877]

3. Hyperacusis

Excessive sensitivity to sound may occur following hearing loss, such as that due to noise trauma, in patients susceptible to migraines, or for psychological reasons. Patients with cochlear dysfunction commonly experience "recruitment," an abnormal sensitivity to loud sounds despite a reduced sensitivity to softer ones. Fitting hearing aids and other amplification devices to patients with recruitment requires use of compression circuitry to avoid uncomfortable overamplification.

Pienkowski M. Loud music and leisure noise is a common cause of chronic hearing loss, tinnitus and hyperacusis. Int J Environ Res Public Health. 2021;18:4236. [PMID: 33923580]

Savard MA et al. Toward cognitive models of misophonia. Hear Res. 2025;458:109184. [PMID: 39874936]

4. Vertigo

ESSENTIALS OF DIAGNOSIS

- Either a sensation of motion when there is no motion or an exaggerated sense of motion in response to movement.
- Duration of vertigo episodes with associated hearing loss or other neurologic issues are the keys to diagnosis.
- Evaluation includes audiogram, electronystagmography (ENG) or videonystagmography (VNG), and head MRI.

General Considerations

Vertigo can be caused by either a peripheral or central etiology, or both (Table 8–2).

Clinical Findings

A. Symptoms and Signs

Vertigo is the cardinal symptom of vestibular disease. Vertigo is typically experienced as a distinct "spinning" sensation or a sense of tumbling or of falling forward or backward. It should be distinguished from imbalance,

Table 8–2. Causes of vertigo (listed in alphabetical order, within categories).

- **Peripheral causes**
  - Benign paroxysmal positioning vertigo
  - Ethanol intoxication
  - Inner ear barotraumas
  - Ménière disease
  - Semicircular canal dehiscence
  - Vestibular neuritis/labyrinthitis
- **Central causes**
  - Cerebellar ataxia syndromes
  - Chiari malformation
  - Multiple sclerosis
  - Seizure
  - Wernicke encephalopathy
- **Mixed central and peripheral causes**
  - Cerebellopontine angle tumors
    - Vestibular schwannoma
    - Meningioma
  - Endocrinopathies
    - Hypothyroidism
    - Pendred syndrome
  - Hyperviscosity syndromes
    - Waldenström macroglobulinemia
  - Infections
    - Lyme disease
    - Syphilis
  - Migraine
  - Stroke and vascular insufficiency
    - Anterior inferior cerebellar artery stroke
    - Posterior inferior cerebellar artery stroke
    - Vasculitides
      - Behçet disease
      - Cogan syndrome
      - Granulomatosis with polyangiitis
      - Susac syndrome
    - Vertebral artery insufficiency
  - Vascular compression

light-headedness, and syncope, all of which are nonvestibular in origin (Table 8–3).

1. Peripheral vestibular disease—Peripheral vestibulopathy may cause vertigo of sudden onset, may be so severe that the patient is unable to walk or stand, and is frequently accompanied by nausea and vomiting. Tinnitus and hearing loss may be associated and provide strong support for a peripheral (ie, otologic) origin.

Table 8–3. Common vestibular disorders: differential diagnosis based on classic presentations.

Duration of Typical Vertiginous Episodes	Auditory Symptoms Present	Auditory Symptoms Absent
Seconds	Perilymphatic fistula	Benign paroxysmal positioning vertigo (cupulolithiasis), vertebrobasilar insufficiency, migraine-associated vertigo
Hours	Ménière disease, syphilis	Migraine-associated vertigo
Days	Labyrinthitis, autoimmune inner ear disease, cerebellopontine angle tumor, ototoxicity	Vestibular neuronitis, migraine-associated vertigo, multiple sclerosis, cerebellar degeneration

Critical elements of the history include the duration of the discrete vertiginous episodes (seconds, minutes to hours, or days) and associated symptoms (hearing loss). Triggers should be sought, including diet (eg, increased salt intake in the case of Ménière disease), stress, fatigue, and bright lights (eg, migraine-associated dizziness).

The physical examination of the patient with vertigo includes evaluation of the ears, observation of eye motion and nystagmus in response to head turning, cranial nerve examination, and Romberg testing. In acute peripheral lesions, nystagmus is usually horizontal with a rotatory component; the fast phase usually beats *away* from the diseased side. Visual fixation tends to inhibit nystagmus except in very acute peripheral lesions or with CNS disease. In benign paroxysmal positioning vertigo, **Dix-Hallpike testing** (quickly lowering the patient to the supine position with the head extending over the edge and placed 30 degrees lower than the body, turned either to the left or right) will elicit a delayed-onset (~10 seconds) fatigable nystagmus. Nonfatigable nystagmus in this position indicates CNS disease.

Since visual fixation often suppresses observed nystagmus, many of these maneuvers are performed with **Frenzel goggles**, which prevent visual fixation, and often bring out subtle forms of nystagmus. The **Fukuda test** can demonstrate vestibular asymmetry when the patient steps in place with eyes closed and consistently rotates in one direction.

2. Central disease—Vertigo arising from CNS disease (Table 8–2) tends to develop gradually and then becomes progressively more severe and debilitating. Nystagmus is not always present but can occur in any direction, may be dissociated in the two eyes, and is often non fatigable, vertical rather than horizontal in orientation, without latency, and unsuppressed by visual fixation. ENG is useful in documenting these characteristics. Evaluation of audiovestibular dysfunction requires MRI of the brain.

Episodic vertigo can occur in patients with diplopia from external ophthalmoplegia and is maximal when the patient looks in the direction where the separation of images is greatest. Cerebral lesions involving the temporal cortex may also produce vertigo; it is sometimes the initial symptom of a seizure. Finally, vertigo may be a feature of a systemic disorder and can occur as a side effect of certain anticonvulsant, antibiotic, hypnotic, analgesic, and tranquilizer medications or of alcohol.

Mahmud M et al. Vestibular neurology for the generalist. J Neurol Neurosurg Psychiatry. 2024;95:1196. [PMID: 39313324]

B. Vestibular Testing

Vestibular investigations, such as audiologic evaluation, caloric stimulation, electro- or videonystagmography (ENG or VNG), vestibular-evoked myogenic potentials (VEMPs), and MRI, are indicated in patients with persistent vertigo or when CNS disease is suspected. These studies help distinguish between central and peripheral lesions and identify causes requiring specific therapy. ENG consists of objective recording of the nystagmus induced by head and body movements, gaze, and caloric stimulation. It is helpful in quantifying the degree of vestibular hypofunction.

Vertigo Syndromes Due to Peripheral Lesions

A. Ménière Disease

The cause of Ménière disease is unknown. The classic syndrome consists of episodic vertigo, with discrete vertigo spells lasting 20 minutes to several hours in association with fluctuating, often low-frequency, sensorineural hearing loss, tinnitus (usually low-tone and "blowing" in quality), and a sensation of unilateral aural pressure (Table 8–3). These symptoms in presence of headaches or migraines may suggest migraine-associated dizziness. *Primary treatment is aimed at decreasing dizzy episodes. There are no treatments for reduction in hearing loss.* Treatment of Ménière disease typically involves preventive measures, including low-salt diet and daily diuretics (eg, acetazolamide). For symptomatic relief of acute vertigo attacks, lorazepam (0.5–1 mg) or diazepam (2–5 mg) can be used. Nausea may be treated with oral meclizine (25 mg). In refractory cases, patients may undergo intratympanic corticosteroid or gentamicin injections, endolymphatic sac decompression, or surgical or vestibular nerve section. There are increasing reports of imaging, such as CT or MRI, for evaluation of Ménière disease.

Tang M et al. Efficacy and safety of acupuncture in the treatment of Meniere's disease: a systematic review and meta-analysis. Front Med (Lausanne). 2024;11:1463821. [PMID: 39722819]

B. Labyrinthitis

Patients with labyrinthitis suffer from acute onset of continuous, usually severe vertigo lasting several days, accompanied by hearing loss and tinnitus. During a recovery period that lasts for several weeks, the vertigo gradually improves. Hearing may return to normal or remain permanently impaired in the involved ear. The cause of labyrinthitis is unknown. Treatment consists of antibiotics, if the patient is febrile or has symptoms of a bacterial infection, oral corticosteroids, and supportive care. Vestibular suppressants are useful during the acute phase of the attack (eg, diazepam) but should be discontinued as soon as feasible to avoid long-term dysequilibrium from inadequate compensation.

Schoo DP et al. New frontiers in managing the dizzy patient. Otolaryngol Clin North Am. 2021;54:1069. [PMID: 34294438]

C. Benign Paroxysmal Positioning Vertigo

Patients living with recurrent spells of vertigo, lasting a few (10–15) seconds per spell, associated with changes in head position (often provoked by rolling over in bed), usually have benign paroxysmal positioning vertigo (BPPV). The term "positioning vertigo" is more accurate than "positional vertigo" because it is *provoked by changes in head position* rather than by the maintenance of a particular posture.

The typical symptoms of BPPV occur in clusters that persist for several days. There is a brief (10–15 seconds) latency period following a head movement before symptoms develop, and the acute vertigo subsides within 10–60 seconds, although the patient may remain imbalanced for several hours. *Dizziness that lasts for more than a few seconds (that is several minutes or hours) is not BPPV.* Constant repetition of the positional change leads to habituation. Since some CNS disorders can mimic BPPV (eg, vertebrobasilar insufficiency), recurrent cases warrant head MRI/MRA. In central lesions, there is no latent period, fatigability, or habituation of the symptoms and signs. Treatment of BPPV involves physical therapy protocols (eg, the **Epley maneuver** or **Brandt-Daroff exercises**), based on the theory that it results from **cupulolithiasis** (free-floating statoconia, also known as otoconia) within a semicircular canal.

Tarnutzer AA et al. Diagnostic errors in the acutely dizzy patient–lessons learned. Brain Sci. 2025;15:55. [PMID: 39851423]

D. Vestibular Neuronitis

In vestibular neuronitis, a paroxysmal, usually single attack of vertigo occurs without accompanying impairment of auditory function and will persist for several days before gradually abating. During the acute phase, examination reveals nystagmus and absent responses to caloric stimulation on one or both sides. The cause of the disorder is unclear though presumed to be viral. Treatment consists of supportive care; vestibular suppressants, such as diazepam 2–5 mg every 6–12 hours during the acute phases of the vertigo only; oral corticosteroids may potentially be used; and antiemetics, such as ondansetron and meclizine, followed by vestibular therapy if the patient does not completely compensate.

Lee JY et al. Clinical characteristics of acute vestibular neuritis according to involvement site. Otol Neurotol. 2020;41:143. [PMID: 31789808]

E. Traumatic Vertigo

Labyrinthine concussion is the most common cause of vertigo following head injury. Symptoms generally diminish within several days but may linger for a month or more. Basilar skull fractures that traverse the inner ear usually result in severe vertigo lasting several days to a week and deafness in the involved ear. Chronic posttraumatic vertigo may result from **cupulolithiasis**. This occurs when traumatically detached statoconia (otoconia) settle on the ampulla of the posterior semicircular canal and cause an excessive degree of cupular deflection in response to head motion. Clinically, this presents as episodic positioning vertigo. Treatment consists of supportive care and vestibular suppressant medication (diazepam) during the acute phase of the attack and vestibular therapy.

F. Perilymphatic Fistula

Leakage of perilymphatic fluid from the inner ear into the tympanic cavity via the round or oval window is a very rare cause of vertigo and sensory hearing loss. Most cases result from physical injury (eg, blunt head trauma, hand slap to ear); extreme barotrauma during airflight, scuba diving, etc; or vigorous Valsalva maneuvers (eg, during weight lifting).

Kitoh R et al; Research Group on Intractable Hearing Disorders and Japan Audiological Society. Clinical practice guidelines for the diagnosis and management of acute sensorineural hearing loss. Auris Nasus Larynx. 2024;51:811. [PMID: 38968877]

G. Cervicogenic Vertigo

Position receptors located in the facets of the cervical spine are important physiologically in the coordination of head and eye movements. Cervical proprioceptive dysfunction is a common cause of vertigo triggered by neck movements. This disturbance often commences after neck injury, particularly hyperextension; it is also associated with degenerative cervical spine disease. Although symptoms vary, vertigo may be triggered by assuming a particular head position as opposed to moving to a new head position (the latter typical of labyrinthine dysfunction). Cervical vertigo may often be confused with migraine-associated vertigo, which is also associated with head movement. Management consists of neck movement exercises to the extent permitted by orthopedic considerations.

Piromchai P et al. The efficacy of self-exercise in a patient with cervicogenic dizziness: a randomized controlled trial. Front Neurol. 2023;14:1121101. [PMID: 36864911]

H. Migrainous Vertigo

Episodic vertigo is frequently associated with migraine headache. Head trauma may also be a precipitating feature. The vertigo may be temporally related to the headache and last up to several hours, or it may also occur in the absence of any headache. Migrainous vertigo may resemble Ménière disease but without associated hearing loss or tinnitus. Accompanying symptoms may include head pressure; visual, motion, or auditory sensitivity; and photosensitivity. Symptoms typically worsen with lack of sleep and anxiety or stress. Food triggers include caffeine, chocolate, and alcohol, among others. There is often a history of motion intolerance (easily carsick as a child). Migrainous vertigo may be familial. Treatment includes dietary and lifestyle changes (improved sleep pattern, avoidance of stress) and antimigraine prophylactic medication.

I. Superior Semicircular Canal Dehiscence

Deficiency in the bony covering of the superior semicircular canal may be associated with vertigo triggered by loud noise exposure, straining, and an apparent conductive hearing loss. **Autophony** is also a common feature. Diagnosis is with coronal HRCT scan and VEMP testing.

Eberhard KE et al. Transmastoid surgery for superior canal dehiscence: prospective longitudinal objective and patient-reported audiovestibular outcomes. Otol Neurotol. 2024;45:184. [PMID: 38206067]

Patel S et al. The history of superior semicircular canal dehiscence: a bibliometric analysis. World Neurosurg. 2024;185: e591. [PMID: 38395350]

Vertigo Syndromes Due to Central Lesions

CNS causes of vertigo include brainstem vascular disease, arteriovenous malformations, tumors of the brainstem and cerebellum, multiple sclerosis, and vertebrobasilar migraine (Table 8–2). Vertigo of central origin often becomes unremitting and disabling. The associated nystagmus is often nonfatigable, vertical rather than horizontal in orientation, without latency, and unsuppressed by visual fixation. ENG is useful in documenting these characteristics. There are commonly other signs of brainstem dysfunction (eg, cranial nerve palsies; motor, sensory, or cerebellar deficits in the limbs) or of increased intracranial pressure. Auditory function is generally spared.

Dieterich M et al. Central vestibular networking for sensorimotor control, cognition, and emotion. Curr Opin Neurol. 2024;37:74. [PMID: 38032266]

DISEASES OF THE CENTRAL AUDITORY & VESTIBULAR SYSTEMS

Lesions of the eighth cranial nerve and central audiovestibular pathways may produce hearing loss and dizziness (Table 8–3). One characteristic of neural hearing loss is deterioration of speech discrimination out of proportion to the decrease in pure-tone thresholds. Another is auditory adaptation, wherein a steady tone appears to the listener to decay and eventually disappear. Auditory evoked responses are useful in distinguishing cochlear from neural losses and may give insight into the site of lesion within the central pathways. The evaluation of central audiovestibular disorders usually requires imaging of the internal auditory canal, cerebellopontine angle, and brain with enhanced MRI.

1. Vestibular Schwannoma (Acoustic Neuroma)

Eighth cranial nerve schwannomas are among the most common intracranial tumors. Most are unilateral, but about 5% are associated with the hereditary syndrome neurofibromatosis type 2, in which bilateral eighth nerve tumors may be accompanied by meningiomas and other intracranial and spinal tumors. These benign lesions arise within the internal auditory canal and gradually grow to involve the cerebellopontine angle, eventually compressing the pons and resulting in hydrocephalus. Their typical auditory symptoms are unilateral hearing loss with a deterioration of speech discrimination exceeding that predicted by the degree of pure-tone loss. Nonclassic presentations, such as sudden unilateral hearing loss, are fairly common. *Any individual with a unilateral or asymmetric sensorineural hearing loss should be evaluated for an intracranial mass lesion.* Vestibular dysfunction more often takes the form of continuous dysequilibrium than episodic vertigo. Diagnosis is made by enhanced MRI. Treatment consists of observation, microsurgical excision, or stereotactic radiotherapy, depending on such factors as patient age, underlying health, and size of the tumor.

Gambacciani C et al. Surgical management of skull base meningiomas and vestibular schwannomas. Curr Opin Oncol. 2022;34:713. [PMID: 36093884]

2. Vascular Compromise

Vertebrobasilar insufficiency is a common cause of vertigo in the older adults. It is often triggered by changes in posture or extension of the neck. Reduced flow in the vertebrobasilar system may be demonstrated noninvasively through MRA. Empiric treatment is with vasodilators and aspirin.

Clark M et al. A review of carotid and vertebral artery dissection. Br J Hosp Med (Lond). 2022;83:1. [PMID: 35506728]

3. Multiple Sclerosis

Patients with multiple sclerosis may suffer from episodic vertigo and chronic imbalance. Hearing loss in this disease is most commonly unilateral and of rapid onset. Spontaneous recovery may occur.

Kattah JC et al. Eye movements in demyelinating, autoimmune and metabolic disorders. Curr Opin Neurol. 2020;33:111. [PMID: 31770124]

OTOLOGIC MANIFESTATIONS OF AIDS

AIDS may result in many otologic signs and symptoms. The pinna and external auditory canal may be affected by Kaposi sarcoma and by persistent and potentially invasive fungal infections (particularly *Aspergillus fumigatus*). Serous otitis media due to eustachian tube dysfunction may arise from adenoidal hypertrophy (HIV lymphadenopathy), recurrent mucosal viral infections, or an obstructing nasopharyngeal tumor (eg, lymphoma). Unfortunately, ventilating tubes are seldom helpful and may trigger profuse watery otorrhea. Acute otitis media is usually caused by typical bacterial organisms, including *Proteus, Staphylococcus*, and *Pseudomonas*, and rarely, by *Pneumocystis jirovecii*. Sensorineural hearing loss is common and, in some cases, results from viral CNS infection. In cases of progressive hearing loss, cryptococcal meningitis and syphilis must be excluded. Acute facial paralysis due to herpes zoster infection (**Ramsay Hunt syndrome**) occurs commonly and follows a clinical course similar to that in nonimmunocompromised patients. Treatment is with high-dose acyclovir (see Chapter 37). Corticosteroids may also be effective as an adjunct.

DISEASES OF THE NOSE & PARANASAL SINUSES

INFECTIONS OF THE NOSE & PARANASAL SINUSES

Rhinosinusitis may be classified by duration of symptoms. Rhinosinusitis is called **acute rhinosinusitis** if < 4 weeks' duration or as **chronic rhinosinusitis** if lasting > 12 weeks, with or without acute exacerbations. Acute rhinosinusitis may also be classified by presumed etiology, such as viral rhinosinusitis or acute bacterial rhinosinusitis.

1. Viral Rhinosinusitis (Common Cold)

ESSENTIALS OF DIAGNOSIS

- Associated malaise, headache, and cough.
- Nasal congestion, facial pressure, rhinorrhea, and hyposmia.
- Erythematous, engorged nasal mucosa without intranasal purulence.
- Symptoms are self-limited, lasting typically < 10 days.

Clinical Findings

Due to the numerous serologic types of rhinoviruses, adenoviruses, and other viruses, patients remain susceptible to the common cold throughout life. These infections, while generally quite benign and self-limited, have been implicated in the development or exacerbation of more serious conditions, such as acute bacterial sinusitis and acute otitis media, asthma, cystic fibrosis, and bronchitis. Nasal congestion, decreased sense of smell, rhinorrhea, and sneezing accompanied by general malaise, throat discomfort and, occasionally, headache, are typical in viral infections. Nasal examination usually shows erythematous, edematous mucosa and a watery discharge. The presence of purulent nasal discharge suggests bacterial rhinosinusitis.

Najafloo R et al. Mechanism of anosmia caused by symptoms of COVID-19 and emerging treatments. ACS Chem Neurosci. 2021;12:3795. [PMID: 34609841]

Treatment

The main treatment for viral rhinitis is supportive care, including rest, hydration, and use of over-the-counter analgesics and decongestants. There are no effective antiviral therapies for either the prevention or treatment of most viral rhinitis despite a common *misperception* among patients that antibiotics are helpful. Buffered hypertonic saline (3–5%) nasal irrigation has been shown to improve symptoms and reduce the need for NSAIDs. Other supportive measures, such as oral decongestants (pseudoephedrine, 30–60 mg every 4–6 hours or 120 mg twice daily), may provide some relief of rhinorrhea and nasal obstruction.

Nasal sprays, such as oxymetazoline or phenylephrine, are rapidly effective but should *not* be used for more than a few days to prevent rebound congestion. Withdrawal of the medication after prolonged use leads to **rhinitis medicamentosa**, an almost addictive need for continuous usage. Topical intranasal corticosteroids (eg, flunisolide, 2 sprays in each nostril twice daily), intranasal anticholinergic (ipratropium 0.06% nasal spray, 2–3 sprays every 8 hours as needed), or a short tapering course of oral prednisone may help during the withdrawal process.

Complications

Other than mild eustachian tube dysfunction or transient middle ear effusion, complications of viral rhinitis are unusual. *Secondary acute bacterial rhinosinusitis is a well-accepted complication of acute viral rhinitis* and is suggested by persistence of symptoms beyond 10 days with purulent green or yellow nasal secretions and unilateral facial or dental pain.

2. Bacterial Rhinosinusitis

ESSENTIALS OF DIAGNOSIS

- Acute onset of symptoms.
- Purulent yellow-green nasal discharge or expectoration.
- Facial pain or pressure over the affected sinus or sinuses.
- Nasal obstruction.
- Associated cough, malaise, fever, and headache.

General Considerations

Compared with viral rhinitis, acute bacterial rhinosinusitis infections are uncommon, but they still affect nearly 20 million Americans annually and account for over 2 billion dollars in health care expenditures. Acute bacterial rhinosinusitis is believed to be the result of impaired mucociliary clearance, inflammation of the nasal cavity mucosa, and obstruction of the ostiomeatal complex. Edematous mucosa causes obstruction of the complex, resulting in the *accumulation of mucus in the sinus cavity that becomes secondarily infected by bacteria*. The largest of these ostiomeatal complexes is deep to the middle turbinate in the middle meatus. This complex is actually a confluence of complexes draining the maxillary, ethmoid, and frontal sinuses. The sphenoid drains from a separate complex between the septum and superior turbinate. The typical pathogens of bacterial rhinosinusitis are *S pneumoniae*, other streptococci, *H influenzae*, and less commonly, *S aureus* and *Moraxella catarrhalis*. Pathogens vary regionally in both prevalence and drug resistance; about 25% of healthy asymptomatic individuals may, if sinus aspirates are cultured, harbor such bacteria as well.

Clinical Findings

A. Symptoms and Signs

There are no agreed-upon criteria for the diagnosis of acute bacterial rhinosinusitis in adults. Major symptoms include purulent nasal drainage, nasal obstruction or congestion, facial pain/pressure, altered smell, cough, and fever. Minor symptoms include headache, otalgia, halitosis, dental pain, and fatigue. Many of the more specific symptoms and signs relate to the affected sinus(es). Bacterial rhinosinusitis can be distinguished from viral rhinitis by persistence of symptoms for > 10 days after onset or worsening of symptoms within 10 days after initial improvement. Acute rhinosinusitis is defined as lasting < 4 weeks and subacute rhinosinusitis, as lasting 4–12 weeks.

Acute maxillary sinusitis is the most common form of acute bacterial rhinosinusitis because the maxillary is the largest sinus with a single drainage pathway that is easily obstructed. Unilateral facial fullness, pressure, and tenderness over the cheek are common symptoms, but may not always be present. Pain may refer to the upper incisor and canine teeth via branches of the trigeminal nerve, which traverse the floor of the sinus. Purulent nasal drainage should be noted with nasal airway obstruction or facial pain (pressure). Maxillary sinusitis may result from dental infection, and teeth that are tender should be carefully examined for signs of abscess. Drainage of the periapical abscess or removal of the diseased tooth typically resolves the sinus infection.

Acute ethmoiditis in adults is often accompanied by maxillary sinusitis, and symptoms are similar to those described above. Localized ethmoid sinusitis may present with pain and pressure over the high lateral wall of the nose between the eyes that may radiate to the orbit.

Sphenoid sinusitis is usually seen in the setting of pansinusitis or infection of all the paranasal sinuses on at least one side. The patient may describe a headache "in the middle of the head" and often point to the vertex.

Acute frontal sinusitis may cause pain and tenderness of the forehead. This is most easily elicited by palpation of the orbital roof just below the medial end of the eyebrow.

Hospital-associated sinusitis is a form of acute bacterial rhinosinusitis that may present without the usual symptoms. Instead, it may be a cause of fever in critically ill patients. It is often associated with prolonged presence of a nasogastric or, rarely, nasotracheal tube causing nasal mucosal inflammation and ostiomeatal complex obstruction. Pansinusitis on the side of the tube is common on imaging studies.

B. Imaging

The diagnosis of acute bacterial rhinosinusitis can usually be made on clinical grounds alone. *Although more sensitive than clinical examination, routine radiographs are not cost-effective and are not recommended by the Agency for Health Care Policy and Research or American Association of Otolaryngology Guidelines.* Consensus guidelines recommend imaging when clinical criteria are difficult to evaluate, when the patient does not respond to appropriate therapy or has been treated repeatedly with antibiotics, when intracranial involvement or CSF rhinorrhea is suspected, when complicated dental infection is suspected, or when symptoms of more serious infection are noted.

When necessary, noncontrast screening coronal CT scans are more cost-effective and provide more information than conventional sinus films. CT provides a rapid and effective means to assess all of the paranasal sinuses, identify areas of greater concern (such as bony dehiscence, periosteal elevation, or maxillary tooth root exposure within the sinus), and direct appropriate therapy. CT scans are reasonably sensitive but are not specific. Swollen soft tissue and fluid may be difficult to distinguish when opacification of the sinus is due to other conditions, such as chronic rhinosinusitis, nasal polyposis, or mucus retention cysts. Sinus abnormalities can be seen in most patients with an upper respiratory infection, while bacterial rhinosinusitis develops in only 2%.

If malignancy, intracranial extension, or opportunistic infection is suspected, MRI with gadolinium should be ordered instead of, or in addition to, CT. MRI will distinguish tumor from fluid, inflammation, and inspissated mucus far better than CT, and will better delineate tumor extent (eg, involvement of adjacent structures, such as the orbit, skull base, and palate). Bone destruction can be demonstrated as well by MRI as by CT.

Treatment

All patients with acute bacterial rhinosinusitis should have careful evaluation of pain. For symptom reduction in viral rhinitis and bacterial rhinosinusitis without complication, NSAIDs, saline nasal sprays, and nasal decongestants (pseudoephedrine, 30–60 mg every 6 hours, up to 240 mg/day; nasal oxymetazoline, 0.05% or oxymetazoline, 0.05–0.1%, one or two sprays in each nostril every 6–8 hours for up to 3 days) can be helpful. In cases of suspected bacterial rhinosinusitis, intranasal corticosteroids (eg, high-dose mometasone furoate 200 mcg each nostril twice daily for 21 days) can reduce nasal symptoms. Other medications, such as mucolytics, vitamin C, probiotics, and antihistamines, have *not* demonstrated efficacy in the management of acute rhinosinusitis.

Antibiotic therapy should be reserved for complicated or protracted acute bacterial rhinosinusitis. Between 40% and

69% of patients with acute bacterial rhinosinusitis improve symptomatically within 2 weeks without antibiotic therapy. Antibiotic treatment is controversial in uncomplicated cases of clinically diagnosed acute bacterial rhinosinusitis because only 5% of patients will note a shorter duration of illness with treatment, and antibiotic treatment is associated with nearly twice the number of adverse events compared with placebo. Antibiotics may be considered when symptoms last > 10 days or when symptoms (including fever, facial pain, and swelling of the face) are severe or when cases are complicated (such as immunodeficiency). In these patients, administration of antibiotics does reduce the incidence of clinical failure by 50% and represents the most cost-effective treatment strategy.

Selection of antibiotics is usually empiric and based on a number of factors, including regional patterns of antibiotic resistance, antibiotic allergy, cost, and patient tolerance. For adults younger than 65 years with mild to moderate acute bacterial rhinosinusitis, the recommended first-line therapy is amoxicillin-clavulanate (500 mg/125 mg orally three times daily or 875 mg/125 mg orally twice daily for 5–7 days), or in those with severe sinusitis, high-dose amoxicillin-clavulanate (2000 mg/125 mg extended-release orally twice daily for 7–10 days). In patients with a high risk for penicillin-resistant *S pneumoniae* (age over 65 years, hospitalization in the prior 5 days, antibiotic use in the prior month, immunocompromised status, multiple comorbidities, or severe sinus infection), the recommended first-line therapy is the high-dose amoxicillin-clavulanate option (2000 mg/125 mg extended-release orally twice daily for 7–10 days). For those with penicillin allergy or hepatic impairment, doxycycline (100 mg orally twice daily or 200 mg orally once daily for 5–7 days) or clindamycin (150–300 mg every 6 hours) plus a cephalosporin (cefixime 400 mg orally once daily or cefpodoxime proxetil 200 mg orally twice daily) for 10 days are options. Macrolides, trimethoprim-sulfamethoxazole, and second- or third-generation cephalosporins are not recommended for empiric therapy. Dupilumab, a monoclonal antibody with inhibition of IL-4 and IL-13, is approved for patients with chronic sinusitis with nasal polyposis.

Hospital-associated infections in critically ill patients are treated differently from community-acquired infections. Removal of a nasogastric tube and improved nasal hygiene (nasal saline sprays, humidification of supplemental nasal oxygen, and nasal decongestants) are critical interventions and often curative in mild cases without aggressive antibiotic use. Endoscopic or transantral cultures may help direct medical therapy in complicated cases. In addition, broad-spectrum antibiotic coverage directed at *P aeruginosa, S aureus* (including methicillin-resistant strains), and anaerobes may be required.

Complications

Local complications of acute bacterial rhinosinusitis include orbital cellulitis and abscess, osteomyelitis, cavernous sinus thrombosis, and intracranial extension. Orbital complications typically occur by extension of ethmoid sinusitis through the lamina papyracea, a thin layer of bone that comprises the medial orbital wall. *Any change in the ocular examination necessitates immediate CT imaging.* Extension in this area may cause orbital cellulitis leading to proptosis, gaze restriction, and orbital pain. Select cases are responsive to intravenous antibiotics, with or without corticosteroids, and should be managed in close conjunction with an ophthalmologist or otolaryngologist, or both. Extension through the lamina papyracea can also lead to subperiosteal abscess formation (orbital abscess). Such abscesses cause marked proptosis, ophthalmoplegia, and pain with medial gaze. While some cases respond to antibiotics, such findings should prompt an immediate referral to a specialist for consideration of decompression and evacuation. Failure to intervene quickly may lead to permanent visual impairment and a "frozen globe."

Osteomyelitis requires prolonged antibiotics as well as removal of necrotic bone. The frontal sinus is most commonly affected, with bone involvement suggested by a tender swelling of the forehead (**Pott puffy tumor**). Following treatment, secondary cosmetic reconstructive procedures may be necessary.

Though rare, intracranial complications of sinusitis can occur either through hematogenous spread, as in cavernous sinus thrombosis and meningitis, or by direct extension, as in epidural and intraparenchymal brain abscesses. **Cavernous sinus thrombosis** is heralded by ophthalmoplegia, chemosis, and visual loss; the diagnosis is most commonly confirmed by MRI. When identified early, cavernous sinus thrombosis typically responds to intravenous antibiotics. Frontal epidural and intracranial abscesses are often clinically silent, but may present with altered mental status, persistent fever, or severe headache.

When to Refer

Failure of acute bacterial rhinosinusitis to resolve after an adequate course of oral antibiotics necessitates referral to an otolaryngologist for evaluation. Endoscopic cultures may direct further treatment choices. Nasal endoscopy and CT scan are indicated when symptoms persist longer than 4–12 weeks. Any patients with suspected extension of disease outside the sinuses should be evaluated urgently by an otolaryngologist and imaging should be obtained.

When to Admit

- Facial swelling and erythema indicative of facial cellulitis.
- Proptosis.
- Vision change or gaze abnormality indicative of orbital cellulitis.
- Abscess or cavernous sinus involvement.
- Mental status changes suggestive of intracranial extension.
- Failure to respond to appropriate first-line treatment or symptoms persisting longer than 4 weeks.

3. Nasal Vestibulitis & *S aureus* Nasal Colonization

Inflammation of the nasal vestibule may result from folliculitis of the hairs that line this orifice and is usually the result of nasal manipulation or hair trimming. Systemic antibiotics effective against *S aureus* (such as dicloxacillin, 250 mg orally four times daily for 7–10 days) are indicated. Topical mupirocin 2% nasal ointment (applied two or three times daily) also may be a helpful addition and may prevent future occurrences. If recurrent, the addition of rifampin (10 mg/kg orally twice daily for the last 4 days of dicloxacillin treatment) may eliminate the *S aureus* carrier state. If a furuncle exists, it should be incised and drained, preferably intranasally. Adequate treatment of these infections is important to prevent retrograde spread of infection through valveless veins into the cavernous sinus and intracranial structures.

S aureus is the leading nosocomial pathogen, and nasal carriage is a well-defined risk factor in the development and spread of nosocomial infections. Nasal and extranasal methicillin-resistant *S aureus* (MRSA) colonizations are associated with a 30% risk of developing an invasive MRSA infection during hospital stays. While the vast majority have no vestibulitis symptoms, screening by nasal swabs and PCR-based assays has demonstrated a 30% rate of *S aureus* colonization in hospital patients and an 11% rate of MRSA colonization in ICU patients. Elimination of the carrier state is challenging, but studies of mupirocin 2% nasal ointment application with chlorhexidine facial washing (40 mg/mL) twice daily for 5 days have demonstrated decolonization in 39% of patients.

Ontario Health (Quality). Pre-surgical nasal decolonization of *Staphylococcus aureus*: a health technology assessment. Ont Health Technol Assess Ser. 2022;22:1. [PMID: 36160757]

4. Invasive Fungal Sinusitis

Invasive fungal sinusitis is rare and includes both rhinocerebral mucormycosis (*Mucor, Absidia*, and *Rhizopus* spp.) and other invasive fungal infections, such as *Aspergillus*. The fungus spreads rapidly through vascular channels and may be lethal if not detected early. Patients with mucormycosis almost invariably have some degree of immunocompromise, such as diabetes mellitus, long-term corticosteroid therapy, neutropenia associated with chemotherapy for hematologic malignancy, or end-stage renal disease. Occasional cases of sinonasal infection with *Aspergillus* spp. have been reported in patients with untreated HIV/AIDS. The initial symptoms may be similar to those of acute bacterial rhinosinusitis, although facial pain is often more severe. Nasal drainage is typically clear or straw-colored, rather than purulent, and visual symptoms may be noted at presentation in the absence of significant nasal findings. On examination, the classic finding of mucormycosis is a black eschar on the middle turbinate, but this finding is not universal and may not be apparent if the infection is deep or high within the nasal bones. Often the mucosa appears normal or simply pale and dry. This may be noted on the hard palate as well. Early diagnosis requires suspicion of the disease and nasal biopsy with silver stains, revealing broad nonseptate hyphae within tissues and necrosis with vascular occlusion. Imaging, such as CT or MRI, may initially show only soft tissue changes. Consequently, biopsy and ultimate debridement should be based on the clinical setting rather than radiographic demonstration of bony destruction or intracranial changes.

Invasive fungal sinusitis represents a medical and surgical emergency. Once recognized, voriconazole may be started by intravenous infusion, and prompt wide surgical debridement is indicated for patients with reversible immune deficiency (eg, poorly controlled hyperglycemia in diabetes). Other antifungals, including amphotericin or the less nephrotoxic lipid-based amphotericin B (Ambisome) and caspofungin, are alternatives to voriconazole and may be added to voriconazole depending on the fungus. Surgical management, while necessary for any possibility of cure, often results in tremendous disfigurement and functional deficits (eg, often resulting in the loss of at least one eye). Even with early diagnosis and immediate appropriate intervention, the prognosis is guarded. In persons with diabetes, the mortality rate is about 20%. If kidney disease is present or develops, mortality is over 50%; in the setting of AIDS or hematologic malignancy with neutropenia, mortality approaches 100%. Whether to undertake aggressive surgical management should be considered carefully because many patients are gravely ill at the time of diagnosis, and overall disease-specific survival is only about 57%.

ALLERGIC RHINITIS

ESSENTIALS OF DIAGNOSIS

- Clear rhinorrhea, sneezing, tearing, eye irritation, and pruritus.
- Associated symptoms include cough, bronchospasm, and eczematous dermatitis.
- Environmental allergen exposure in the presence of allergen-specific IgE.

General Considerations

Allergic rhinitis is very common in the United States, with a prevalence of 20–30% of adults and up to 40% of children. Allergic rhinitis adversely affects school and work performance, costing about $6 billion annually in the United States through direct costs of therapy as well as the indirect costs of sleep deprivation, fatigue and reduced productivity, or absenteeism. Seasonal allergic rhinitis is most commonly caused by pollens and spores. Flowering shrub and tree pollens are most common in the spring, flowering plants and grasses in the summer, and ragweed and molds in the fall. *Climate change may have an impact on the occurrence of allergic rhinitis* since increased temperature and carbon dioxide exposure cause increased pollen production in ragweed plants and since the extended duration of summer correlates with longer periods of pollen production in these and other flowering weeds. Dust, household mites, air pollution, and pet dander may produce year-round symptoms, termed "**perennial rhinitis**."

Clinical Findings

The symptoms of "hay fever" are similar to those of viral rhinitis but are usually persistent and may show seasonal variation. Nasal symptoms are often accompanied by eye irritation, pruritus, conjunctival erythema, and excessive tearing. Many patients have a strong family history of atopy or allergy.

The clinician should be careful to distinguish allergic rhinitis from other types of nonallergic rhinitis. **Vasomotor rhinitis** (sometimes called **senile rhinitis**) is caused by increased sensitivity of the vidian nerve and is a common cause of clear rhinorrhea in older adults. Often patients will report that they have troubling rhinorrhea in response to numerous nasal stimuli, including warm or cold air, odors or scents, light, or particulate matter. Other types of rhinitis, including gustatory, atrophic, and drug-induced rhinorrhea, have also been described.

On physical examination, the mucosa of the turbinates is usually pale or violaceous because of venous engorgement. This is in contrast to the erythema of viral rhinitis. Nasal polyps, which are yellowish boggy masses of hypertrophic mucosa, are associated with long-standing allergic rhinitis.

Treatment

A. Intranasal Corticosteroids

Intranasal corticosteroid sprays remain the mainstay of treatment of allergic rhinitis. They are more effective and frequently less expensive than nonsedating antihistamines, though patients should be reminded that there may be a delay in onset of relief of 2 or more weeks. Corticosteroid sprays may also shrink hypertrophic nasal mucosa and nasal polyps, thereby providing an improved nasal airway and ostiomeatal complex drainage. Because of this effect, intranasal corticosteroids are critical in treating allergy in patients prone to recurrent acute bacterial rhinosinusitis or chronic rhinosinusitis. Available preparations include beclomethasone (42 mcg/spray twice daily per nostril), flunisolide (25 mcg/spray twice daily per nostril), mometasone furoate (200 mcg once daily per nostril), budesonide (100 mcg twice daily per nostril), and fluticasone propionate (200 mcg once daily per nostril). All are considered equally effective. Probably the most critical factors are compliance with regular use and proper introduction into the nasal cavity. In order to deliver medication to the region of the middle meatus, proper application involves *holding the bottle straight up with the head tilted forward and pointing the bottle toward the ipsilateral ear when spraying.*

B. Antihistamines

Antihistamines offer temporary, but immediate, control of many of the most troubling symptoms of allergic rhinitis. Effective oral antihistamines include nonsedating loratadine (10 mg once daily), desloratadine (5 mg once daily), and fexofenadine (60 mg twice daily or 120 mg once daily), and minimally sedating cetirizine (10 mg once daily). Brompheniramine or chlorpheniramine (4 mg orally every 6–8 hours, or 8–12 mg orally every 8–12 hours as a sustained-release tablet) and clemastine (1.34–2.68 mg orally twice daily) may be less expensive but are usually associated with some drowsiness. The safety and efficacy of the newer, less-sedating antihistamines is so compelling that one of them, the H_1-receptor antagonist nasal spray azelastine (1–2 sprays per nostril daily), is included in the treatment guidelines of many consensus statements; however, some patients object to its bitter taste. Other side effects of oral antihistamines besides sedation include xerostomia and antihistamine tolerance (with eventual return of allergy symptoms despite initial benefit after several months of use). In such patients, typically those with perennial allergy, alternating effective antihistamines periodically can control symptoms over the long term. A nasal spray containing the corticosteroid mometasone (25 mcg) and the H_1-inhibitor olopatadine hydrochloride (665 mcg) (Ryaltris) is approved for seasonal allergic rhinitis (2 sprays in each nostril daily).

C. Adjunctive Treatment Measures

Antileukotriene medications, such as montelukast (10 mg/day orally), alone or with cetirizine (10 mg/day orally) or loratadine (10 mg/day orally), may improve nasal rhinorrhea, sneezing, and congestion. Cromolyn sodium and sodium nedocromil may be useful adjunct agents for allergic rhinitis. They work by stabilizing mast cells and preventing proinflammatory mediator release. As topical agents, they have very few side effects, but they must be initiated *well before* allergen exposure (up to 4 weeks before). The most useful form of cromolyn is probably the ophthalmologic preparation placed dropwise into the nasal cavity. Intranasal cromolyn is cleared rapidly and must be administered four times daily for continued symptom relief. In practice, it is not nearly as effective as inhaled corticosteroid.

Intranasal anticholinergic agents, such as ipratropium bromide 0.03% or 0.06% sprays (42–84 mcg per nostril three times daily), may be helpful adjuncts when rhinorrhea is a major symptom. They are not as effective for treating allergic rhinitis but are more useful for treating vasomotor rhinitis.

Avoiding or reducing exposure to airborne allergens is the most effective means of alleviating symptoms of allergic rhinitis. Depending on the allergen, this can be extremely difficult. Maintaining an allergen-free environment by covering pillows and mattresses with plastic covers, substituting synthetic materials (foam mattress, acrylics) for animal products (wool, horsehair), and removing dust-collecting household fixtures (carpets, drapes, bedspreads, wicker) is worth the attempt to help more troubled patients. Air purifiers and dust filters may also aid in maintaining an allergen-free environment. Nasal saline irrigations are a useful adjunct in the treatment of allergic rhinitis to mechanically flush the allergens from the nasal cavity. When symptoms are extremely bothersome, a search for offending allergens may prove helpful. This can either be done by serum radioallergosorbent test (RAST) testing or skin testing by an allergist.

In some cases, allergic rhinitis symptoms are inadequately relieved by medication and avoidance measures. Often, such patients have a strong family history of atopy and may also have lower respiratory manifestations, such as allergic asthma. Referral to an otolaryngologist or allergist for **immunotherapy** may be appropriate. Such treatment involves proper identification of offending allergens, progressively increasing doses of allergen(s), and eventual maintenance dose administration over a period of 3–5 years. Immunotherapy has been proven to reduce circulating IgE levels in patients with allergic rhinitis and reduce the need for allergy medications. Both subcutaneous and topical immunotherapy have been shown to be effective in the long-term treatment of refractory allergic rhinitis.

OLFACTORY DYSFUNCTION

ESSENTIALS OF DIAGNOSIS

- Subjective diminished smell or taste sensation.
- Lack of objective nasal obstruction.
- Objective decrease in olfaction demonstrated by testing.

General Considerations

Anatomic blockage of the nasal cavity with subsequent airflow disruption is the most common cause of olfactory dysfunction (hyposmia or anosmia). Polyps, septal deformities, and nasal tumors may be the cause. Due to localized inflammation, transient olfactory dysfunction often accompanies the common cold, nasal allergies, and perennial rhinitis through changes in the nasal and olfactory epithelium. About 20% of olfactory dysfunction is idiopathic, although it often follows a viral illness.

CNS neoplasms, especially those that involve the olfactory groove or temporal lobe, also may affect olfaction and should be considered in patients with no other explanation for their hyposmia. Head trauma is also a rare but severe cause of olfactory dysfunction due to shearing of the olfactory sensory cells. Head trauma accounts for < 5% of cases of hyposmia but is more commonly associated with anosmia than with hyposmia. Absent, diminished, or distorted smell has been reported in a wide variety of endocrine, nutritional, and nervous disorders.

Clinical Findings

Evaluation of olfactory dysfunction should include a thorough history of systemic illnesses and medication use as well as a physical examination focusing on the nose and nervous system. Nasal obstruction (from polyps, trauma, foreign bodies, or nasal masses) can cause functional hyposmia. Most clinical offices are not set up to test olfaction, but such tests may at times be worthwhile if only to assess whether a patient possesses any sense of smell at all.

Treatment

Olfactory dysfunction secondary to nasal polyposis, obstruction, and chronic rhinosinusitis may respond to surgically removing the anatomic blockage, as with endoscopic sinus surgery. Unfortunately, there is no specific treatment for primary disruption of olfaction; some disturbances spontaneously resolve. The degree of olfactory dysfunction is the greatest predictor of recovery, with less severe olfactory dysfunction recovering at a much higher rate. In permanent olfactory dysfunction, counseling should be offered about seasoning foods (such as using pepper that stimulates the trigeminal as well as olfactory chemoreceptors, rather than table salt) and safety issues (such as installing home smoke alarms and using electric rather than gas appliances).

EPISTAXIS

ESSENTIALS OF DIAGNOSIS

- Bleeding from a unilateral anterior nasal cavity along the septum is most common.
- Most cases may be successfully treated by direct pressure on the bleeding site for 15 minutes. When this is inadequate, topical sympathomimetics and various nasal tamponade methods are usually effective.
- Posterior, bilateral, or large-volume epistaxis should be triaged immediately to a specialist in a critical care setting.

General Considerations

Epistaxis is an extremely common problem in the primary care setting. Bleeding is most common in the anterior septum where a confluence of veins creates a superficial venous plexus (**Kiesselbach plexus**). Predisposing factors include nasal trauma (nose picking, foreign bodies, forceful nose blowing), rhinitis, nasal mucosal drying from low humidity or supplemental nasal oxygen, deviation of the nasal septum, atherosclerotic disease, hereditary hemorrhagic telangiectasia (**Osler-Weber-Rendu syndrome**), inhaled nasal cocaine (or other drugs), and alcohol abuse. Poorly controlled hypertension is associated with epistaxis. Anticoagulation or antiplatelet medications may be associated with a higher incidence, more frequent recurrence, and greater difficulty in control of epistaxis, but they do not cause it.

Clinical Findings

Laboratory assessment of bleeding parameters may be indicated, especially in recurrent epistaxis. Once the acute episode has passed, careful examination of the nose and paranasal sinuses is indicated to rule out neoplasia and hereditary hemorrhagic telangiectasia. Repeated evaluation for diagnosis and treatment of clinically significant hypertension should be performed following control of epistaxis and removal of any packing.

Treatment

Most cases of anterior epistaxis may be successfully treated by direct pressure on the site by compression of the nares continuously for 15 minutes. Venous pressure is reduced in the sitting position, and slight leaning forward. Positioning the head backwards is not recommended because this may result in blood going toward the airway, resulting in possible aspiration. Similarly, pinching the bridge of the nose is generally ineffective as the origin of bleeding typically occurs at the tip. Short-acting topical nasal decongestants (eg, phenylephrine, 0.125–1% solution, one or two sprays or oxymetazoline), which act as vasoconstrictors, may also help. When the bleeding does not readily subside, the nose should be examined, using good illumination and suction, in an attempt to locate the bleeding site. When directly visible, the bleeding site may be cauterized with silver nitrate, diathermy, or electrocautery. A supplemental patch of Surgicel or Gelfoam may be helpful with a moisture barrier, such as petroleum-based ointment, to prevent drying and crusting.

Occasionally, a site of bleeding may be inaccessible to direct control, or attempts at direct control may be unsuccessful. In such cases, there are a number of alternatives. When the site of bleeding is anterior, a hemostatic sealant, pneumatic or other nasal tamponade, or anterior packing may suffice as the latter may be accomplished with several feet of lubricated iodoform packing systematically placed in the floor of the nose and then the vault of the nose.

About 5% of nasal bleeding originates in the posterior nasal cavity, commonly associated with atherosclerotic disease and hypertension. In such cases, it may be necessary to consult an otolaryngologist for a pack to occlude the choana before placing a pack anteriorly. In emergency settings, double balloon packs (Epistat) may facilitate rapid control of bleeding with little or no mucosal trauma. Because such packing is uncomfortable, bleeding may persist, and vasovagal syncope is possible, hospitalization for monitoring and stabilization is indicated. Posterior nasal packing is quite uncomfortable and may require an opioid analgesic for pain control.

Surgical management of epistaxis, through ligation of the nasal arterial supply (internal maxillary artery and ethmoid arteries) is indicated when direct pressure and nasal packing fail. The most common approach to surgical treatment is endoscopic sphenopalatine artery ligation. This method has a reported efficacy of 73–100% in studies; however, it may miss bleeds caused by the ethmoid arterial supply. Alternatively, endovascular epistaxis control is highly effective (75–92%) and can address all sources of intranasal bleeding except those from the anterior ethmoid artery. Its use may be reserved for when a surgical approach fails because it is associated with a 1.1–1.5% risk of stroke.

After control of epistaxis, the patient is advised to avoid straining and vigorous exercise for several days. Nasal saline should be applied to the packing frequently to keep the packing moist. Avoidance of hot or spicy foods and tobacco is also advisable, since these may cause nasal vasodilation. Avoiding nasal trauma, including nose picking, is an obvious necessity. Lubrication with petroleum jelly or bacitracin ointment and increased home humidity may also be useful ancillary measures. Finally, antistaphylococcal antibiotics (eg, cephalexin, 500 mg orally four times daily, or clindamycin, 150 mg orally four times daily) generally are indicated to reduce the risk of toxic shock syndrome developing while the packing remains in place (at least 5 days).

When to Refer

- Patients with recurrent epistaxis, large-volume epistaxis, and episodic epistaxis with associated nasal obstruction should be referred to an otolaryngologist for endoscopic evaluation and possible imaging.
- Those with ongoing bleeding beyond 15 minutes should be taken to a local emergency department if the clinician is not prepared to manage acute epistaxis.

NASAL TRAUMA

The nasal pyramid is the most frequently fractured bone in the body. Fracture is suggested by crepitance or palpably mobile bony segments. Epistaxis and pain are common, as are soft-tissue hematomas ("black eye"). It is important to make certain that there is no palpable step-off of the infraorbital rim, which would indicate the presence of a zygomatic complex fracture. Radiologic confirmation may at times be helpful but is not necessary in uncomplicated nasal fractures. It is also important to assess for possible concomitant additional facial, spine, pulmonary, or intracranial injuries when the circumstances of injury are suggestive, as in the case of automobile and motorcycle accidents.

Treatment is aimed at maintaining long-term nasal airway patency and cosmesis. Closed reduction can be performed under local or general anesthesia; closed reduction under general anesthesia appears to afford better patient satisfaction and decreased need for subsequent revision septoplasty or rhinoplasty.

Intranasal examination should be performed in all cases to rule out septal hematoma, which appears as a widening of the anterior septum, visible just posterior to the columella. The septal cartilage receives its only nutrition from its closely adherent mucoperichondrium. An untreated subperichondrial hematoma will result in loss of the nasal cartilage with resultant saddle nose deformity, septal perforation, or both. Septal hematomas may become infected, with *S aureus* most commonly, and should be drained with an incision in the inferior mucoperichondrium on both sides. The drained fluid should be sent for culture.

Packing for 2–5 days is often helpful to help prevent reformation of the hematoma. Antibiotics with antistaphylococcal efficacy (eg, cephalexin, 500 mg four times daily, or clindamycin, 150 mg four times daily) should be given for 3–5 days or the duration of the packing to reduce the risk of toxic shock syndrome.

TUMORS & GRANULOMATOUS DISEASE

1. Benign Nasal Tumors

A. Nasal Polyps

Nasal polyps are pale, edematous, mucosally covered masses commonly seen in patients with allergic rhinitis. They may result in chronic nasal obstruction and a diminished sense of smell. In patients with nasal polyps and a history of asthma, aspirin should be avoided because it may precipitate a severe episode of bronchospasm, known as **triad asthma** (Samter triad). Such patients may have an immunologic salicylate sensitivity.

Use of topical intranasal corticosteroids improves the quality of life in patients with nasal polyposis and chronic rhinosinusitis. Initial treatment with topical nasal corticosteroids (see Allergic Rhinitis section for specific medications) for 1–3 months is usually successful for small polyps and may reduce the need for operation. A short course of oral corticosteroids (eg, prednisone, 6-day course using 21 [5 mg] tablets: 6 tablets [30 mg] on day 1 and tapering by 1 tablet [5 mg] each day) may also be of benefit, but when polyps are massive or medical management is unsuccessful obstructing polyps may be removed surgically. Polyps may readily be removed using endoscopic sinus surgery techniques. It may be necessary to remove polyps from the ethmoid, sphenoid, and maxillary sinuses to provide longer-lasting relief and open the affected sinuses. Intranasal corticosteroids should be continued following polyp removal to prevent recurrence, and the clinician should consider allergen testing to determine the offending allergen and avoidance measures. There are emerging treatments using biologics, such as dupilumab, for treatment of chronic rhinosinusitis with polyps.

B. Inverted Papillomas

Inverted papillomas are benign tumors caused by HPV that usually arise on the lateral nasal wall. They present with unilateral nasal obstruction and occasionally hemorrhage. They are often easily seen on anterior rhinoscopy as cauliflower-like growths in or around the middle meatus. *Because squamous cell carcinoma is seen in about 10% of inverted or schneiderian papillomas, complete excision is strongly recommended.* This usually requires an endoscopic medial maxillectomy. While rare, very extensive disease may require an open inferior or total maxillectomy for complete removal. Because recurrence rates for inverted papillomas are reported to be as high as 20%, subsequent clinical and radiologic follow-up is imperative. All excised tissue (not just a portion) should be carefully reviewed by the pathologist to be sure no carcinoma is present.

2. Malignant Nasopharyngeal & Paranasal Sinus Tumors

Though rare, malignant tumors of the nose, nasopharynx, and paranasal sinuses are quite problematic because they tend to remain asymptomatic until late in their course. *Squamous cell carcinoma is the most common cancer found in the sinuses and nasopharynx.* It is especially common in the nasopharynx, where it obstructs the eustachian tube and results in serous otitis media. Nasopharyngeal carcinoma (nonkeratinizing squamous cell carcinoma or lymphoepithelioma) is usually associated with elevated IgA antibody to the viral capsid antigen of the Epstein-Barr virus (EBV). It is particularly common in patients of southern Chinese descent and has a weaker association with tobacco exposure than other head and neck squamous cell carcinomas. Adenocarcinomas, mucosal melanomas, sarcomas, and non-Hodgkin lymphomas are less commonly encountered neoplasms of this area.

Early symptoms are nonspecific, mimicking those of rhinitis or sinusitis. Unilateral nasal obstruction, otitis media, and discharge are common, with pain and recurrent hemorrhage often clues to the diagnosis of cancer. *All adults with persistent unilateral nasal symptoms or new otitis media should be thoroughly evaluated with nasal endoscopy and nasopharyngoscopy.* A high index of suspicion remains a key to early diagnosis of these tumors. Patients often present with advanced symptoms, such as proptosis, expansion of a cheek, or ill-fitting maxillary dentures. Malar hypesthesia, due to involvement of the infraorbital nerve, is common in maxillary sinus tumors. Biopsy is necessary for definitive diagnosis, and MRI is the best imaging study to delineate the extent of disease and plan appropriate surgery and radiation.

Treatment depends on the tumor type and the extent of disease. Early-stage disease may be treated with radiation therapy alone, but advanced nasopharyngeal carcinoma is best treated with concurrent radiation and chemotherapy. Chemoradiation therapy significantly decreases local, nodal, and distant failures and increases progression-free and overall survival in advanced disease. Locally recurrent nasopharyngeal carcinoma in selected cases may be treated with repeat irradiation protocols or surgery with moderate success and a high degree of concern about local wound healing. Other squamous cell carcinomas are best treated—when resectable—with a combination of surgery and irradiation. Cranial base surgery, which can be done endoscopically using image navigation, appears to be an effective modality in improving the overall prognosis in paranasal sinus malignancies eroding the ethmoid roof. Although the prognosis is poor for advanced tumors, the results of treating resectable tumors of paranasal sinus origin have improved with the wider use of skull base resections and intensity-modulated radiation therapy. Cure rates are often 45–60%.

3. Sinonasal Inflammatory Disease (Granulomatosis with Polyangiitis & Sarcoidosis)

The nose and paranasal sinuses are involved in over 90% of cases of **granulomatosis with polyangiitis**. It is often not realized that involvement at these sites is *more common* than involvement of lungs or kidneys. Examination shows blood-stained crusts and friable mucosa. Biopsy, when positive, shows necrotizing granulomas and vasculitis. Other recognized sites of granulomatosis with polyangiitis in the head and neck include the subglottis and the middle ear. For treatment of granulomatosis with polyangiitis, see Chapter 23.

Sarcoidosis commonly involves the paranasal sinuses and is clinically similar to other chronic sinonasal inflammatory processes. Sinonasal symptoms, including rhinorrhea, nasal obstruction, and hyposmia or anosmia, may precede diagnosis of sarcoidosis in other organ systems. Clinically, the turbinates appear engorged with small white granulomas. Biopsy shows classic noncaseating granulomas. Notably, patients with sinonasal involvement generally have more trouble managing sarcoidosis in other organ systems.

Polymorphic reticulosis (midline malignant reticulosis, idiopathic midline destructive disease, lethal midline granuloma)—as the multitude of apt descriptive terms suggests—is not well understood but appears to be a nasal T-cell or NK-cell lymphoma. In contrast to granulomatosis with polyangiitis, involvement is limited to the mid-face, and there may be extensive bone destruction. Many destructive lesions of the mucosa and nasal structures labeled as polymorphic reticulosis are in fact non-Hodgkin lymphoma of either NK-cell or T-cell origin. Immunophenotyping, especially for CD56 expression, is essential in the histologic evaluation. Even when apparently localized, these lymphomas have a poor prognosis, with progression and death within a year the rule.

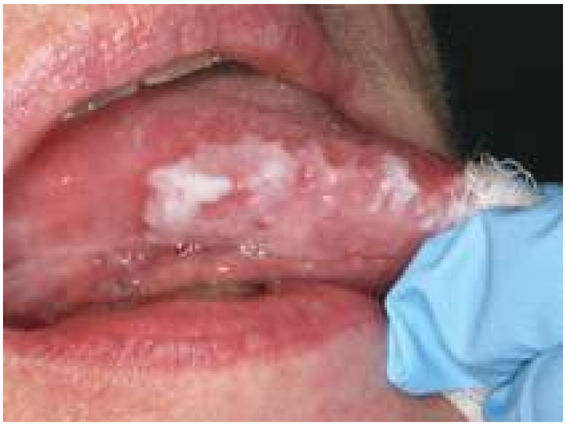
DISEASES OF THE ORAL CAVITY & PHARYNX

LEUKOPLAKIA, ERYTHROPLAKIA, LICHEN PLANUS, & OROPHARYNGEAL CANCER

ESSENTIALS OF DIAGNOSIS

- **Leukoplakia:** A white plaque-like lesion that cannot be removed by rubbing the mucosal surface.
- **Erythroplakia:** Similar to leukoplakia except that it has a definite erythematous component.
- **Oral lichen planus:** Most commonly presents as lacy leukoplakia but may be erosive; definitive diagnosis requires biopsy.
- **Oral cancer:** Early lesions appear as leukoplakia or erythroplakia; more advanced lesions will be larger, painful, and can involve the tongue, gums, hard palate, inner lining of the lips or cheek. Ulceration may be present.
- **Oropharyngeal cancer:** Masses arising from the throat (tonsils, base of tongue, soft palate, or pharyngeal wall) typically presenting with painful swallowing, persistent ear pain, and weight loss.



▲ **Figure 8–5.** Leukoplakia with moderate dysplasia on the lateral border of the tongue. (Used, with permission, from Ellen Eisenberg, DMD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine,* 2nd ed. McGraw-Hill, 2013.)

Leukoplakic regions range from small to several centimeters in diameter (Figure 8–5). Histologically, they are often hyperkeratoses occurring in response to chronic irritation (eg, from dentures, tobacco, lichen planus); about 2–6%, however, represent either dysplasia or early invasive squamous cell carcinoma. *Distinguishing between **leukoplakia** and **erythroplakia** is important because about 90% of cases of erythroplakia are either dysplasia or carcinoma.* **Squamous cell carcinoma** accounts for 90% of oral cancer. Alcohol and tobacco use are the major epidemiologic risk factors.

The differential diagnosis may include oral candidiasis, necrotizing sialometaplasia, pseudoepitheliomatous hyperplasia, median rhomboid glossitis, and vesiculoerosive inflammatory disease, such as erosive lichen planus. This should not be confused with the brown-black gingival melanin pigmentation—diffuse or speckled—common in non-White persons, blue-black embedded fragments of dental amalgam, or other systemic disorders associated with general pigmentation (neurofibromatosis, familial polyposis, Addison disease). Intraoral melanoma is extremely rare and carries a dismal prognosis.

Any area of erythroplakia, enlarging area of leukoplakia, or a lesion that has submucosal depth on palpation or irregular appearance associated with pain or other symptoms should have an incisional biopsy. Ulcerative lesions are particularly suspicious and worrisome. Specialty referral should be sought early both for diagnosis and treatment. A systematic intraoral examination—including the lateral tongue, floor of the mouth, gingiva, buccal area, palate, and tonsillar fossae—and palpation of the neck for enlarged lymph nodes should be part of any general physical examination. Patients with current or former tobacco use or moderate alcohol drinking history are at higher risk of malignancy. Indirect or fiberoptic examination of the nasopharynx, oropharynx, hypopharynx, and larynx by an otolaryngologist, head and neck surgeon should be considered for such patients when there is unexplained or persistent throat or ear pain, oral or nasal bleeding, or oral erythroplakia. Fine-needle aspiration (FNA) biopsy may expedite the diagnosis if an enlarged lymph node is found.

To date, there remain no approved therapies for reversing or stabilizing leukoplakia or erythroplakia. The mainstays of management are surveillance following elimination of carcinogenic irritants (eg, smoking tobacco, chewing tobacco or betel nut, drinking alcohol) along with serial biopsies and excisions.

Oral lichen planus is a relatively common (0.5–2% of the population) chronic inflammatory autoimmune disease that may be difficult to diagnose clinically because of its numerous distinct phenotypic subtypes. For example, the reticular pattern may mimic candidiasis or hyperkeratosis, while the erosive pattern may mimic squamous cell carcinoma. Management begins with distinguishing it from other oral lesions. Exfoliative cytology or a small incisional or excisional biopsy is indicated, especially if squamous cell carcinoma is suspected. Therapy of lichen planus is aimed at managing pain and discomfort. Daily topical corticosteroid remains the most effective treatment for symptomatic lichen planus, but cyclosporine, retinoids, and tacrolimus have also been used. Many experts think there is a low rate (1%) of squamous cell carcinoma arising within lichen planus (in addition to the possibility of clinical misdiagnosis) and prevention of malignant transformation remains a goal of treatment.

Hairy leukoplakia occurs on the lateral border of the tongue and is a common early finding in HIV infection (see Chapter 36). It often develops quickly and appears as slightly raised leukoplakic areas with a corrugated or "hairy" surface (Figure 8–6). While much more prevalent in patients with HIV, hairy leukoplakia can occur following solid organ transplantation and is associated with EBV infection and long-term systemic corticosteroid use. Hairy leukoplakia waxes and wanes over time with generally modest irritative symptoms. Acyclovir, valacyclovir, and famciclovir have all been used for treatment but produce only temporary resolution of the condition. It does not appear to predispose to malignant transformation.

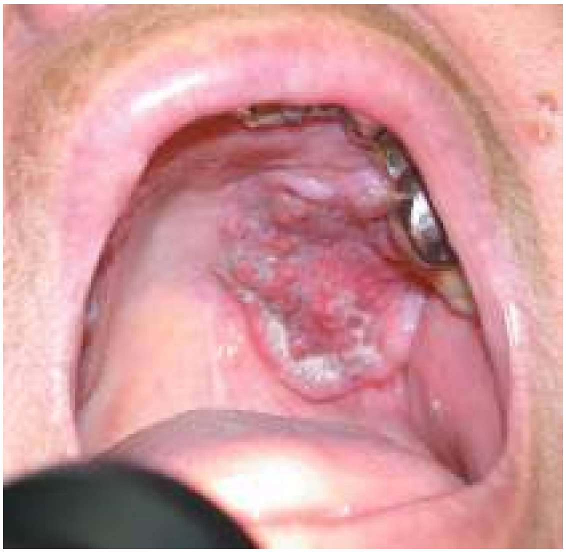

Figure 8–7. Squamous cell carcinoma of the palate. (Used, with permission, from Frank Miller, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine,* 2nd ed. McGraw-Hill, 2013.)

Oral cavity squamous cell carcinoma can be hard to distinguish from other oral lesions, but early detection is the key to successful management (Figure 8–7). Raised, firm, ulcerative lesions are highly suspicious and generally quite painful on even gentle palpation. Lesions < 3 mm in depth have a low propensity to metastasize. Most patients in whom the tumor is detected before it is 2 cm in diameter are cured by local resection. Radiation is reserved for patients with metastatic disease or tumors with adverse features, and chemotherapy is added if there are positive margins or if involved lymph nodes have extranodal extension. Large tumors are usually treated with a combination of resection, removal of lymph nodes from the neck (neck dissection), and external beam radiation. Reconstruction, if required, is done at the time of resection and can involve the use of myocutaneous flaps or vascularized free tissue transfer with or without bone. Novel fluorescence-guided surgeries are being developed to improve detection of margins and decrease recurrence.

Oropharyngeal squamous cell carcinoma generally presents later than oral cavity squamous cell carcinoma. The lesions tend to be larger and are often buried within the lymphoid tissue of the palatine or lingual tonsils. Most patients note only unilateral odynophagia and weight loss, but ipsilateral cervical lymphadenopathy is often identified by the careful clinician. While these tumors are typically associated with known carcinogens such as tobacco and alcohol, their epidemiology has changed dramatically over the past 25 years. Despite demonstrated reductions in tobacco and alcohol use within developed nations, the incidence of oropharyngeal squamous cell carcinoma has increased over this period. Known as a possible cause of head and neck cancer since 1983, *HPV—most commonly, type 16/18—is believed to be the cause of up to 70% of all oropharyngeal squamous cell carcinoma.* HPV-positive tumors are readily distinguished by immunostaining of primary tumor or FNA biopsy specimens for the p16 protein, a tumor suppressor protein that is highly correlated with the presence of HPV. These tumors often present in advanced stages of the disease with regional cervical lymph node metastases (stages III and IV) but have a better prognosis than similarly staged lesions in tobacco and alcohol users. This difference in disease control is so apparent in multicenter studies that, based on the presence or absence of the p16 protein, two distinct staging systems for oropharyngeal squamous cell carcinoma were introduced in 2018.

ORAL CANDIDIASIS

ESSENTIALS OF DIAGNOSIS

- Fluctuating throat or mouth discomfort.
- Associated with systemic or local immunosuppression, such as recent corticosteroid, chemotherapy, or antibiotic use.
- Erythema of the oral cavity or oropharynx with creamy-white, curd-like patches.
- Rapid resolution of symptoms with appropriate treatment.

Clinical Findings

A. Symptoms and Signs

Oral candidiasis (**thrush**) is usually painful and looks like creamy-white curd-like patches overlying erythematous mucosa (see Figure 6–11). Because these *white areas are easily rubbed off* (eg, by a tongue depressor)—unlike leukoplakia or lichen planus—only the underlying irregular erythema may be seen. Oral candidiasis is commonly associated with the following risk factors: (1) use of dentures, (2) debilitated state with poor oral hygiene, (3) diabetes mellitus, (4) anemia, (5) chemotherapy or local irradiation, (6) corticosteroid use (oral or systemic), or (7) broad-spectrum antibiotics. Another manifestation of candidiasis is **angular cheilitis** (also seen in nutritional deficiencies) (Figure 8–8).

B. Diagnostic Studies

The diagnosis is made clinically. A wet preparation using potassium hydroxide will reveal spores and may show nonseptate mycelia. Biopsy will show intraepithelial pseudomycelia of *Candida albicans*.

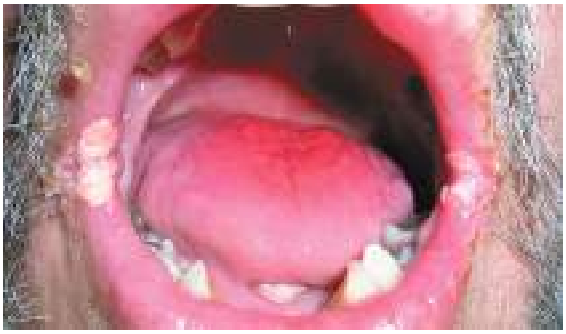

Figure 8–8. Severe angular cheilitis in a man with HIV with oral thrush. (Reproduced with permission from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine,* 2nd ed. McGraw-Hill, 2013.)

Candidiasis is often the first manifestation of HIV infection, and HIV testing should be considered in patients with no known predisposing cause for *Candida* overgrowth (see also Chapter 36). The US Department of Health Services Clinical Practice Guideline for Evaluation and Management of Early HIV Infection recommends examination of the oral mucosa with each clinician visit as well as at a dental examination every 6 months for individuals living with HIV.

Treatment

Effective antifungal therapy may be achieved with any of the following: fluconazole (100 mg orally daily for 7 days), ketoconazole (200–400 mg orally with breakfast [requires acidic gastric environment for absorption] for 7–14 days), clotrimazole troches (10 mg dissolved orally five times daily), or nystatin mouth rinses (500,000 units [5 mL of 100,000 units/mL] held in the mouth before swallowing three times daily). In patients with HIV infection, however, longer courses of therapy with fluconazole may be needed, and oral itraconazole (200 mg/day) may be indicated in fluconazole-refractory cases. Many of the *Candida* species in these patients are resistant to first-line azoles and may require newer medications, such as voriconazole. In addition, 0.12% chlorhexidine or half-strength hydrogen peroxide mouth rinses may provide local relief. Nystatin powder (100,000 units/g) applied to dentures three or four times daily and rinsed off for several weeks may help denture wearers.

GLOSSITIS, GLOSSODYNIA, & BURNING MOUTH SYNDROME

Inflammation of the tongue with loss of filiform papillae leads to a red, smooth-surfaced tongue (**glossitis**). Rarely painful, it may be secondary to nutritional deficiencies (eg, niacin, riboflavin, iron, or vitamin E), drug reactions, dehydration, irritants, or foods and liquids, and possibly to autoimmune reactions or psoriasis. If the primary cause cannot be identified and corrected, empiric nutritional replacement therapy may be of value.

Glossodynia is burning and pain of the tongue, which may occur with or without glossitis. In the absence of any clinical findings, it has been termed **"burning mouth syndrome."** Glossodynia with glossitis has been associated with diabetes mellitus, medications (eg, diuretics), tobacco, xerostomia, and candidiasis as well as the listed causes of glossitis. The burning mouth syndrome typically has no identifiable associated risk factors and seems to be most common in postmenopausal women. Treating possible underlying causes, changing long-term medications to alternative ones, and smoking cessation may resolve symptoms of glossitis. Effective treatments for the burning mouth syndrome include α-lipoic acid and clonazepam. Clonazepam is most effective as a rapid-dissolving tablet placed on the tongue in doses from 0.25 mg to 0.5 mg every 8–12 hours. Both glossodynia and the burning mouth syndrome are benign, and reassurance that there is no infection or tumor is likely to be appreciated. Unilateral symptoms, symptoms that cannot be related to a specific medication, and symptoms and signs involving regions supplied by other cranial nerves all may suggest neuropathology, and imaging of the brain, brainstem, and skull base with MRI should be considered.

INTRAORAL ULCERATIVE LESIONS

1. Necrotizing Ulcerative Gingivitis (Trench Mouth, Vincent Angina)

Necrotizing ulcerative gingivitis, often caused by an infection with both spirochetes and fusiform bacilli, is common in young adults under stress (classically in students at examination time). Underlying systemic diseases may also predispose to this disorder. Clinically, there is painful acute gingival inflammation and necrosis, often with bleeding, halitosis, fever, and cervical lymphadenopathy. Warm half-strength peroxide rinses and oral penicillin (250 mg three times daily for 10 days) may help. Dental gingival curettage may prove necessary.

Schroeder FMM et al. Clinical and immunological features of chronic ulcerative stomatitis: a systematic review. J Oral Pathol Med. 2022;51:501. [PMID: 35092104]

2. Aphthous Ulcer (Canker Sore, Ulcerative Stomatitis)

Aphthous ulcers are very common and easy to recognize. Their cause remains uncertain, although an association with human herpesvirus 6 has been suggested. Found on freely moving, nonkeratinized mucosa (eg, buccal and labial mucosa and not attached gingiva or palate), they may be single or multiple, are usually recurrent, and appear as painful small round ulcerations with yellow-gray fibrinoid centers surrounded by red halos. Minor aphthous ulcers are < 1 cm in diameter and generally heal in 10–14 days. Major aphthous ulcers are > 1 cm in diameter and can be disabling due to the degree of associated oral pain. Stress seems to be a major predisposing factor to the eruptions of aphthous ulcers.

Treatment is challenging because no single systemic treatment has proven effective. Avoiding local irritants, such as certain toothpastes, may decrease symptoms and episodes. Topical corticosteroids (triamcinolone acetonide, 0.1%, or fluocinonide ointment, 0.05%) in an adhesive base (Orabase Plain) do appear to provide symptomatic relief in many patients. Other topical therapies shown to be effective in controlled studies include diclofenac 3% in hyaluronan 2.5%, doxymycine-cyanoacrylate, mouthwashes containing the enzymes amyloglucosidase and glucose oxidase, and amlexanox 5% oral paste. A 1-week tapering course of prednisone (40–60 mg/day) has also been used successfully. Cimetidine maintenance therapy may be useful in patients with recurrent aphthous ulcers. Thalidomide has been used selectively in recurrent aphthous ulcerations in patients with HIV.

Large or persistent areas of ulcerative stomatitis may be secondary to erythema multiforme or drug allergies, acute herpes simplex, pemphigus, pemphigoid, epidermolysis bullosa acquisita, bullous lichen planus, Behçet disease, or IBD. Squamous cell carcinoma may occasionally present in this fashion. When the diagnosis is not clear, incisional biopsy is indicated.

Philipone EM et al. Ulcerative and inflammatory lesions of the oral mucosa. Oral Maxillofac Surg Clin North Am. 2023;35:219. [PMID: 36805903]

3. Herpes Stomatitis

Herpes gingivostomatitis is common, mild, and short-lived. Clinically, there is initial burning, followed by typical small vesicles that rupture and form scabs. Lesions are most commonly found on the attached gingiva and mucocutaneous junction of the lip, but lesions can also form on the tongue, buccal mucosa, and soft palate. In most adults, it requires no intervention. In immunocompromised persons, however, reactivation of herpes simplex virus infection is frequent and may be severe. Acyclovir (200–800 mg orally five times daily for 7–10 days) or valacyclovir (1000 mg orally twice daily for 7–10 days) may shorten the course and reduce postherpetic pain. *These treatments may be effective only when started within 24–48 hours of the onset of initial symptoms (pain, itching, burning) and are not effective once vesicles have erupted.* Differential diagnosis includes aphthous stomatitis, erythema multiforme, syphilitic chancre, and carcinoma.

PHARYNGITIS & TONSILLITIS

ESSENTIALS OF DIAGNOSIS

- Centor criteria for streptococcal pharyngitis: exudate or swelling on tonsils, anterior cervical adenopathy, fever, lack of cough.
- Goal is to treat group A β-hemolytic streptococcal infection to prevent subsequent rheumatic fever (rash, arthralgias, myocarditis) and other sequelae (glomerulonephritis, posterior pharyngeal abscess).

General Considerations

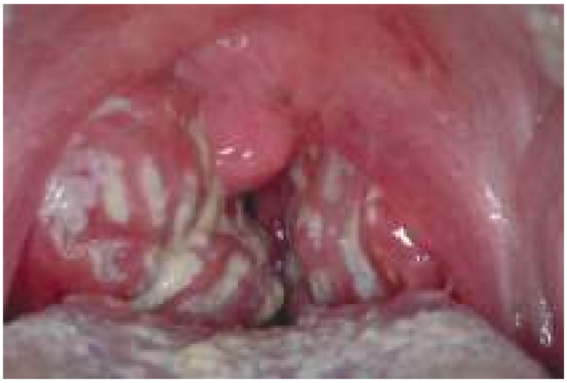
Pharyngitis and tonsillitis account for over 10% of all office visits to primary care clinicians and 50% of outpatient antibiotic use. The main concern is determining who is likely to have a **group A β-hemolytic streptococcal (GABHS) infection**, since this can lead to subsequent complications, such as rheumatic fever and glomerulonephritis. A second public health policy concern is reducing the extraordinary cost (both in dollars and in the development of antibiotic-resistant *S pneumoniae*) associated with unnecessary antibiotic use.

Clinical Findings

A. Symptoms and Signs

The clinical features most suggestive of GABHS pharyngitis include fever over 38°C, tender anterior cervical adenopathy, lack of a cough, and pharyngotonsillar exudate (Figure 8–9). These four features (**the Centor criteria**), when present, strongly suggest GABHS. When two or three of the four are present, there is an intermediate likelihood of GABHS. When only one criterion is present, GABHS is unlikely. Sore throat may be severe, with odynophagia, tender adenopathy, and a scarlatiniform rash. An elevated white count and left shift are also possible. Hoarseness, cough, and coryza are not suggestive of this disease. It is also rare to have GABHS in individuals younger than 3 years old.

Marked lymphadenopathy and a shaggy, white-purple tonsillar exudate, often extending into the nasopharynx, suggest mononucleosis, especially if present in a young adult. With about 90% sensitivity, lymphocyte-to-white-blood-cell ratios of > 35% suggest EBV infection and not tonsillitis. Hepatosplenomegaly and a positive heterophile



▲ **Figure 8–9.** Marked exudative pharyngitis and tonsillitis due to group A β-hemolytic streptococci. (Used, with permission, from Lawrence B. Stack, MD, in Knoop KJ, Stack LB, Storrow AB, Thurman RJ. *The Atlas of Emergency Medicine,* 5th ed. McGraw Hill, 2021.)

agglutination test or elevated anti-EBV titer are corroborative. However, about one-third of patients with infectious mononucleosis have secondary streptococcal tonsillitis, requiring treatment. *Ampicillin should routinely be avoided if mononucleosis is suspected* because it induces a rash that might be misinterpreted by the patient as a penicillin allergy. Diphtheria (extremely rare but described in persons with alcohol use disorder) presents with low-grade fever and an ill patient with a gray tonsillar pseudomembrane.

The most common pathogens other than GABHS in the differential diagnosis of "sore throat" are viruses, *Neisseria gonorrhoeae, Mycoplasma*, and *Chlamydia trachomatis*. Rhinorrhea and lack of exudate would suggest a virus, but in practice it is not possible to confidently distinguish viral upper respiratory infection from GABHS on clinical grounds alone. Infections with *Corynebacterium diphtheria*, anaerobic streptococci, and *Corynebacterium haemolyticum* (which responds better to erythromycin than penicillin) may also mimic pharyngitis due to GABHS. See also Chapter 38 for bacterial considerations.

B. Laboratory Findings

A single-swab throat culture is 90–95% sensitive and the **rapid antigen detection testing (RADT)** is 90–99% sensitive for GABHS. Results from the RADT are available in about 15 minutes. Routine throat culture in refractory cases may also be helpful to guide antibiotic selection or identify fewer common microbes associated with chronic infection.

▶ Treatment

The Infectious Diseases Society of America recommends laboratory confirmation of the clinical diagnosis by means of either throat culture or RADT of the throat swab. The American College of Physicians–American Society of Internal Medicine (ACP-ASIM), in collaboration with the CDC, advocates use of a clinical algorithm alone—in lieu of microbiologic testing—for confirmation of the diagnosis in adults for whom the suspicion of streptococcal infection is high. Others examine the assumptions of the ACP-ASIM guideline for using a clinical algorithm alone and question whether those recommendations will achieve the stated objective of dramatically decreasing excess antibiotic use. A reasonable strategy to follow is that patients with zero or one Centor criterion are at very low risk for GABHS and therefore do not need throat cultures or RADT of the throat swab and should not receive antibiotics. Patients with two or three Centor criteria need throat cultures or RADT of the throat swab, since positive results would warrant antibiotic treatment. Patients who have all four Centor criteria are likely to have GABHS and can receive empiric therapy without throat culture or RADT.

Oral antibiotics are the preferred first-line therapy. Penicillin V potassium (250 mg orally three times daily or 500 mg twice daily for 10 days) and cefuroxime axetil (250 mg orally twice daily for 5–10 days) are both effective. The efficacy of a 5-day regimen of penicillin V potassium appears to be similar to that of a 10-day course, with a 94% clinical response rate and an 84% streptococcal eradication rate. Erythromycin (also active against *Mycoplasma* and *Chlamydia*) is a reasonable alternative to penicillin in allergic patients. Cephalosporins are somewhat more effective than penicillin in producing bacteriologic cures; 5-day courses of cefpodoxime and cefuroxime have been successful. The macrolide antibiotics have also been reported to be successful in shorter-duration regimens. Azithromycin (500 mg once daily), because of its long half-life, needs to be taken for only 3 days. For patients in whom adherence to medication is in question, or those unable to take oral medication, a single intramuscular injection of benzathine penicillin or procaine penicillin, 1.2 million units is an effective alternative.

Adequate antibiotic treatment usually avoids the streptococcal complications of scarlet fever, rheumatic myocarditis, glomerulonephritis, and local abscess formation.

Antibiotics for treatment failures are also somewhat controversial. Surprisingly, penicillin-tolerant strains are not isolated more frequently in those who fail treatment than in those treated successfully with penicillin. The reasons for failure appear to be complex, and a second course of treatment with the same medication is reasonable. Alternatives to penicillin include cefuroxime and other cephalosporins, dicloxacillin (which is β-lactamase–resistant), and amoxicillin with clavulanate. When there is a history of penicillin allergy, alternatives should be used, such as erythromycin. Erythromycin resistance—with failure rates of about 25%—is an increasing problem in many areas. In cases of severe penicillin allergy, cephalosporins should be avoided since cross-reaction occurs in > 8% of cases.

Ancillary treatment of pharyngitis includes analgesics and anti-inflammatory agents, such as aspirin, acetaminophen, and corticosteroids. In meta-analysis, corticosteroids increased the likelihood of complete pain resolution at 24 hours by threefold without an increase in recurrence or adverse events. Some patients find that salt water gargling is soothing. In severe cases, anesthetic gargles and lozenges (eg, benzocaine) may provide additional symptomatic relief. Occasionally, odynophagia is so intense that hospitalization for intravenous hydration and antibiotics is necessary. (See Chapter 38.)

Patients who have had rheumatic fever should be treated with a continuous course of antimicrobial prophylaxis (penicillin G, 500 mg once daily orally, or erythromycin, 250 mg twice daily orally) for at least 5 years.

PERITONSILLAR ABSCESS & CELLULITIS

When infection penetrates the tonsillar capsule and involves the surrounding tissues, peritonsillar cellulitis results. Following therapy, peritonsillar cellulitis usually either resolves over several days or evolves into peritonsillar abscess. Peritonsillar abscess (**quinsy**) and cellulitis present with severe sore throat, odynophagia, trismus, medial deviation of the soft palate and peritonsillar fold, and an abnormal muffled ("hot potato") voice. CT may be a useful adjunct to clinical suspicion, but imaging is *not* required for the diagnosis. The existence of an abscess may be confirmed by aspirating pus from the peritonsillar fold just superior and medial to the upper pole of the tonsil. A 19-gauge or 21-gauge needle should be passed medial to the molar and no deeper than 1 cm, because the internal carotid artery may lie more medially than its usual location and pass posterior and deep to the tonsillar fossa. Most commonly, patients with peritonsillar abscess present to the emergency department and receive a dose of parenteral amoxicillin (1 g), amoxicillin-sulbactam (3 g), or clindamycin (600–900 mg). Less severe cases and patients who are able to tolerate oral intake may be treated for 7–10 days with oral antibiotics, including amoxicillin, 500 mg three times a day; amoxicillin-clavulanate, 875 mg twice a day; or clindamycin, 300 mg four times daily.

Although antibiotic treatment is generally undisputed, there is controversy regarding the surgical management of peritonsillar abscess. Methods include needle aspiration, incision and drainage, and tonsillectomy. Some clinicians incise and drain the area and continue with parenteral antibiotics, whereas others aspirate only and monitor as an outpatient. The data are largely equivocal for all three approaches. In patients with more severe or recurrent peritonsillar abscesses, it may be appropriate to consider immediate tonsillectomy (quinsy tonsillectomy) in the acutely infected setting, although practitioners have moved away from this approach because of the potential for complications. About 10% of patients with peritonsillar abscess exhibit relative indications for tonsillectomy after the infection has resolved. All three approaches are effective. Regardless of the method used, one must be sure the abscess is adequately treated, since complications such as extension to the retropharyngeal, deep neck, and posterior mediastinal spaces are possible. Bacteria may also be aspirated into the lungs, resulting in pneumonia. There is controversy about whether a single abscess is a sufficient indication for tonsillectomy; about 30% of patients aged 17–30 who do not undergo early planned tonsillectomy following peritonsillar abscess ultimately undergo surgery, and only about 13% of those over 30 have their tonsils removed. Recurrent or atypical peritonsillar abscesses in older adults should also be evaluated for an underlying head and neck malignancy.

DEEP NECK INFECTIONS

ESSENTIALS OF DIAGNOSIS

- Marked acute neck pain and swelling.
- Abscesses are emergencies because rapid airway compromise may occur.
- May spread to the mediastinum or cause sepsis.

General Considerations

Deep neck abscesses most commonly originate from odontogenic infections. Other causes include suppurative lymphadenitis; direct spread of pharyngeal infection; penetrating trauma; pharyngoesophageal foreign bodies; cervical osteomyelitis; and intravenous injection of the internal jugular vein, especially in people with substance use disorders. **Ludwig angina** is the most commonly encountered neck space infection. It is a cellulitis of the sublingual and submaxillary spaces, often arising from infection of the mandibular dentition. **Ludwig angina is an emergency as it may cause rapid upper airway compromise and necessitate creation of a surgical airway**. Recurrent deep neck infection may suggest an underlying congenital lesion, such as a branchial cleft cyst. Suppurative lymphadenopathy in middle-aged persons who smoke cigarettes and drink alcohol regularly should be considered a manifestation of malignancy (typically metastatic squamous cell carcinoma) until proven otherwise.

Clinical Findings

Patients with Ludwig angina have edema and erythema of the upper neck under the chin and often of the floor of the mouth. The tongue may be displaced upward and backward by the posterior spread of cellulitis, and coalescence of pus is often present in the floor of mouth. This may lead to occlusion of the airway. Microbiologic isolates include streptococci, staphylococci, *Bacteroides*, and *Fusobacterium*. Patients with diabetes may have different flora, including *Klebsiella*, and a more aggressive clinical course.

Patients with deep neck abscesses usually present with marked neck pain and swelling. Fever is common but not always present. *Deep neck abscesses are emergencies because they may rapidly compromise the airway.* Untreated or inadequately treated, they may spread to the mediastinum or cause sepsis.

Contrast-enhanced CT usually augments the clinical examination in defining the extent of the infection. It often will distinguish inflammation and phlegmon (requiring antibiotics) from abscess (requiring drainage) and define for the surgeon the extent of an abscess. CT with MRI may also identify thrombophlebitis of the internal jugular vein secondary to oropharyngeal inflammation. This condition, known as **Lemierre syndrome**, is rare and usually associated with severe headache. The presence of pulmonary infiltrates consistent with septic emboli in the setting of a neck abscess should lead one to suspect Lemierre syndrome or injection drug use, or both.

Treatment

Usual doses of penicillin plus metronidazole, ampicillin-sulbactam, clindamycin, or selective cephalosporins are good initial choices for treatment of Ludwig angina. Culture and sensitivity data are then used to refine the choice. Dental consultation is advisable to address the offending tooth or teeth. External drainage via bilateral submental incisions is required if the airway is threatened or when medical therapy has not reversed the process.

Treatment of deep neck abscesses includes securing the airway, intravenous antibiotics, and incision and drainage. When the infection involves the floor of the mouth, base of the tongue, or the supraglottic or paraglottic space, the airway may be secured either by intubation or tracheotomy. Tracheotomy is preferable in the patients with substantial pharyngeal edema, since attempts at intubation may precipitate acute airway obstruction. Bleeding in association with a deep neck abscess is very rare but suggests carotid artery or internal jugular vein involvement and requires prompt neck exploration both for drainage of pus and for vascular control.

Patients with Lemierre syndrome require prompt institution of antibiotics appropriate for *Fusobacterium necrophorum* as well as the more usual upper airway pathogens. The use of anticoagulation in treatment is of no proven benefit.

SNORING

ESSENTIALS OF DIAGNOSIS

- Noise produced on inspiration due to upper aerodigestive tract blockage during sleep.
- Snoring is associated with obstructive sleep apnea (OSA) but may not alone disrupt sleep quality.

General Considerations

Ventilation disorders during sleep are extremely common. *While OSA occurs in 5–10% of Americans, clinically relevant snoring may occur in as many as 59%.* In general, sleep-disordered breathing problems are attributed to narrowing of the upper aerodigestive tract during sleep due to changes in position, muscle tone, and soft tissue hypertrophy or laxity. The most common sites of obstruction are the oropharynx and the base of the tongue. The spectrum of the problem ranges from simple snoring without cessation of airflow to OSA with long periods of apnea and life-threatening physiologic sequelae. OSA is discussed in Chapter 9. In contrast to OSA, snoring is almost exclusively *a social problem*, and despite its prevalence and association with OSA, there is comparatively little known about the management of this problem.

Clinical Findings

A. Symptoms and Signs

All patients who report snoring should be evaluated for OSA as discussed in Chapter 9. Symptoms of OSA (including snoring, excessive daytime somnolence, daytime headaches, and weight gain) may be present in as many as 30% of patients without demonstrable apnea or hypopnea on formal testing. Clinical examination should include examination of the nasal cavity, nasopharynx, oropharynx, and larynx to help exclude other causes of dynamic airway obstruction. In many cases of isolated snoring, the palate and uvula appear enlarged and elongated with excessive mucosa hanging below the muscular portion of the soft palate.

B. Imaging and Diagnostic Testing

Sleep examination with **polysomnography** is strongly advised in the evaluation of a patient who reports snoring. Radiographic imaging of the head or neck is generally not necessary. Additional testing may include sleep endoscopy.

Treatment

Expeditious and inexpensive management solutions for snoring are sought, often with little or no benefit. Diet modification and physical exercise can lead to improvement in snoring through the weight loss and improvement in pharyngeal tone that accompanies overall physical conditioning. Position change during sleep can be effective, and time-honored treatments, such as placing a golf or tennis ball into a pocket sewn on the back of the pajama top worn during sleep, may satisfactorily eliminate symptoms by ensuring recumbency on one side. Although numerous pharmacologic therapies have been endorsed, none demonstrate any significant utility when scrutinized.

Anatomic management of snoring can be challenging. As with OSA, snoring can come from a number of sites in the upper aerodigestive tract. While medical or surgical correction of nasal obstruction may help alleviate snoring problems, most interventions aim to improve airflow through the nasopharynx and oropharynx. Nonsurgical options include mandibular advancement appliances designed to pull the base of the tongue forward and continuous positive airway pressure via face or nasal mask. Adherence to both of these treatment options is problematic because snorers without OSA do not notice the physiologic benefits of these devices noted by patients with sleep apnea.

Surgical correction of snoring is most commonly directed at the soft palate and tongue base. Historical approaches involved resection of redundant mucosa and the uvula similar to uvulopalatopharyngoplasty that is used for OSA. Regardless of how limited the procedure or what technique was used, the postoperative pain, expense of general anesthesia, and high recurrence rates limit the utility of these procedures. Office-based approaches are more widely attempted because of these limitations. Most of these procedures aim to stiffen the palate to prevent vibration rather than remove it. A series of procedures, including injection snoreplasty, radiofrequency thermal fibrosis, and an implantable palatal device, have been used with variable success and patient tolerance. The techniques can be technically challenging. Persistent symptoms may occur following initial treatment necessitating costly (and sometimes painful) repeat procedures. The durability of these procedures in alleviating symptoms is also poorly understood, and late failures can lead to patient and clinician frustration. Newer approaches include hypoglossal nerve stimulation which directly stimulates movement of the tongue to increase space of the airway.

DISEASES OF THE SALIVARY GLANDS

ACUTE INFLAMMATORY SALIVARY GLAND DISORDERS

1. Sialadenitis

Acute bacterial sialadenitis most commonly affects either the parotid or submandibular gland. It typically presents with acute swelling of the gland, increased pain and swelling with meals, and tenderness and erythema of the duct opening. Pus often can be massaged from the duct. Sialadenitis often occurs in the setting of dehydration or in association with chronic illness. Underlying Sjögren syndrome and chronic periodontitis may contribute. Ductal obstruction, often by an inspissated mucous plug, is followed by salivary stasis and secondary infection. The most common organism recovered from purulent draining saliva is *S aureus*. Treatment consists of intravenous antibiotics, such as nafcillin (1 g intravenously every 4–6 hours), and measures to increase salivary flow, including hydration, warm compresses, sialagogues (eg, lemon drops), and massage of the gland. Treatment can usually then be switched to an oral agent based on clinical improvement and microbiologic results to complete a 10-day treatment course. Less severe cases can often be treated with oral antibiotics with similar spectrum. Complete resolution of parotid swelling and pain can take 2–3 weeks. Failure of the process to improve and ultimately resolve on this regimen suggests abscess formation, ductal stricture, stone, or tumor causing obstruction. Ultrasound or CT scan may be helpful in establishing the diagnosis. In the setting of acute illness, a severe and potentially life-threatening form of sialadenitis, sometimes called suppurative sialadenitis, may develop. The causative organism is usually *S aureus*, but often no pus will drain from Stensen papilla. These patients often do not respond to rehydration and intravenous antibiotics and thus may require operative incision and drainage to resolve the infection. In patients with bilateral parotid sialadenitis, mumps should be considered.

2. Sialolithiasis

Calculus formation is more common in the **Wharton duct** (draining the submandibular glands) than in the **Stensen duct** (draining the parotid glands). Clinically, a patient may note postprandial pain and local swelling, often with a history of recurrent acute sialadenitis. Stones in the Wharton duct are usually large and radiopaque, whereas those in the Stensen duct are usually radiolucent and smaller. Those very close to the orifice of the Wharton duct may be palpated manually in the anterior floor of the mouth and removed intraorally by dilating or incising the distal duct. Those > 1.5–2 cm from the duct are too close to the lingual nerve to be removed safely in this manner. Similarly, dilation of the Stensen duct, located on the buccal surface opposite the second maxillary molar, may relieve distal stricture or allow a small stone to pass. Sialoendoscopy for the management of chronic sialolithiasis is superior to extracorporeal shock-wave lithotripsy and fluoroscopically guided basket retrieval. Repeated episodes of sialadenitis are usually associated with stricture and chronic infection. If the obstruction cannot be safely removed or dilated, excision of the gland may be necessary to relieve recurrent symptoms.

CHRONIC INFLAMMATORY & INFILTRATIVE DISORDERS OF THE SALIVARY GLANDS

Numerous infiltrative disorders may cause unilateral or bilateral parotid gland enlargement. Sjögren syndrome and sarcoidosis are examples of lymphoepithelial and granulomatous diseases that may affect the salivary glands. Metabolic disorders, including alcohol use disorder, diabetes mellitus, and vitamin deficiencies, may also cause diffuse enlargement. Several medications have been associated with parotid enlargement, including thioureas, iodine, and medications with cholinergic effects (eg, phenothiazines), which stimulate salivary flow and cause more viscous saliva.

SALIVARY GLAND TUMORS

A general rule of thumb is that the smaller the size of the salivary gland with a present mass, the more likely the possibility of malignancy. Approximately 80% of salivary gland tumors occur in the parotid gland. In adults, about 80% of these are benign. In the submandibular triangle, it is sometimes difficult to distinguish a primary submandibular gland tumor from a metastatic submandibular space node. Only 50–60% of primary submandibular tumors are benign. Tumors of the minor salivary glands are most likely to be malignant, with adenoid cystic carcinoma predominating, and may be found throughout the oral cavity or oropharynx.

Most parotid tumors present as an asymptomatic mass in the superficial part of the gland. Their presence may have been noted by the patient for months or years. Facial nerve involvement and pain correlate strongly with malignancy. Tumors may extend deep to the plane of the facial nerve or may originate in the parapharyngeal space. In such cases, medial deviation of the soft palate is visible on intraoral examination. MRI and CT scans have largely replaced sialography in defining the extent of tumor. At least one study demonstrates the potential benefit of enhanced MRI imaging in distinguishing among Warthin tumors and pleomorphic adenomas and malignant salivary gland tumors. Ultrasonography is a simple and effective initial test for identification of a suspected mass.

When the clinician encounters a patient with an otherwise asymptomatic salivary gland mass where tumor is the most likely diagnosis, the choice is whether to simply excise the mass via a parotidectomy with facial nerve dissection or submandibular gland excision or to first obtain an FNA biopsy. The **Milan System for Reporting Salivary Gland Cytopathology** is the accepted guide for diagnosis and management of salivary gland lesions based on biopsy results. In benign and small, low-grade malignant tumors, no additional treatment is needed. Postoperative irradiation is indicated for larger and high-grade cancers.

DISEASES OF THE LARYNX

HOARSENESS & STRIDOR

The primary symptoms of laryngeal disease are hoarseness and stridor. **Hoarseness** is caused by an abnormal vibration of the vocal folds. The voice is breathy when too much air passes incompletely apposed vocal folds, as in unilateral vocal fold paralysis or vocal fold mass. The voice is harsh when the vocal folds are stiff and vibrate irregularly, as is the case in laryngitis or malignancy. Heavy, edematous vocal folds produce a rough, low-pitched vocal quality. **Stridor** (a high-pitched, typically inspiratory, sound) is the result of turbulent airflow from a narrowed upper airway. Airway narrowing at or above the vocal folds produces inspiratory stridor. Airway narrowing below the vocal fold level produces either expiratory or biphasic stridor. The timing and rapidity of onset of stridor are critically important in determining the seriousness of the airway problem. **All cases of stridor should be evaluated by a specialist and rapid-onset stridor should be evaluated emergently.**

Evaluation of an abnormal voice begins with obtaining a history of the circumstances preceding its onset and an examination of the airway. *All patients with hoarseness that has persisted beyond 2 weeks should be evaluated by an otolaryngologist with laryngoscopy.* Especially when the patient has a history of tobacco use, laryngeal cancer or lung cancer (leading to paralysis of a recurrent laryngeal nerve), or concerns for cough and aspiration, must be strongly considered. In addition to structural causes of dysphonia, laryngoscopy can help identify functional problems with the voice, including vocal fold paralysis, muscle tension dysphonia, and spasmodic dysphonia.

COMMON LARYNGEAL DISORDERS

1. Acute Laryngitis

Acute laryngitis is probably the most common cause of hoarseness, which may persist for a week or so after other symptoms of an upper respiratory infection have cleared. Supportive care includes resting the voice, drinking enough fluid to stay hydrated, and breathing humidified air. The patient should be warned to avoid vigorous use of the voice (singing, shouting) until their voice returns to normal, since persistent use may lead to the formation of traumatic vocal fold hemorrhage, polyps, and cysts. Although thought to be usually viral in origin, both *M catarrhalis* and *H influenzae* may be isolated from the nasopharynx at higher than expected frequencies. Despite this finding, *a meta-analysis has failed to demonstrate any convincing evidence that antibiotics significantly alter the natural resolution of acute laryngitis*. Erythromycin may speed improvement of hoarseness at 1 week and cough at 2 weeks when measured subjectively. Oral or intramuscular corticosteroids may be used in highly selected cases of professional vocalists to speed recovery and allow scheduled performances. Examination of the vocal folds and assessment of vocal technique are mandatory prior to corticosteroid initiation, since inflamed vocal folds are at greater risk for hemorrhage and the subsequent development of traumatic vocal fold pathology.

Huang T et al. Efficacy of inhaled budesonide on serum inflammatory factors and quality of life among children with acute infectious laryngitis. Am J Otolaryngol. 2021;42:102820. [PMID: 33188988]

2. Laryngopharyngeal Reflux

ESSENTIALS OF DIAGNOSIS

- Commonly associated with hoarseness, throat irritation, heartburn, foreign body sensation, and chronic cough.
- Symptoms typically occur when upright, and many patients do not experience classic heartburn.
- Laryngoscopy is critical to exclude other causes of hoarseness.
- Diagnosis is often made based on response to PPI therapy.
- Treatment failure with PPIs is common and suggests other etiologies.

Gastroesophageal reflux into the larynx (laryngopharyngeal reflux) is considered a cause of chronic hoarseness when other causes of abnormal vocal fold vibration (such as tumor or nodules) have been excluded by laryngoscopy. GERD has also been suggested as a contributing factor to other symptoms, such as throat clearing, throat discomfort, chronic cough, a sensation of postnasal drip, esophageal spasm, and some cases of asthma. Since less than half of patients with laryngeal acid exposure have typical symptoms of heartburn and regurgitation, the lack of such symptoms should not be construed as eliminating this cause. Indeed, *most patients with symptomatic laryngopharyngeal reflux, as it is now called, do not meet criteria for GERD by pH probe testing* and these entities must be considered separately. The prevalence of this condition is hotly debated in the literature, and laryngopharyngeal reflux may not be as common as once thought.

Evaluation should initially exclude other causes of dysphonia through laryngoscopy; consultation with an otolaryngologist is advisable. Many clinicians opt for an empiric trial of a PPI since no gold standard exists for diagnosing this condition. *Such an empiric trial should* not *precede visualization of the vocal folds to exclude other causes of hoarseness.* When used, the American Academy of Otolaryngology–Head and Neck Surgery recommends twice-daily therapy with full-strength PPI (eg, omeprazole 40 mg orally twice daily or equivalent) for a minimum of 3 months. Patients may note improvement in symptoms after 3 months, but the changes in the larynx often take 6 months to resolve. If symptoms improve and cessation of therapy leads to symptoms again, then a PPI is resumed at the lowest dose effective for remission, usually daily but at times on a demand basis. Although H_2-receptor antagonists are an alternative to PPIs, they are generally both less clinically effective and less cost-effective. Nonresponders should undergo pH testing and manometry. Twenty-four-hour pH monitoring of the pharynx should best document laryngopharyngeal reflux and is advocated by some as the initial management step, but it is costly, more difficult, and less available than lower esophageal monitoring alone. **Double pH probe** (proximal and distal esophageal probes) testing is the best option for evaluation, since lower esophageal pH monitoring alone does not correlate well with laryngopharyngeal reflux symptoms. Oropharyngeal pH probe testing is available, but its ability to predict response to reflux treatment in patients with laryngopharyngeal reflux is not known.

3. Recurrent Respiratory Papillomatosis

Papillomas are common lesions of the larynx and other sites where ciliated and squamous epithelia meet. Unlike oral papillomas, recurrent respiratory papillomatosis typically becomes symptomatic, with hoarseness that occasionally progresses over weeks to months. These papillomas are almost always due to HPV types 6 and 11. Repeated laser vaporizations or cold knife resections via operative laryngoscopy are the mainstay of treatment. Severe cases can cause airway compromise in adults and may require treatment as often as every 6 weeks to maintain airway patency. Extension can occur into the trachea and lungs. Tracheotomy should be avoided, if possible, since it introduces an additional squamociliary junction for which papillomas appear to have an affinity. Interferon treatment has been under investigation for many years but is only indicated in severe cases with pulmonary involvement. Rarely, cases of malignant transformation have been reported (often in smokers), but recurrent respiratory papillomatosis should generally be thought of as a benign condition. Cidofovir (a cytosine nucleotide analog in use to treat cytomegalovirus retinitis) has been used with success as intralesional therapy for recurrent respiratory papillomatosis. Because cidofovir causes adenocarcinomas in laboratory animals, its potential for carcinogenesis is being monitored. The quadrivalent and new 9 serotype recombinant human HPV vaccines (Gardasil and Gardasil 9) offer hope for the eventual prevention of this benign, but terribly morbid, disease.

4. Epiglottitis

Epiglottitis (or, more correctly, **supraglottitis**) should be suspected when a patient presents with a rapidly developing sore throat or when odynophagia (pain on swallowing) is out of proportion to apparently minimal oropharyngeal findings on examination. It is more common in patients with diabetes and may be viral or bacterial in origin. Rarely in the era of *H influenzae* type b vaccine is this bacterium isolated in adults. Unlike in children, indirect laryngoscopy is generally safe and may demonstrate a swollen, erythematous epiglottis. Lateral plain radiographs may demonstrate an enlarged epiglottis (the epiglottis "thumb sign"). Initial treatment is hospitalization for intravenous antibiotics—eg, ceftizoxime, 1–2 g intravenously every 8–12 hours; or cefuroxime, 750–1500 mg intravenously every 8 hours; and dexamethasone, usually 4–10 mg as initial bolus, then 4 mg intravenously every 6 hours—and observation of the airway. Corticosteroids may be tapered as symptoms and signs resolve. Similarly, substitution of oral antibiotics may be appropriate to complete a 10-day course. Less than 10% of adults require intubation. Indications for intubation are dyspnea, rapid pace of sore throat (where progression to airway compromise may occur before the effects of corticosteroids and antibiotics), and endolaryngeal abscess noted on CT imaging. If the patient is not intubated, prudence suggests monitoring oxygen saturation with continuous pulse oximetry and initial admission to a monitored unit.

MASSES OF THE LARYNX

1. Traumatic Lesions of the Vocal Folds

Vocal fold nodules are smooth, paired lesions that form at the junction of the anterior one-third and posterior two-thirds of the vocal folds. They are a common cause of hoarseness resulting from vocal abuse. In adults, they are referred to as "singer's nodules" and in children as "screamer's nodules." Treatment requires modification of voice habits, and referral to a speech therapist is indicated. While nearly all true nodules will resolve with behavior modification, recalcitrant nodules may require surgical excision. Often, additional pathology, such as a polyp or cyst, may be encountered.

Vocal fold polyps are unilateral masses that form within the superficial lamina propria of the vocal fold. They are related to vocal trauma and seem to follow resolution of vocal fold hemorrhage. Small, sessile polyps may resolve with conservative measures, such as voice rest and corticosteroids, but larger polyps are often irreversible and require operative removal to restore normal voice.

Vocal fold cysts are also considered traumatic lesions of the vocal folds and are either true cysts with an epithelial lining or pseudocysts. They typically form from mucus-secreting glands on the inferior aspect of the vocal folds. Cysts may fluctuate in size from week to week and cause a variable degree of hoarseness. They rarely, if ever, resolve completely and may leave behind a sulcus, or vocal fold scar, if they decompress or are marsupialized. Such scarring can be a frustrating cause of permanent dysphonia.

Polypoid corditis is different from vocal fold polyps and may form from loss of elastin fibers and loosening of the intracellular junctions within the lamina propria. This loss allows swelling of the gelatinous matrix of the superficial lamina propria (called **Reinke edema**). These changes in the vocal folds are strongly associated with smoking, but also with vocal abuse, chemical industrial irritants, and hypothyroidism. While this problem is common in both male and female smokers, women seem more troubled by the characteristic decline in modal pitch caused by the increased mass of the vocal folds. If the patient stops smoking or the lesions cause stridor and airway obstruction, surgical resection of the hyperplastic vocal fold mucosa may be indicated to improve the voice or airway, or both.

A common but often unrecognized cause of hoarseness and odynophonia are **contact ulcers** or their close relatives, **granulomas**. Both lesions form on the vocal processes of the arytenoid cartilages, and patients often can correctly inform the clinician which side is affected. The cause of these ulcers and granulomas is disputed, but they are clearly related to trauma and may be related to exposure of the underlying perichondrium. They are common following intubation and generally resolve quite quickly. Chronic ulceration or granuloma formation has been associated with gastroesophageal reflux but is also common in patients with muscle tension dysphonia. Treatment is often multimodal, and an inhaled corticosteroid (eg, fluticasone 440 mcg twice daily) may be the most effective pharmacologic therapy. Adjunctive treatment measures include PPI therapy (omeprazole 40 mg orally twice daily, or equivalent) and voice therapy with special attention to vocal hygiene. Rare cases can be quite stubborn and persistent without efficacious therapy. Surgical removal is rarely, if ever, required for nonobstructive lesions.

Fan RS et al. Clinical voice outcomes for two voice rest protocols after phonomicrosurgery. Laryngoscope. 2024;134:2812. [PMID: 38217412]

2. Laryngeal Leukoplakia

Leukoplakia of the vocal folds is commonly *found in association with hoarseness in smokers*. Direct laryngoscopy with biopsy is advised in almost all cases. Histologic examination usually demonstrates mild, moderate, or severe dysplasia. In some cases, invasive squamous cell carcinoma is present in the initial biopsy specimen. Cessation of smoking may reverse or stabilize mild or moderate dysplasia. Some patients—estimated to be < 5% of those with mild dysplasia and about 35–60% of those with severe dysplasia—will subsequently develop squamous cell carcinoma. Treatment options include PPI therapy, close follow-up with laryngovideostroboscopy, serial resection, and external beam radiation therapy.

3. Squamous Cell Carcinoma of the Larynx

ESSENTIALS OF DIAGNOSIS

- New and persistent (> 2 weeks' duration) voice changes and hoarseness, especially in a smoker.
- Persistent throat pain, especially with swallowing; weight loss; neck mass; hemoptysis.
- Stridor or other symptoms of a compromised airway.

General Considerations

Squamous cell carcinoma of the larynx, the most common malignancy of the larynx, occurs almost exclusively in patients with a history of significant tobacco use. Prevalence and mortality of laryngeal cancer are estimated at 2.76 cases/year per 100,000 individuals, 14.33 cases/year per 100,000 individuals, and 1.66 deaths/year per 100,000 individuals, respectively. The incidence and prevalence have increased by 12% and 24%, respectively, during the past three decades. Mortality has declined by ~5%. Squamous cell carcinoma is usually seen in men aged 50–70 years. There may be an association between laryngeal cancer and HPV type 16 or 18 infection, but this association is much less strong than that between HPV 16 or 18 and oropharyngeal cancer. In both cancer types, the association with HPV seems to be strongest in nonsmokers. Early detection is the key to maximizing posttreatment voice, swallowing, and breathing function.

Clinical Findings

A. Symptoms and Signs

A change in voice quality is most often the presenting symptom, although throat or ear pain, hemoptysis, dysphagia, weight loss, and airway compromise may occur. Because of their early impact on vocal quality, glottic cancers are among the smallest detectable human malignancies and treatment success is very high with early lesions. Neck metastases are not common in **early glottic (true vocal fold) cancer** in which the vocal folds are mobile, but a third of patients in whom there is impaired fold mobility will also have involved lymph nodes at neck dissection. **Supraglottic carcinoma** (false vocal folds, aryepiglottic folds, epiglottis), on the other hand, often metastasizes to both sides of the neck early in the disease. Complete head and neck examination, including laryngoscopy, is mandatory for any person with the concerning symptoms listed under Essentials of Diagnosis.

B. Imaging and Laboratory Studies

Radiologic evaluation by CT or MRI is helpful in assessing tumor extent. Imaging evaluates neck nodes, tumor volume, and cartilage sclerosis or destruction. A chest CT scan is almost always indicated to evaluate for a second primary lesion or metastases. Laboratory evaluation includes CBC and liver biochemical tests. Formal cardiopulmonary evaluation may be indicated, especially if partial laryngeal surgery is being considered. All partial laryngectomy candidates should have good to excellent lung function and exercise tolerance because chronic microaspiration may be expected following the procedure. A PET scan or CT-PET scan may be indicated to assess for distant metastases when there appears to be advanced local or regional disease.

C. Biopsy

Diagnosis is made by biopsy at the time of laryngoscopy when true fold mobility and arytenoid fixation, as well as surface tumor extent, can be evaluated. Most otolaryngologists recommend esophagoscopy and bronchoscopy at the same time to exclude synchronous primary tumor. Although an FNA biopsy of an enlarged neck node may have already been done, it is generally acceptable to assume radiographically enlarged neck nodes (> 1–1.5 cm) or nodes with necrotic centers are neck metastases. Open biopsies of nodal metastases should be *discouraged* because they may lead to higher rates of tumor treatment failure.

D. Tumor Staging

The American Joint Committee on Cancer (AJCC) staging of laryngeal cancers uses the TNM system to describe tumor extent and can be used for prognosis. Early laryngeal cancers, T1 and T2 (stage I and II) lesions, involve 1–2 laryngeal subsites locally with normal vocal fold mobility, and have no nodal metastases or profound functional abnormalities. T3 and T4 lesions may involve multiple laryngeal subsites with limitation of vocal fold mobility. These locally advanced lesions are stage III or IV cancers, and any size tumor with regional nodal metastases is at least a stage III tumor. Stage I and II lesions are generally treated with single-modality therapy (surgery or radiation), while multimodality therapy, usually including chemotherapy with radiation therapy, is reserved for more advanced stage III and IV lesions.

Treatment

Treatment of laryngeal carcinoma has four goals: cure, preservation of safe and effective swallowing, preservation of useful voice, and avoidance of a permanent tracheostoma. For early glottic and supraglottic cancers, radiation therapy is the standard of care since cure rates are > 95% and 80%, respectively. That said, radiation therapy carries substantial morbidity, and many early tumors (T1 and T2 lesions, without involved nodes) and selected advanced tumors (T3) may be treated with partial laryngectomy if at least one cricoarytenoid unit can be preserved. Five-year locoregional cure rates exceed 80–90% with surgery, and patient-reported satisfaction is excellent. In supraglottic tumors, even when clinically N0, elective limited neck dissection is indicated following surgical resection because of the high risk of neck node involvement.

Advanced stage III and IV tumors represent a challenging and ever-changing treatment dilemma. Twenty-five years ago, total laryngectomy was often recommended for such patients. However, the 1994 VA study (with induction cisplatin and 5-fluorouracil followed by irradiation alone in responders) demonstrated that two-thirds of patients could preserve their larynx. Subsequent studies have further defined **multimodal therapy**. Cisplatin-based chemotherapy concomitant with radiation therapy has been shown to be superior to either irradiation alone or induction chemotherapy followed by radiation. The same benefits have been demonstrated with the epidermal growth factor receptor blocker cetuximab with lower overall systemic toxicity and better patient tolerance. However, chemoradiation using either cetuximab or cisplatin is associated with prolonged gastrostomy-dependent dysphagia.

The high rate of dysphagia and morbidity associated with severe laryngeal stenosis following chemoradiation has prompted potential for **organ preservation therapy**. Organ preservation surgery should be considered and discussed as an alternative to chemoradiation but may require referral to an appropriate regional center where such techniques are offered. After thorough evaluation of candidacy and discussion of the treatment options, patient choice plays a critical role in the ultimate decision to pursue surgery or chemoradiation as a definitive treatment modality. The patient and treating clinicians must carefully consider different early and late side effects and complications associated with different treatment modalities.

The presence of malignant adenopathy in the neck affects the prognosis greatly. Supraglottic tumors metastasize early and bilaterally to the neck, and this must be included in the treatment plans even when the neck is apparently uninvolved. Glottic tumors in which the true vocal folds are mobile (T1 or T2) have a < 5% rate of nodal involvement; when a fold is immobile, the rate of ipsilateral nodal involvement climbs to about 30%. An involved neck is treated by surgery or chemoradiation, or both. This decision will depend on the treatment chosen for the larynx and the extent of neck involvement.

Total laryngectomy is largely reserved for patients with advanced resectable tumors with extralaryngeal spread or cartilage involvement, for those with persistent tumor following chemoradiation, and for patients with recurrent or second primary tumor following previous radiation therapy. In these cases, the larynx is entirely removed rendering a patient aphonic and with a permanent stoma in their neck through which they breathe. Voice rehabilitation via a primary or secondary tracheoesophageal puncture with voice prosthesis placement produces intelligible and serviceable speech in about 75–85% of patients. Indwelling prostheses that are changed every 3–6 months are a common alternative to patient-inserted prostheses, which need changing more frequently.

Long-term follow-up is critical in head and neck cancer patients. In addition to the 3–4% annual rate of second tumors and monitoring for recurrence, psychosocial aspects of treatment are common. Dysphagia, impaired communication, and altered appearance may result in patient difficulties adapting to the workplace and to social interactions. In addition, smoking cessation and alcohol abatement are common challenges. Nevertheless, about 65% of patients with larynx cancer are cured, most have useful speech, and many resume their prior livelihoods with adaptations.

When to Refer

Specialty referral should be sought early for diagnosis and treatment.

When to Admit

- Airway compromise, hemorrhage, dehydration, significant weight loss.
- To determine an effective pain management regimen for severe pain.

VOCAL FOLD PARALYSIS

Vocal fold paralysis can result from a lesion or damage to either the vagus or recurrent laryngeal nerve. It may result in breathy dysphonia, effortful voicing, aspiration, and rarely airway compromise. Common causes of **unilateral recurrent laryngeal nerve** involvement include thyroid surgery (and occasionally thyroid cancer), other neck surgery (anterior discectomy and carotid endarterectomy), and mediastinal or apical involvement by lung cancer. Skull base tumors often involve or abut upon lower cranial nerves and may affect the **vagus nerve** directly, or the vagus nerve may be damaged during surgical management of the lesion. While iatrogenic injury is the most common cause of unilateral vocal fold paralysis, the second most common cause is idiopathic. However, before deciding whether the paralysis is due to iatrogenic injury or is idiopathic, the clinician must exclude other causes, such as malignancy. In the absence of other cranial neuropathies, a CT scan with contrast from the skull base to the aorto-pulmonary window (the span of the recurrent laryngeal nerve) should be performed. If other cranial nerve deficits or high vagal weakness with palate paralysis is noted, an MRI scan of the brain and brainstem is warranted.

Unilateral vocal fold paralysis is occasionally temporary and may take over a year to resolve spontaneously. Surgical management of persistent or irrecoverable symptomatic unilateral vocal fold paralysis has evolved over the last several decades. The primary goal is medialization of the paralyzed fold in order to create a stable platform for vocal fold vibration. Additional goals include advancing diet and improving pulmonary toilet by facilitating cough. Success has been reported for years with injection laryngoplasty using Teflon, Gelfoam, fat, and collagen. Once the paralysis is determined to be permanent, formal medialization thyroplasty may be performed by creating a small window in the thyroid cartilage and placing an implant between the thyroarytenoid muscle and inner table of the thyroid cartilage. This procedure moves the vocal fold medially and creates a stable platform for bilateral, symmetric mucosal vibration.

Unlike unilateral fold paralysis, **bilateral vocal fold paralysis** usually causes inspiratory stridor with deep inspiration and may cause rapid airway compromise. If the onset of bilateral fold paralysis is insidious, it may be asymptomatic at rest, and the patient may have a normal voice. However, **the acute onset of bilateral vocal fold paralysis with inspiratory stridor at rest should be managed by a specialist immediately in a critical care environment**. Causes of bilateral fold paralysis include thyroid surgery, esophageal cancer, and ventricular shunt malfunction. Unilateral or bilateral fold immobility may also be seen in trauma, cricoarytenoid arthritis secondary to advanced rheumatoid arthritis, intubation injuries, glottic and subglottic stenosis, and laryngeal cancer. The goal of intervention is the creation of a safe airway with minimal reduction in voice quality and airway protection from aspiration. A number of fold lateralization procedures for bilateral paralysis have been advocated as a means of removing the tracheotomy tube.

CRICOTHYROTOMY & TRACHEOSTOMY

The three main approaches to secure an airway include endotracheal intubation, cricothyrotomy, and tracheostomy. In an acute airway emergency where the airway above the trachea is blocked (ie, due to trauma, mass, or bleeding), cricothyrotomy secures an airway more rapidly than tracheotomy, with fewer potential immediate complications (eg, pneumothorax and hemorrhage). Depending on the airway emergency, a cricothyrotomy may need to be converted to a tracheostomy after the airway has been secured.

There are two primary indications for tracheotomy: airway obstruction at or above the level of the larynx and respiratory failure requiring prolonged mechanical ventilation. Tracheotomies may be performed via an open or percutaneous approach. In experienced hands, the various methods of percutaneous tracheotomy have been documented to be safe for carefully selected patients. Simultaneous videobronchoscopy can reduce the incidence of major complications. The major cost reduction comes from avoiding the operating room. Bedside tracheotomy (in the ICU) achieves similar cost reduction and is advocated by some experts as slightly less costly than the percutaneous procedures.

The most common indication for elective tracheotomy is the need for prolonged mechanical ventilation. There is no firm rule about how many days a patient must be intubated before conversion to tracheotomy should be advised. The incidence of serious complications, such as subglottic stenosis, increases with extended endotracheal intubation. *As soon as it is apparent that the patient will require protracted ventilatory support, tracheotomy should replace the endotracheal tube.* Less frequent indications for tracheostomy are life-threatening aspiration pneumonia, the need to improve pulmonary toilet to correct problems related to insufficient clearing of tracheobronchial secretions, and obstructive sleep apnea.

Posttracheotomy care requires humidified air to prevent secretions from crusting and occluding the inner cannula of the tracheotomy tube. The tracheotomy tube should be cleaned several times daily. The most frequent early complication of tracheotomy is dislodgment of the tracheotomy tube. Surgical creation of an inferiorly based tracheal flap sutured to the inferior neck skin may make reinsertion of a dislodged tube easier. It should be recalled that the act of swallowing requires elevation of the larynx, which is limited by tracheotomy. Therefore, frequent tracheal and bronchial suctioning is often required to clear the aspirated saliva as well as the increased tracheobronchial secretions. Care of the skin around the tracheostoma is important to prevent maceration and secondary infection.

FOREIGN BODIES IN THE UPPER AERODIGESTIVE TRACT

FOREIGN BODIES IN THE TRACHEA & BRONCHI

Aspiration of foreign bodies occurs much less frequently in adults than in children. Older adults and those who wear dentures appear to be at greatest risk. Wider familiarity with the **Heimlich maneuver** has reduced deaths. If the maneuver is unsuccessful, cricothyrotomy may be necessary in the acute setting.

If there is no airway compromise, a CXR may reveal a radiopaque foreign body. Detection of radiolucent foreign bodies may be aided by CT or inspiration-expiration films that demonstrate air trapping distal to the obstructed segment. Atelectasis and pneumonia may occur later. Tracheal and bronchial foreign bodies should be removed under general anesthesia with rigid or flexible bronchoscopy by a skilled endoscopist working with an experienced anesthesiologist.

FOREIGN BODIES IN THE ESOPHAGUS

Foreign bodies in the esophagus create are typically not life-threatening situations. However, the acuity may rise depending on the type of foreign body (eg, a button battery) or if the airway is compromised. **Button battery ingestion is a surgical emergency.** If there is no concern for caustic ingestion or airway compromise, there is typically time to consult an otolaryngologist for management. It is a useful diagnostic sign of complete obstruction if the patient is drooling or cannot handle secretions. Patients may often point to the exact level of the obstruction. Indirect laryngoscopy often shows pooling of saliva at the esophageal inlet. Plain films may detect radiopaque foreign bodies, such as chicken bones. Coins tend to align in the coronal plane in the esophagus and in the sagittal direction in the trachea. If a foreign body is suspected, a CT or barium swallow may also help make the diagnosis.

The treatment of an esophageal foreign body depends on identification of its cause. In children, swallowed nonfood objects are common. In adults, however, food foreign bodies are more common, and there is the greater possibility of underlying esophageal pathology. If there is nothing sharp, such as a bone, some clinicians advocate a hospitalized 24-hour observation period prior to esophagoscopy, noting that spontaneous passage of the foreign body will occur in 50% of adult patients. In the management of meat obstruction, the use of papain (meat tenderizer) should be discouraged because it can damage the esophageal mucosa and lead to stenosis or perforation. Esophageal foreign bodies that do not pass need to be removed surgically. Endoscopic removal and examination are usually best via flexible esophagoscopy or rigid laryngoscopy and esophagoscopy. Complications of penetrating or erosive esophageal foreign bodies may include mediastinitis or erosion in the trachea with associated tracheitis.

DISEASES PRESENTING AS NECK MASSES

The differential diagnosis of neck masses is heavily dependent on the location in the neck, the age of the patient, and the presence of associated disease processes. Rapid growth and tenderness suggest an inflammatory process, while firm, painless, and slowly enlarging masses are often neoplastic. In young adults, most neck masses are benign (branchial cleft cyst, thyroglossal duct cyst, reactive lymphadenitis), although malignancy should always be considered (lymphoma, metastatic thyroid carcinoma). Lymphadenopathy is common in persons with HIV, but a growing or dominant mass may well represent lymphoma. *In adults over age 40, cancer is the most common cause of persistent neck mass and should be definitively ruled out.* A metastasis from squamous cell carcinoma arising within the mouth, pharynx, larynx, or upper esophagus should be suspected. Risk factors for squamous cell carcinoma include smoking and HPV exposure. Especially among patients younger than 30 or older than 70, lymphoma also should be considered. In all cases, a comprehensive otolaryngologic examination is needed. Imaging and pathologic evaluation of the neck mass via FNA biopsy is likely to be the next step if a primary tumor is not obvious on physical examination.

CONGENITAL LESIONS PRESENTING AS NECK MASSES IN ADULTS

1. Branchial Cleft Cysts

Branchial cleft cysts usually present as a soft cystic mass along the anterior border of the sternocleidomastoid muscle. These lesions are usually recognized in the second or third decades of life, often when they suddenly swell or become infected. To prevent recurrent infection and possible carcinoma, they should be completely excised, along with their fistulous tracts.

First branchial cleft cysts present high in the neck, sometimes just below the ear. A fistulous connection with the floor of the external auditory canal may be present. Second branchial cleft cysts, which are far more common, may communicate with the tonsillar fossa. Third branchial cleft cysts, which may communicate with the piriform sinus, are rare and present low in the neck.

2. Thyroglossal Duct Cysts

Thyroglossal duct cysts occur along the embryologic course of the thyroid's descent from the tuberculum impar of the tongue base to its usual position in the low neck. Although they may occur at any age, they are most common before age 20. They present as a midline neck mass, often just below the hyoid bone, which moves with swallowing. Surgical excision is recommended to prevent recurrent infection and rare malignancy. This requires removal of the entire fistulous tract along with the middle portion of the hyoid bone through which many of the fistulas pass. CT or ultrasound or both are often obtained preoperatively to understand associated neck anatomy, including position of the thyroid.

INFECTIOUS & INFLAMMATORY NECK MASSES

1. Reactive Cervical Lymphadenopathy

Normal lymph nodes in the neck are usually < 1 cm in length. Infections involving the pharynx, salivary glands, and scalp often cause tender enlargement of neck nodes. Enlarged nodes are common in persons with HIV. Except for the occasional node that suppurates and requires incision and drainage, treatment is directed against the underlying infection. *An enlarged node (larger than 1.5 cm) or node with a necrotic center that is not associated with an obvious infection should be further evaluated, especially if the patient has a history of smoking, alcohol use, or prior cancer.* Other common indications for FNA biopsy of a node include its persistence or continued enlargement. Common causes of cervical adenopathy include cancer (eg, squamous cell carcinoma, lymphoma, occasional metastases from non-head and neck sites) and infection (eg, reactive nodes, mycobacteria, and cat-scratch disease). Rare causes of adenopathy include Kikuchi disease (histiocytic necrotizing lymphadenitis) and autoimmune adenopathy.

2. Tuberculous & Nontuberculous Mycobacterial Lymphadenitis

Granulomatous neck masses are uncommon in the United States unless there are specific risk factors for particular infectious exposures or granulomatous hereditary or autoimmune illness. The differential diagnosis includes mycobacterial adenitis, sarcoidosis, and cat-scratch disease due to *Bartonella henselae*. The incidence of mycobacterial lymphadenitis is on the rise both in immunocompromised and immunocompetent individuals. The usual presentation of granulomatous disease in the neck is simply single or matted nodes. Although mycobacterial adenitis can extend to the skin and drain externally (as described for atypical mycobacteria and referred to as scrofula), this late presentation is no longer common.

FNA biopsy is usually the best initial diagnostic approach: cytology, smear for acid-fast bacilli, mycobacterial culture, and a sensitivity test can all be done. PCR from FNA (or from excised tissue) is the most sensitive test and is particularly useful when conventional methods have not been diagnostic but clinical impression remains consistent for tuberculous infection. While FNA has a high sensitivity (about 88%), its specificity is low (49%); thus, an excisional biopsy is often required to confirm the diagnosis.

For atypical (nontuberculous) infection of the lymph nodes, treatment depends on the sensitivity results of culture, but antibiotics likely to be useful include 6 months of isoniazid and rifampin and, for at least the first 2 months, ethambutol—all in standard dosages. Some would totally excise the involved nodes prior to chemotherapy, depending on location and other factors, but this can lead to chronic draining fistulas.

Yadav V et al. Primary subglottic laryngeal tuberculosis mimicking as malignancy: a rare case report. Indian J Otolaryngol Head Neck Surg. 2024;76:6003. [PMID: 39559153]

3. Lyme Disease

Lyme disease, caused by the spirochete *Borrelia burgdorferi* and transmitted by ticks of the *Ixodes* genus, may have protean manifestations, but over 75% of patients have symptoms involving the head and neck. Facial paralysis, hearing loss, dysesthesias, dysgeusia, or other cranial neuropathies are most common. Headache, pain, and cervical lymphadenopathy may occur. It is essential to ask patients with cranial neuropathies about risk factors for Lyme disease. See Chapter 39 for a more detailed discussion.

CANCER METASTASES

In older adults, 80% of firm, persistent, and enlarging neck masses are metastatic in origin. The majority of these arise from squamous cell carcinoma of the upper aerodigestive tract, such as nasopharynx, tonsils, tongue base, and larynx. A complete head and neck examination may reveal the cancer of origin, but often imaging and examination under anesthesia are necessary to detect the primary lesion. Detecting the primary lesion is essential since it may directly impact oncologic treatment modalities. Initial radiologic screening exams typically include a CT, MRI, or PET. After imaging, many patients require direct laryngoscopy, esophagoscopy, and tracheobronchoscopy to further elucidate the primary lesion. At this time, biopsies may be taken for suspicious lesions. FNA of neck masses are also routine and may help determine the diagnosis while evaluation of the primary malignancy is ongoing. *Open neck biopsy should only be performed by head and neck surgeons experienced in the management of head and neck cancer since complications from open biopsy may make subsequent formal neck dissections more challenging if cancer is detected.* With the exception of papillary thyroid carcinoma, non–squamous cell metastases to the neck are infrequent. While cancers that are not primary in the head or neck seldom metastasize to the cervical lymph nodes, the supraclavicular lymph nodes are quite often involved by lung, gastroesophageal, and breast cancers. Infradiaphragmatic cancers, with the exception of renal cell carcinoma and testicular cancer, rarely metastasize to the neck.

Patel MR et al. The widespread application of trans-oral robotic surgery in HPV-related head and neck cancer: one size does not fit all. J Natl Cancer Inst. 2025;117:388. [PMID: 39699215]

LYMPHOMA

About 10% of lymphomas present in the head and neck. Multiple rubbery nodes, especially in young adults or in patients who have AIDS, are suggestive of lymphoma. A thorough physical examination may demonstrate other sites of nodal or organ involvement. FNA biopsy may be diagnostic, but open biopsy is often required to determine architecture and an appropriate treatment course.

Belinda Rivera-Lebron, MD, MS, FCCP

DISORDERS OF THE AIRWAYS

Disorders of the airways can be classified as those that involve the upper airways—those above and including the vocal folds—and those that involve the lower airways.

DISORDERS OF THE UPPER AIRWAYS

Acute obstruction of the upper airway can be immediately life-threatening and must be relieved promptly to avoid asphyxia. Causes of acute upper airway obstruction include trauma to the larynx or pharynx, foreign body aspiration, laryngospasm, laryngeal edema or angioedema, infections (acute epiglottitis, Ludwig angina, pharyngeal or retropharyngeal abscess), and acute allergic laryngitis.

Chronic obstruction of the upper airway may be caused by goiter, carcinoma of the pharynx or larynx, laryngeal or subglottic stenosis, laryngeal granulomas or webs, or bilateral vocal fold paralysis. Laryngeal or subglottic stenosis may become evident weeks or months after endotracheal intubation. Laryngomalacia refers to the collapse of the supraglottic structures during inspiration. Inspiratory stridor, intercostal retractions on inspiration, a palpable inspiratory thrill over the larynx, and wheezing localized to the neck or trachea on auscultation are characteristic findings. Flow-volume loops may show characteristic flow limitations. Soft-tissue radiographs of the neck may show supraglottic or subglottic narrowing. CT and MRI scans can reveal exact sites of obstruction. Flexible endoscopy may be diagnostic, but caution is necessary to avoid exacerbating upper airway edema and precipitating critical airway narrowing.

Vocal fold dysfunction (also known as **inducible laryngeal obstruction [ILO]**) is characterized by transient, reversible narrowing of the larynx due to paradoxical vocal fold adduction during inspiration, expiration, or both. It presents as dyspnea and wheezing that may mimic asthma or exercise-induced asthma but may be distinguished by the lack of response to bronchodilator therapy, normal spirometry immediately after an attack, spirometric evidence of upper airway obstruction in a flow-volume loop, and a negative bronchial provocation test. However, vocal fold dysfunction may coexist with asthma or may be induced by exercise (exercise-induced laryngeal obstruction), inhalational irritant exposures (smoke, fumes, cleaning chemicals), laryngopharyngeal reflux of gastric contents, or psychological stress. Definitive diagnosis requires direct visualization of adduction of the vocal folds on inspiration. Acute treatment consists of reassurance and supportive care until the episode spontaneously subsides; continuous positive airway pressure or helium-oxygen mixture (heliox) also can be utilized. For long-term prevention, avoidance of precipitants (including psychogenic contributors) and speech therapy are utilized. Botulinum toxin injections have been used in refractory cases to treat bilateral vocal fold hypomobility, laryngeal dystonia, and inducible laryngeal obstruction.

Koh J et al. A new paradigm for vocal cord dysfunction/inducible laryngeal obstruction: swift diagnosis and streamlined management pathways. Respirology. 2023;28:911. [PMID: 37612245]

Leong P et al. Diagnosis of vocal cord dysfunction/inducible laryngeal obstruction: an international Delphi consensus study. J Allergy Clin Immunol. 2023;152:899. [PMID: 37343843]

DISORDERS OF THE LOWER AIRWAYS

Tracheal obstruction may be intrathoracic (below the suprasternal notch) or extrathoracic. Fixed tracheal obstruction may be caused by acquired or congenital tracheal stenosis, primary or secondary tracheal neoplasms, extrinsic compression (tumors of the lung, thymus, or thyroid; lymphadenopathy; congenital vascular rings; aneurysms; etc), foreign body aspiration, tracheal granulomas and papillomas, tracheal trauma, or idiopathic subglottic stenosis. Variable or dynamic tracheal obstruction may be caused by tracheomalacia, foreign body aspiration, and retained secretions.

Acquired **tracheal stenosis** is usually secondary to previous tracheotomy or endotracheal intubation. Daily endotracheal tube (ETT) care including monitoring cuff pressure (ideally, 20–30 cm H_2O) to avoid overinflation, oral and endotracheal suctioning of secretions, and regular ETT rotation may help prevent tracheal stenosis. Onset of symptoms usually occurs weeks to months after tracheal decannulation or extubation. Symptoms may include dyspnea, dysphonia, dysphagia, cough, and inability to clear pulmonary secretions, but mild stenosis may be asymptomatic. Physical findings may be absent until tracheal diameter is reduced 50% or more, when wheezing, a palpable tracheal thrill, and harsh breath sounds may be detected. The diagnosis is confirmed by CT of the trachea, PFT with flow-volume loop or bronchoscopy. Management options include balloon dilation, surgical resection with reconstruction, stent placement, or laser. Tracheostomy may be considered in those with refractory disease.

Bronchial obstruction may be caused by retained pulmonary secretions, aspiration, foreign bodies, bronchomalacia, bronchogenic carcinoma, compression by extrinsic masses, and tumors metastatic to the airway. Clinical and radiographic findings vary depending on the location of the obstruction and the degree of airway narrowing. Symptoms include dyspnea, cough, wheezing, and, if infection is present, fever and chills. A history of recurrent pneumonia in the same lobe or segment or slow resolution (> 3 months) of pneumonia on successive radiographs suggests the possibility of bronchial obstruction and the need for bronchoscopy. Radiographic findings include atelectasis (local parenchymal collapse), postobstructive infiltrates, and air trapping caused by unidirectional expiratory obstruction. CT scanning may demonstrate the nature and exact location of obstruction. Bronchoscopy is the definitive diagnostic study, particularly if tumor or foreign body aspiration is suspected. Management includes the use of bronchoscopic electrocautery, argon plasma coagulation, and laser and radiofrequency ablation.

ASTHMA

ESSENTIALS OF DIAGNOSIS

- Respiratory symptoms, such as wheeze, dyspnea, or cough, which may be variable in time and severity.
- Variable expiratory airflow obstruction on PFT or positive bronchoprovocation challenge.

General Considerations

Asthma is a common disease, affecting approximately 5–10% of the population. It is more common in male than female children (7% versus 5.4%) and in female than male adults (10.8 versus 6.5%). There is a genetic predisposition to asthma, and rates vary by race and ethnicity. In the United States, Black persons are 44% more likely than White persons to have asthma. Prevalence, hospitalizations, and fatal asthma have all increased in the United States over the past 20 years. Each year, approximately 10 million office visits, 1.8 million emergency department visits, and > 3500 deaths in the United States are attributed to asthma. Hospitalization rates are highest among Black persons and children, and death rates are consistently highest among Black persons aged 15–24 years. The National Asthma Education and Prevention Program (NAEPP) and the Global Initiative for Asthma (GINA) report provide a comprehensive and updated resources that address asthma diagnosis, assessment, management, and evidence-based recommendations.

Definition & Pathogenesis

Asthma is a chronic disorder of the airways that results in an array of respiratory symptoms and signs and is characterized by variable levels of airway expiratory obstruction and hyperresponsiveness. The most common pathogeneses of asthma include airway inflammation with eosinophils, neutrophils, and lymphocytes (especially T cells); goblet cell hyperplasia; plugging of small airways with mucus; collagen deposition beneath the basement membrane; bronchial smooth muscle hypertrophy; airway edema; mast cell activation; and denudation of airway epithelium. The pathophysiology of asthma is heterogeneous, but a division into T2-high and T2-low endotypes (marked by high and low levels, respectively, of classic Th2 cytokines such as interleukin [IL]-4, IL-5, and IL-13) has been shown to be important in the selection of targeted biologic therapies.

Many clinical phenotypes of asthma have been identified. The most common is **allergic asthma**, which usually begins in childhood and is associated with other allergic diseases (eg, eczema, allergic rhinitis, food allergy). Exposure of sensitive patients to inhaled allergens may cause symptoms immediately (early asthmatic response) or 4–6 hours after allergen exposure (late asthmatic response). Common allergens include house dust mites (often found in pillows, mattresses, upholstered furniture, carpets, and drapes), cockroaches, cat dander, and seasonal pollens. In response to inhaled triggers (eg, allergens, respiratory pathogens, particulate matter), epithelial-derived interleukins are produced which play a key role in activating downstream Th2 cells, group 2 innate lymphoid cells (ILC2s), and other immune effector cells.

Allergic asthma, late-onset T2-high asthma, and **aspirin/NSAID-associated respiratory disease** are T2-high phenotypes. Teo2-low asthma phenotypes include **nonallergic asthma**, which tends to occur in adults and be marked by neutrophilic inflammation and variable response to standard therapies. **Asthma with persistent airflow limitation** is thought to be due to airway remodeling. **Asthma with obesity** refers to prominent respiratory symptoms in patients with obesity with little airway inflammation.

Nonspecific precipitants of asthma include upper respiratory tract infections, rhinosinusitis, postnasal drip, aspiration, gastroesophageal reflux, changes in the weather, stress, and exercise. Exposure to **products of combustion** (eg, tobacco, methamphetamines, diesel fuel, and other agents) increases asthma symptoms and the need for medications and reduces lung function. **Air pollution** (increased air levels of respirable particles, ozone, SO_2, and NO_2) precipitates asthma symptoms and increases emergency department visits and hospitalizations. Selected individuals may experience asthma symptoms after exposure to aspirin (aspirin-exacerbated respiratory disease), NSAIDs, or tartrazine dyes. Other **medications** may precipitate asthma symptoms (see Table 9–23). **Occupational asthma** is triggered by various agents in the workplace and may occur weeks to years after initial exposure and sensitization. Women may experience **catamenial asthma** at predictable times during the menstrual cycle. **Exercise-induced bronchoconstriction** begins during exercise or within 3 minutes after its end, peaks within 10–15 minutes, and then resolves by 60 minutes. This phenomenon is thought to be a consequence of the airways' warming and humidifying an increased volume of expired air during exercise. **Cough-variant asthma** has cough instead of wheezing as the predominant symptom of bronchial hyperreactivity.

Clinical Findings

Symptoms and signs vary widely among patients as well as within individuals over time. The level of asthma control is assessed by the frequency of day and nighttime symptoms and need for reliever medications as listed in Table 9–1.

A. Symptoms and Signs

Asthma symptoms include episodic wheezing, shortness of breath, chest tightness, and cough. Symptoms vary over time and in intensity and are often worse at night or in the early morning. Asthma symptoms may occur spontaneously or be precipitated or exacerbated by many different triggers, as discussed above.

Some physical examination findings increase the probability of asthma. Nasal mucosal swelling, increased secretions, and polyps are often seen in patients with allergic asthma. Eczema, atopic dermatitis, or other allergic skin disorders may also be present. Wheezing, a prolonged expiratory phase, or both during normal breathing are suggestive of airflow obstruction; wheezing during forced expiration does not. Chest examination may be normal between exacerbations in patients with mild asthma. During severe asthma exacerbations, airflow may be too limited to produce wheezing, and the only diagnostic clue on auscultation may be globally reduced breath sounds with prolonged expiration. Hunched shoulders and use of accessory muscles of respiration suggest an increased work of breathing.

B. Laboratory Findings

The T2-high phenotype of asthma is associated with eosinophilia. A blood eosinophil count > 150–300 cells/mcL is recommended for classifying the eosinophilic phenotype according to the European Respiratory Society and the American Thoracic Society and identifies persons with severe asthma who are candidates for targeted monoclonal antibody therapies. Serum IgE may also be helpful to guide selection of biologic therapy in persons with moderate to severe asthma or when allergic bronchopulmonary aspergillosis is suspected.

C. Pulmonary Function Testing

Pulmonary function testing with either spirometry or PEF measurements are important for the diagnosis and management of patients with asthma.

Important **spirometry measurements** include FEV_1, FVC, and FEV_1/FVC before and after the administration of a short-acting bronchodilator. These measurements help determine the presence and extent of airflow obstruction and whether it is immediately reversible. Airflow obstruction is indicated by a reduced FEV_1/FVC ratio, generally below 0.7 or the lower limit of normal. Significant reversibility of airflow obstruction was previously defined by an increase of 12% or more and 200 mL in FEV_1 or FVC after inhaling a short-acting bronchodilator. Recommendations by the American Thoracic Society and the European

Table 9–1. Assessing asthma control.

Components of Asthma Control	Classification of Asthma Control		
	Well Controlled	Partly Controlled	Not Controlled
Daytime asthma symptoms > 2 ×/week Nighttime awakenings due to asthma Interference with normal activity due to asthma Reliever medication needed for asthma symptoms > 2 ×/week	None of these components within past 4 weeks	1 or 2 of these components within past 4 weeks	3 or 4 of these components within past 4 weeks

Adapted from National Asthma Education and Prevention Program. Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. National Institutes of Health Pub. No. 08-4051. Bethesda, MD, 2007, and Global Initiative for Asthma. Global Strategy for Asthma Management and Prevention 2022. Available at https://ginasthma.org

Respiratory Society Technical Standards Committee define a bronchodilator response by an increase in FEV_1 or FVC of > 10% relative to the predicted value. A positive bronchodilator response supports the diagnosis of asthma, but a lack of responsiveness does not exclude the diagnosis in a person who currently lacks obstruction. Severe airflow obstruction can result in air trapping, with an increase in residual volume (RV) and consequent reduction in FVC, mimicking a restrictive ventilatory defect pattern.

Bronchoprovocation testing with inhaled histamine or methacholine may be useful when asthma is suspected despite nondiagnostic spirometry. Bronchial provocation is not recommended if the FEV_1 is < 65% of predicted. A positive methacholine test is defined as a fall in the FEV_1 of 20% or more at exposure to a methacholine concentration of ≤ 8 mg/mL. A negative methacholine test has a negative predictive value for asthma of 95%. Exercise challenge testing may be useful in patients with symptoms of exercise-induced bronchospasm.

PEF meters are handheld devices designed as personal monitoring tools. PEF monitoring can establish peak flow variability, quantify asthma severity, and provide both patient and clinician with relatively objective measurements on which to base treatment titration decisions. Reliability of peak flow measurements may be affected by incorrect calibration and patient technique or effort. Comparison with reference values is less helpful than comparison with the patient's own baseline. PEF shows diurnal variation; it is generally lowest on first awakening and highest several hours before the midpoint of the waking day. PEF should be measured in the morning before the administration of a bronchodilator and in the afternoon after taking a bronchodilator. A 20% change in PEF values from morning to afternoon or from day to day suggests inadequately controlled asthma. PEF values < 200 L/min indicate severe airflow obstruction.

D. Additional Testing

Routine CXRs in patients with asthma are usually normal or only show hyperinflation. Chest imaging is indicated when pneumonia, which may mimic asthma, or a complication of asthma (eg, pneumothorax) is suspected.

Evaluations for paranasal sinus disease or gastroesophageal reflux should be considered in patients with persistent, severe, or refractory asthma symptoms.

Complications

Complications of asthma include exhaustion, dehydration, airway infection, tussive syncope, and, rarely, pneumothorax. Acute hypercapnic and hypoxemic respiratory failure occurs in severe disease.

Differential Diagnosis

Patients who have atypical symptoms or poor response to therapy may have one of several conditions that mimic asthma. **Upper airway disorders** that mimic asthma include vocal fold paralysis, vocal fold dysfunction syndrome, narrowing of the supraglottic airway, and laryngeal masses or dysfunction. **Lower airway disorders** include foreign body aspiration, tracheal masses or narrowing, tracheobronchomalacia, airway edema (eg, angioedema or inhalation injury), nonasthmatic COPD (chronic bronchitis or emphysema), bronchiectasis, allergic bronchopulmonary aspergillosis (mycosis), cystic fibrosis, eosinophilic pneumonia, hypersensitivity pneumonitis, sarcoidosis, and bronchiolitis obliterans. A **systemic vasculitis** with pulmonary involvement may have an asthmatic component, such as eosinophilic granulomatosis with polyangiitis. **Cardiac disorders** include HF ("cardiac asthma") and pulmonary hypertension. **Psychiatric causes** include conversion disorders ("functional" asthma), emotional laryngeal wheezing, or episodic laryngeal dyskinesis. Rarely, Münchausen syndrome or malingering may explain a patient's symptom presentation.

Approach to Management

Personalized asthma management is a continuous cycle that involves assessment, treatment adjustment, and periodic review with the goals of optimal symptom control; minimization of future risks, including exacerbations; and prevention of asthma-related deaths, as recommended in the updated 2024 GINA report. **Asthma assessment** includes the level of asthma control, risk factors for exacerbations, asthma severity, treatment adjustment, and periodic lung function testing.

1. Asthma control—Level of control is assessed by evaluating symptoms. Patients are asked about their past 4 weeks including frequency of symptoms (days per week), awakening from sleep, and use of reliever therapy (short-acting β-agonist [SABA], inhaled corticosteroid [ICS]-formoterol, or ICS-SABA) for symptom relief (Table 9–1). Patients should also be asked about activity limitation.

2. Risk factors for exacerbations—Poor symptom control increases risk of exacerbations. Other risk factors include more than one exacerbation in the previous year; inadequate ICS use (due to under-treatment, poor adherence, or incorrect inhaler technique); and other comorbidities, such as chronic sinusitis, GERD, obesity, and smoking.

3. Asthma severity—Severity is evaluated retrospectively from the level of treatment needed to control symptoms and exacerbations. Table 9–2 describes the step therapy in a personalized asthma management plan. Typically, mild asthma responds to Step 1 or 2 treatments, moderate asthma to Step 3 treatment, and severe asthma to Step 4 or 5 treatments. It is important to distinguish between uncontrolled and severe asthma in patients who are using Step 4 or Step 5 treatments. The clinician must assess inhaler technique, medication adherence, comorbidities (eg, obstructive sleep apnea, GERD), and ongoing exposure to allergens as causes of poor asthma control ("uncontrolled" asthma). If the patient still requires Step 4 or 5 therapy after these issues have been addressed, then the patient has "severe" asthma and should be referred to a pulmonary or asthma specialist. Serial lung function testing is beneficial

Table 9–2. Step therapy in personalized asthma management plan.

	Preferred	Alternative
Steps 1 and 2	Low-dose ICS-formoterol as needed **or** Low-dose ICS daily and SABA as needed **or** Concomitant ICS and SABA as needed	LTRA daily and SABA as needed **or** Cromolyn **or** Nedocromil **or** Zileuton **or** Theophylline and SABA as needed
Step 3	Combination low-dose ICS plus formoterol daily and as needed	Medium-dose ICS daily and SABA as needed **or** Low-dose ICS-LABA daily **or** Low-dose ICS **plus** LAMA daily **or** Low-dose ICS **plus** LTRA and SABA as needed **or** Low-dose ICS daily **plus** theophylline or zileuton and SABA as needed
Step 4	Combination medium-dose ICS-formoterol daily and as needed	Medium-dose ICS-LABA daily **or** Medium-dose ICS **plus** LAMA daily and SABA as needed **or** Medium-dose ICS **plus** LTRA daily **or** Medium-dose ICS **plus** zileuton daily and SABA as needed **or** Medium-dose ICS **plus** theophylline daily
Step 5	Medium-high dose ICS-LABA plus LAMA and SABA as needed	Medium-high dose ICS-LABA daily **or** High-dose ICS **plus** LTRA and SABA as needed
Step 6	High-dose ICS-LABA plus oral systemic corticosteroids plus SABA as needed	

at time of diagnosis, 3–6 months after treatment initiation, and periodically thereafter but is not necessarily needed at every visit.

4. Treatment adjustment—The goals of asthma therapy are to minimize chronic symptoms that interfere with normal activity (including exercise), prevent recurrent exacerbations, reduce or eliminate the need for emergency department visits or hospitalizations, and maintain normal or near-normal pulmonary function. A multidisciplinary approach using pharmacologic and nonpharmacologic strategies is best to address disease pathogenesis and modifiable risk factors. Pharmacologic agents that satisfy the patient's expectations of asthma care with the fewest adverse events should be prescribed. Management should include stepping up therapy if asthma remains uncontrolled despite adherence and good inhaler technique and stepping down if asthma is well controlled to find the minimum effective therapeutic dose. Nonpharmacologic interventions include increasing physical activity and breathing exercises. Significant reduction in exposure to nonspecific airway irritants in all patients or to inhaled allergens in atopic patients may reduce symptoms and medication needs. Comorbid conditions that impair asthma management (eg, smoking, rhinosinusitis, GERD, obesity, obstructive sleep apnea) should be identified and treated. The asthma plan of care, level of symptom control, and patient satisfaction should be reviewed on a periodic basis and facilitated by guided patient self-management education and skills training. Self-management includes self-monitoring of symptoms or peak flow; a written action plan; and regular review of asthma control, treatment, and skills with a health care professional.

5. Periodic lung function testing—Serial spirometry is beneficial at time of diagnosis, 3–6 months after treatment initiation, and periodically thereafter to monitor the disease trajectory and response to therapy.

Treatment

A. Pharmacologic Agents

Asthma medications can be divided into three categories: (1) **long-term controller** medications (Table 9–3) used long-term to reduce airway inflammation, symptoms, and risk of future exacerbations, (2) **reliever** medications (Table 9–4) used on an as-needed basis to relieve breakthrough symptoms, and (3) **add-on therapies** for severe asthma. See Table 9–2 for a personalized management plan for asthma to control symptoms and minimize future risk.

Most asthma medications are administered by inhalation or oral dosing. Inhalation of an appropriate agent results in a more rapid onset of pulmonary effects and fewer systemic effects compared with the oral dose required to achieve the same effect. Proper inhaler technique and the use of an inhalation chamber (a "spacer") with metered-dose inhalers (MDIs) decrease oropharyngeal drug deposition and improve drug delivery to the lung. Nebulizer therapy is reserved for patients who are acutely ill and those who cannot use inhalers because of difficulties with coordination, understanding, or cooperation.

1. Inhaled corticosteroids—ICSs are essential controller medications (Tables 9–4 and 9–5). Once the diagnosis of asthma is made, early initiation of ICS therapy leads to a greater improvement in lung function than delayed therapy. Prescribing as-needed or daily controller ICS at the start of asthma therapy conveys a message to patients that both symptom control and risk reduction are the mainstays

Table 9–3. Long-term controller medications for asthma.

Medication	Dosage Form	Adult Dose	Comments
Inhaled Corticosteroids (ICS)			**(See Table 9–5)**
Systemic Corticosteroids			**(Applies to all three corticosteroids)**
Methylprednisolone	2-, 4-, 6-, 8-, 16-, 32-mg tablets	40–60 mg	• Administer single dose in am either daily or on alternate days (alternate-day therapy may produce less adrenal suppression) as needed for control. • Short courses or "bursts" as single or two divided doses for 3–10 days are effective for establishing control when initiating therapy or during a period of gradual deterioration. • There is no evidence that tapering the dose following improvement in symptom control and pulmonary function prevents relapse.
Prednisolone	5-mg tablets; 5 mg/5 mL, 15 mg/5 mL oral solution	40–60 mg	
Prednisone	1-, 2.5-, 5-, 10-, 20-, 50-mg tablets; 5 mg/mL oral solution	7.5–60 mg	
Inhaled LABA			**Should not be used for symptom relief or exacerbations. Use with ICS.**
Formoterol	Inhalation: 20 mcg/2 mL nebulizer (DPI discontinued by US FDA)	20 mcg every 12 hours	• Additional doses should not be administered for at least 12 hours. • Agents should be used only with their specific inhaler and should not be taken orally. • Decreased duration of protection against EIB may occur with regular use.
Salmeterol	DPI: 50 mcg/actuation	1 blister every 12 hours	
Combined Medication			
Budesonide/formoterol	HFA MDI: 80 mcg/4.5 mcg 160 mcg/4.5 mcg	2 inhalations twice daily; dose depends on severity of asthma	• 80/4.5 mcg for asthma not controlled on low- to medium-dose ICS. • 160/4.5 mcg for asthma not controlled on medium- to high-dose ICS.
Fluticasone/salmeterol	DPI: 100 mcg/50 mcg 250 mcg/50 mcg 500 mcg/50 mcg HFA: 45 mcg/21 mcg 115 mcg/21 mcg 230 mcg/21 mcg	1 inhalation twice daily; dose depends on severity of asthma	• 100/50 mcg DPI or 45/21 mcg HFA for asthma not controlled on low- to medium-dose ICS. • 250/50 mcg DPI or 115/21 mcg HFA for asthma not controlled on medium- to high-dose ICS.
Fluticasone furoate/vilanterol	DPI: 100 mcg/25 mcg or 200 mcg/25 mcg per blister	1 puff inhaled daily	• Once-daily asthma maintenance.
Mometasone/formoterol	100 mcg/5 mcg/spray 200 mcg/5 mcg/spray	2 inhalations twice daily	
Cromolyn and Nedocromil			
Cromolyn	MDI: 0.8 mg/puff Nebulizer: 20 mg/ampule	2 puffs four times daily 1 ampule four times daily	• 4- to 6-week trial may be needed to determine maximum benefit. • Dose by MDI may be inadequate to affect hyperresponsiveness. • One dose before exercise or allergen exposure provides effective prophylaxis for 1–2 hours. Not as effective for EIB as SABA. • Once control is achieved, the frequency of dosing may be reduced.
Nedocromil	MDI: 1.75 mg/puff	2 puffs four times daily	
Inhaled Long-Acting Anticholinergic			**Should not be used for symptom relief or exacerbations. Use with ICS.**
Tiotropium	DPI: 18 mcg/blister	1 blister daily	
Leukotriene Receptor Antagonists			
Montelukast	4- or 5-mg chewable tablet; 10-mg tablet	10 mg daily at bedtime	• Exhibits a flat dose-response curve. Doses > 10 mg will not produce a greater response in adults.

(continued)

Table 9–3. Long-term controller medications for asthma. (continued)

Medication	Dosage Form	Adult Dose	Comments
Zafirlukast	10- or 20-mg tablet	20-mg tablet twice daily	• Administration with meals decreases bioavailability; take at least 1 hour before or 2 hours after meals. • Monitor for symptoms and signs of hepatic dysfunction.
5-Lipoxygenase Inhibitor			
Zileuton	600-mg tablet	600 mg four times daily	• Monitor hepatic enzyme (ALT).
Methylxanthines			
Theophylline	Liquids, sustained-release tablets, and capsules	Starting dose: 10 mg/kg/day up to 300 mg maximum Usual maximum dose: 800 mg/day	• Adjust dose to achieve serum concentration of 5–15 mcg/mL after at least 48 hours on same dose. • Due to wide interpatient variability in theophylline metabolic clearance, routine serum theophylline level monitoring is important.
Monoclonal Antibodies			
Omalizumab	Subcutaneous injection	Dependent on pretreatment IgE level; up to 375 mg every 2 weeks	• Binds to IgE; prevents interaction with IgE receptor on mast cells and basophils. • Carries black-box warning of anaphylaxis. • Suggested IgE level 30–1500 IU/mL.
Mepolizumab	Subcutaneous injection	100 mg every 4 weeks	• Binds to IL-5; prevents interaction with receptor. • Suggested AEC ≥ 150–300/mcL (0.15–0.3 × 10^9/L).
Reslizumab	Intravenous injection	3 mg/kg every 4 weeks	• Binds to IL-5; prevents interaction with receptor. • Carries black-box warning of anaphylaxis. • Suggested AEC ≥ 400/mcL (0.4 × 10^9/L).
Benralizumab	Subcutaneous injection	30 mg every 4 weeks for 3 doses, then every 8 weeks	• Binds to IL-5 receptor; blocks receptor-ligand interaction and also causes apoptosis of basophils and eosinophils. • Suggested AEC ≥ 300/mcL (0.3 × 10^9/L).
Dupilumab	Subcutaneous injection	200 or 300 mg every 2 weeks	• Binds to IL-4Rα; blocks IL-4 and IL-13 signaling. • Suggested AEC ≥ 150/mcL (0.15 × 10^9/L) or FENO ≥ 25 ppb, or both.

AEC, absolute eosinophil count; DPI, dry powder inhaler; EIB, exercise-induced bronchospasm; FENO, fractional exhaled nitric oxide; HFA, hydrofluoroalkane; LABA, long-acting β_2-agonist; MDI, metered-dose inhaler; SABA, short-acting β_2-agonist.

of asthma treatment. The most important determinants of medication choice, device, and dose are a patient's symptoms and risk factors, along with practical issues (eg, cost, delivery mechanism). ICS dosages are classified as low-, medium-, and high-dose strengths. Dosages for ICS vary depending on the specific agent and delivery device (Table 9–5). For patients who require high-dose ICS to achieve adequate symptom control, the dose of ICS should be decreased after 3 months of good control to the lowest dose that preserves symptom control and minimizes exacerbation risk.

Concomitant use of an MDI and an inhalation chamber coupled with mouth washing after ICS use decreases systemic absorption and local side effects (cough, dysphonia, oropharyngeal candidiasis). Dry powder inhalers (DPIs) are not used with an inhalation chamber. Systemic effects (adrenal suppression, osteoporosis, skin thinning, easy bruising, and cataracts) may occur with high-dose ICS therapy. Combination inhalers with an ICS and a long-acting β_2-agonist (LABA) offer convenient treatment of asthma. The GINA report recommends low-dose inhaled corticosteroid/formoterol as its preferred agent due to clinical evidence but notes that its cost and availability in different countries must be taken into consideration. Budesonide/formoterol is listed as a WHO essential medication.

2. β-Agonists—β-Agonists are divided into SABAs and LABAs. SABAs (Table 9–4), including albuterol, levalbuterol, bitolterol, pirbuterol, and terbutaline, are

Table 9–4. Reliever medications for asthma.

Medication	Dosage Form	Adult Dose	Comments
Inhaled Short-Acting β_2-Agonists (SABA)			
Albuterol CFC	MDI: 90 mcg/puff, 200 puffs/canister	2 puffs 5 minutes before exercise 2 puffs every 4–6 hours as needed	• An increasing use or lack of expected effect indicates diminished control of asthma. • Not recommended for long-term daily treatment. Regular use exceeding 2 days/week for symptom control (not prevention of EIB) indicates the need to step up therapy. • Differences in potency exist, but all products are essentially comparable on a per-puff basis. • May double usual dose for mild exacerbations. • Prime the inhaler by releasing four actuations before use. • Periodically clean HFA activator, as drug may block/plug orifice.
Albuterol HFA	MDI: 90 mcg/puff, 200 puffs/canister	2 puffs 5 minutes before exercise 2 puffs every 4–6 hours as needed	
Pirbuterol CFC	MDI: 200 mcg/puff, 400 puffs/canister	2 puffs 5 minutes before exercise 2 puffs every 4–6 hours as needed	
Levalbuterol HFA	MDI: 45 mcg/puff, 200 puffs/canister	2 puffs 5 minutes before exercise 2 puffs every 4–6 hours as needed	
Albuterol	Nebulizer solution: 0.63 mg/3 mL 1.25 mg/3 mL 2.5 mg/3 mL 5 mg/mL (0.5%)	1.25–5 mg in 3 mL of saline every 4–8 hours as needed	• May mix with budesonide inhalant suspension, cromolyn, or ipratropium nebulizer solutions. • May double dose for severe exacerbations.
Levalbuterol (R-albuterol)	Nebulizer solution: 0.31 mg/3 mL 0.63 mg/3 mL 1.25 mg/0.5 mL 1.25 mg/3 mL	0.63–1.25 mg every 8 hours as needed	• Compatible with budesonide inhalant suspension. The product is a sterile-filled, preservative-free, unit dose vial.
Anticholinergics			
Ipratropium HFA	MDI: 17 mcg/puff, 200 puffs/canister	2–3 puffs every 6 hours	• Evidence is lacking for anticholinergics producing added benefit to β_2-agonists in long-term asthma control therapy.
	Nebulizer solution: 0.25 mg/mL (0.025%)	0.25 mg every 6 hours	
Ipratropium with albuterol	MDI: 18 mcg/puff of ipratropium bromide and 90 mcg/puff of albuterol, 200 puffs/canister	2–3 puffs every 6 hours	
	Nebulizer solution: 0.5 mg/3 mL ipratropium bromide and 2.5 mg/3 mL albuterol	3 mL every 4–6 hours	• Contains EDTA to prevent discolorations of the solution. This additive does not induce bronchospasm.
Anti-Inflammatory Relievers (Low-Dose ICS and Rapid Acting Bronchodilator)			
ICS-Albuterol	Albuterol/Budesonide MDI: 90 mcg/80 mcg per actuation	2 puffs every 4 hours as needed	Max 12 puffs/day
Budesonide/Formoterol	MDI: 80 mcg/4.5 mcg per actuation	1–2 puffs every 4 hours as needed	• Max 12 puffs/day including total maintenance plus as needed, delivering maximum 54 mcg of formoterol. • Should not be used as reliever if maintained on different ICS/LABA.
Beclomethasone/Formoterol	MDI: 100 mcg/6 mcg per actuation	1–2 puffs every 4 hours as needed	Max 8 inhalations per day
Systemic Corticosteroids			
Methylprednisolone	2-, 4-, 6-, 8-, 16-, 32-mg tablets	40–60 mg/day as single or 2 divided doses	• Short courses or “bursts” are effective for establishing control when initiating therapy or during a period of gradual deterioration. • The burst should be continued until symptoms resolve and the PEF is at least 80% of personal best. This usually requires 3–10 days but may require longer. There is no evidence that tapering the dose following improvements prevents relapse.

(*continued*)

Table 9–4. Reliever medications for asthma. (continued)

Medication	Dosage Form	Adult Dose	Comments
Prednisolone	5-mg tablets; 5 mg/5 mL, 15 mg/5 mL oral solution	40–60 mg/day as single or 2 divided doses	
Prednisone	1-, 2.5-, 5-, 10-, 20-, 50-mg tablets; 5 mg/mL oral solution	40–60 mg/day as single or 2 divided doses	
Methylprednisolone acetate	Repository injection: 40 mg/mL 80 mg/mL	240 mg intramuscularly once	• May be used in place of a short burst of oral corticosteroids in patients who are vomiting or if adherence is a problem.

CFC, chlorofluorocarbon; EIB, exercise-induced bronchospasm; HFA, hydrofluoroalkane; MDI, metered-dose inhaler.
Adapted from National Asthma Education and Prevention Program. Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. National Institutes of Health Pub. No. 08-4051. Bethesda, MD, 2007.

mainstays of reliever or rescue therapy for asthma patients. There is no convincing evidence to support the use of one agent over another. All patients with asthma should have immediate access to a reliever therapy with rapid onset bronchodilator containing a β-agonist; relievers can be SABA, ICS-SABA, or ICS-formoterol. The use of anti-inflammatory relievers on as needed basis for symptom relief may decrease the rate of exacerbation. Administration before exercise effectively prevents exercise-induced bronchoconstriction.

Inhaled SABA therapy is as effective as oral or parenteral β-agonist therapy in relaxing airway smooth muscle and improving acute asthma and offers the advantages of rapid onset of action (< 5 minutes) with fewer systemic side effects. Repetitive administration produces incremental bronchodilation. One or two inhalations of a SABA from an MDI are usually sufficient for mild to moderate symptoms. Severe exacerbations frequently require higher doses: 6–12 puffs every 30–60 minutes of albuterol by MDI with an inhalation chamber or 2.5 mg by nebulizer provide

Table 9–5. Estimated clinically comparable daily dosages for inhaled corticosteroids for adults with asthma.

Medication	Low Daily Dose	Medium Daily Dose	High Daily Dose
Beclomethasone dipropionate HFA 40 or 80 mcg/puff	80–240 mcg	> 240–480 mcg	> 480 mcg
Budesonide dipropionate DPI 90, 180, or 200 mcg/inhalation	180–400 mcg	> 400–800 mcg	> 800 mcg
Flunisolide 250 mcg/puff	500–1000 mcg	> 1000–2000 mcg	> 2000 mcg
Flunisolide HFA 80 mcg/puff	320 mcg	> 320–640 mcg	> 640 mcg
Fluticasone propionate **HFA/MDI:** 44, 110, or 220 mcg/puff **DPI:** 50, 100, or 250 mcg/inhalation	88–264 mcg 100–300 mcg	> 264–440 mcg > 300–500 mcg	> 440 mcg > 500 mcg
Mometasone furoate DPI 200 mcg/puff	200 mcg	400 mcg	> 400 mcg
Triamcinolone acetonide 75 mcg/puff	300–750 mcg	> 750–1500 mcg	> 1500 mcg

DPI, dry powder inhaler; HFA, hydrofluoroalkane; MDI, metered-dose inhaler.
Notes:

- The most important determinant of appropriate dosing is the clinician’s judgment of the patient’s response to therapy. Most of clinical benefit from inhaled corticosteroid therapy is seen at low doses; responsiveness varies among patients.
- Potential drug interactions: Several inhaled corticosteroids, including fluticasone, budesonide, and mometasone, are metabolized in the GI tract and liver by CYP 3A4 isoenzymes. Potent inhibitors of CYP 3A4, such as ritonavir and ketoconazole, have the potential for increasing systemic concentrations of these inhaled corticosteroids by increasing oral availability and decreasing systemic clearance. Some cases of clinically significant Cushing syndrome and secondary adrenal insufficiency have been reported.

Adapted from National Asthma Education and Prevention Program. Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. National Institutes of Health Pub. No. 08-4051. Bethesda, MD, 2007, and Global Initiative for Asthma. Global Strategy for Asthma Management and Prevention, 2019. (Available from: www.ginasthma.org.)

equivalent bronchodilation. Administration by nebulization does not offer more effective delivery than MDIs used correctly but does provide higher doses. With most SABAs, the recommended dose by nebulizer for acute asthma (albuterol, 2.5 mg) is 25–30 times that delivered by a single activation of the MDI (albuterol, 0.09 mg). This difference suggests that standard dosing of inhalations from an MDI may be insufficient in the setting of an acute exacerbation. Independent of dose, nebulizer therapy may be more effective in patients who are unable to coordinate inhalation of medication from an MDI because of age, agitation, or severity of the exacerbation.

GINA recommends against SABA-only treatment of asthma in adults or adolescents and does not recommend scheduled daily use of SABAs. Although SABA is effective as a quick relief medication, patients who are treated with SABA alone are at increased risk for asthma-related death and urgent health care even if their symptoms are controlled.

LABAs provide bronchodilation for up to 12 hours after a single dose. Salmeterol and formoterol are LABAs available for asthma in the United States. In combination with an ICS, they are indicated for maintenance therapy of asthma. LABAs should not be used as monotherapy because they have no anti-inflammatory effect and because monotherapy has been associated with a small but significant increased risk of severe or fatal asthma attacks in two large studies. Based on clinical trial data in patients with mild asthma, combination inhalers containing formoterol and low-dose budesonide are the preferred option, which have demonstrated a 64% reduction in severe exacerbations compared with SABA-only treatment and noninferiority for severe exacerbations compared to low-dose ICS alone.

3. Systemic corticosteroids—Systemic corticosteroids (oral prednisone or prednisolone or parenteral methylprednisolone) are most effective in achieving prompt control of asthma during acute exacerbations. Systemic corticosteroids are effective as primary treatments for patients with moderate to severe asthma exacerbations and for patients with exacerbations that do not respond promptly and completely to inhaled SABA therapy. These medications speed the resolution of airflow obstruction and reduce the rate of relapse. Delays in administering corticosteroids may result in progressive impairment. Therefore, patients with moderate to severe asthma should be prescribed oral corticosteroids so they are available for early, at-home administration, when needed. The minimal effective dose of systemic corticosteroids for asthma patients has not been identified. Outpatient prednisone “burst” therapy is 0.5–1 mg/kg/day (typically 40–60 mg) in 1–2 doses for 3–7 days. Severe exacerbations requiring hospitalization typically require 1 mg/kg of prednisone or methylprednisolone every 6–12 hours for 48 hours or until the FEV_1 (or PEF rate) returns to 50% of predicted (or 50% of baseline). The dose is then decreased to 0.5 mg/kg/day until the PEF reaches 70% of predicted or personal best. No clear advantage has been found for higher doses of corticosteroids. It may be prudent to administer corticosteroids intravenously to critically ill patients to avoid concerns about altered GI absorption.

In patients with refractory, poorly controlled asthma, or patients with frequent exacerbations despite optimized inhaler therapy, systemic corticosteroids may be required for the long-term suppression of symptoms. Repeated efforts should be made to reduce the dose to the minimum needed to control symptoms. Concurrent treatment with calcium supplements and vitamin D should be initiated to prevent corticosteroid-induced bone mineral loss with long-term administration. Bone mineral density testing after 3 or more months of cumulative systemic corticosteroid exposure can guide the use of bisphosphonates for treatment of steroid-induced osteoporosis. Rapid discontinuation of systemic corticosteroids after long-term use may precipitate adrenal insufficiency.

4. Anticholinergics—Anticholinergic agents reverse vagally mediated bronchospasm but not allergen- or exercise-induced bronchospasm. They may decrease mucous gland hypersecretion. Both **short-acting muscarinic antagonists** (SAMAs) and **long-acting muscarinic antagonists** (LAMAs) are available. Ipratropium bromide, a SAMA, is less effective than SABA for relief of acute bronchospasm but is the inhaled drug of choice for patients with intolerance to SABA or bronchospasm due to β-blocker medications. Ipratropium bromide reduces the rate of hospital admissions when added to inhaled SABAs in patients with moderate to severe asthma exacerbations. Studies have shown that the addition of tiotropium to medium-dose ICS and salmeterol improves lung function and reduces the frequency of asthma exacerbations.

5. Leukotriene modifiers—Leukotrienes are potent mediators that contribute to airway obstruction and asthma symptoms by contracting airway smooth muscle, increasing vascular permeability and mucous secretion, and attracting and activating airway inflammatory cells. **Zileuton** is a 5-lipoxygenase inhibitor that decreases leukotriene production, and **zafirlukast** and **montelukast** are cysteinyl leukotriene receptor antagonists. In RCTs, these agents caused modest improvements in lung function and reductions in asthma symptoms and lessened the need for SABA rescue therapy. These agents are less effective than ICS for exacerbation reduction or as first-line controller therapy but may be considered as alternatives in patients with asthma who are unable to take an ICS or who experience undesirable corticosteroid side effects.

6. Monoclonal antibody agents—Patients with asthma who require monoclonal antibody therapies should be evaluated by either a pulmonologist or allergist experienced in their use. **Omalizumab** is a recombinant antibody that binds IgE without activating mast cells. Clinical trials in patients with moderate to severe asthma and elevated serum IgE levels have found that omalizumab, when administered subcutaneously every 2–4 weeks, reduced the need for corticosteroids. Three other IL-5 antagonist monoclonal antibodies (anti-IL-5/5R) are approved for the treatment of severe asthma with peripheral blood eosinophilia that has not responded to standard treatments: **reslizumab**

(administered intravenously every 4 weeks), **mepolizumab** (administered subcutaneously every 4 weeks), and **benralizumab** (administered subcutaneously every 4–8 weeks). **Dupilumab** is a monoclonal antibody (anti-IL-4Rα) that, when administered subcutaneously every 2 weeks, inhibits overactive signaling of IL-4 and IL-13.

7. Phosphodiesterase inhibitor—Theophylline provides mild bronchodilation in patients with asthma. It also has anti-inflammatory and immunomodulatory properties, enhances mucociliary clearance, and strengthens diaphragmatic contractility. Sustained-release theophylline preparations are effective in controlling nocturnal symptoms and as added therapy in patients with moderate or severe persistent asthma whose symptoms are inadequately controlled by inhaled corticosteroids. Low-dose sustained-release theophylline is included as a less effective option in Step 3 treatment. Neither theophylline nor aminophylline is recommended for therapy of acute asthma exacerbations.

8. Mediator inhibitors—Cromolyn sodium and **nedocromil** are long-term control medications that prevent asthma symptoms and improve airway function in patients with mild persistent or exercise-induced asthma.

B. Desensitization

Immunotherapy for specific allergens may be considered in selected patients with asthma who have exacerbations when exposed to allergens to which they are sensitive and when unresponsive to environmental control measures or other therapies. Studies show a reduction in asthma symptoms in patients treated with single-allergen immunotherapy. Because of the risk of immunotherapy-induced bronchoconstriction, it should be administered only in a setting where such complications can be immediately treated.

C. Vaccination

All adult patients with asthma should receive appropriate pneumococcal, influenza, and COVID-19 vaccination. (See Community Acquired Pneumonia: Prevention for full description.) The use of the intranasal live attenuated influenza vaccine may be associated with asthma exacerbations in young children.

Treatment of Asthma Exacerbations

Asthma expert panels including GINA and National Asthma Education and Prevention Program iterate the importance of patient education in early recognition and intervention of asthma exacerbations. An asthma action plan developed by care providers can assist the patient in their daily routine care and outline worsening signs or symptoms that suggest the need for health care evaluation. Symptoms of exacerbations include progressive breathlessness, increasing chest tightness, decreased peak flow, and lack of improvement after SABA therapy (Table 9–6). Most instances of uncontrolled asthma are mild and may be managed by patients at home with self-management plans. More severe exacerbations with persistent or worsening symptoms require evaluation and management by a health care provider who can assess the patient's exacerbation severity, respiratory status, and risk factors for asthma-related mortality and direct management accordingly (Figure 9–1).

A. Mild to Moderate Exacerbations

Mild asthma exacerbations are characterized by only minor changes in airway function (PEF > 60% of best) with minimal symptoms and signs of airway dysfunction. Many such patients respond quickly and fully to an inhaled SABA alone, or combination glucocorticoid with a fast-acting β-agonist (budesonide-albuterol, budesonide-formoterol) which may need to be continued at increased doses, eg, every 3–4 hours for 24–48 hours. If SABA alone being used, patients may also require a short-term increase in ICS to four times the usual dose. In patients not improving after 48 hours, a 5- to 7-day course of oral corticosteroids (eg, prednisone 0.5–1.0 mg/kg/day) may be necessary.

The principal goals for treating moderate asthma exacerbations are correcting hypoxemia, reversing airflow obstruction, and reducing the likelihood of obstruction recurrence. Early intervention may lessen the severity and shorten the duration of an exacerbation. Airflow obstruction is treated with continuous administration of an **inhaled SABA** and the early administration of **systemic corticosteroids.** Systemic corticosteroids should be given to patients who have a peak flow < 70% of baseline or who do not respond to several treatments of SABA. Serial measurements of lung function to quantify the severity of airflow obstruction and its response to treatment are useful. The improvement in FEV_1 after 30–60 minutes of treatment correlates significantly with the severity of the asthma exacerbation. Serial measurement of airflow in the emergency department may reduce the rate of hospital admissions for asthma exacerbations. Post-exacerbation care planning is important. All patients, regardless of severity, should be provided with (1) necessary medications and how to use them, (2) instruction in self-assessment, (3) a follow-up appointment, and (4) an action plan for managing recurrence.

B. Severe Exacerbations

Severe exacerbations of asthma can be life-threatening and require immediate treatment. Patients should immediately receive **oxygen**, high doses of an **inhaled SABA**, and **systemic corticosteroids**. A brief history pertinent to the exacerbation can be completed while such treatment is being initiated. More detailed assessments, including laboratory studies, add little early on and should be postponed until after therapy is instituted. Early initiation of **oxygen therapy** is paramount because asphyxia is a common cause of asthma deaths. Supplemental oxygen should be given to maintain an $Sao_2 > 90\%$ or a $Pao_2 > 60$ mm Hg. Oxygen-induced hypoventilation is extremely rare in patients with asthma, and concern for hypercapnia should never delay correction of hypoxemia.

Table 9–6. Evaluation and classification of severity of asthma exacerbations.

	Mild	Moderate	Severe	Respiratory Arrest Imminent
Symptoms				
Breathlessness	While walking	At rest, limits activity	At rest, interferes with conversation	While at rest, mute
Talks in	Sentences	Phrases	Words	Silent
Alertness	May be agitated	Usually agitated	Usually agitated	Drowsy or confused
Signs				
Respiratory rate	Increased	Increased	Often > 30/minute	> 30/minute
Body position	Can lie down	Prefers sitting	Sits upright	Unable to recline
Use of accessory muscles, suprasternal retractions	Usually not	Commonly	Usually	Paradoxical thoracoabdominal movement
Wheezing	Moderate, often only end expiratory	Loud; throughout exhalation	Usually loud; throughout inhalation and exhalation	Absent
Pulse/minute	< 100	100–120	> 120	Bradycardia
Pulsus paradoxus	Absent < 10 mm Hg	May be present 10–25 mm Hg	Often present > 25 mm Hg	Absence suggests respiratory muscle fatigue
Functional Assessment				
PEF or FEV$_1$ % predicted or % personal best	≥ 70%	40–69%	< 40%	< 25%
Pao$_2$ (on air, mm Hg)	Normal[1]	≥ 60[1]	< 60: possible cyanosis	< 60: possible cyanosis
Pco$_2$ (mm Hg)	< 42[1]	< 42[1]	≥ 42[1]	≥ 42[1]
Sao$_2$ (on air)	> 95%[1]	90–95%[1]	< 90%[1]	< 90%[1]

[1] Test not usually necessary.

Sao$_2$, oxygen saturation.

Adapted from National Asthma Education and Prevention Program. Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma. National Institutes of Health Pub. No. 08-4051. Bethesda, MD, 2007.

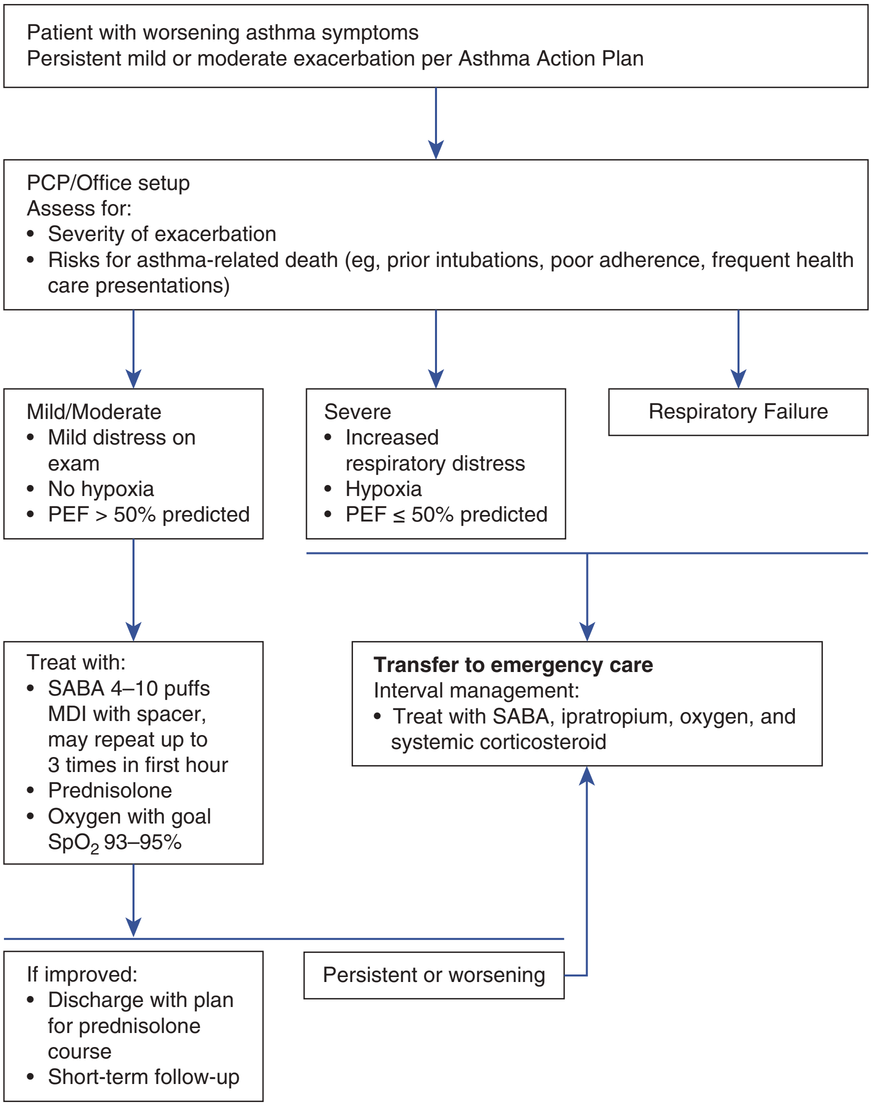
Frequent high-dose delivery of an **inhaled SABA** is indicated and usually well tolerated in severe airway obstruction. At least three MDI or nebulizer treatments should be given in the first hour of therapy. Some studies suggest that continuous therapy is more effective than intermittent administration of these agents, but there is no clear consensus as long as similar doses are administered. After the first hour, the frequency of administration varies according to improvements in airflow and symptoms and occurrence of side effects. **Ipratropium bromide** reduces the rate of hospital admissions when added to inhaled SABAs in patients with moderate to severe asthma exacerbations.

Systemic corticosteroids are administered as detailed above. **Intravenous magnesium sulfate** (2 g intravenously over 20 minutes) is not recommended for routine use in asthma exacerbations. However, a 2 g infusion over 20 minutes may reduce hospitalization rates in acute severe asthma (FEV$_1$ < 25% of predicted on presentation or failure to respond to initial treatment).

Mucolytic agents (eg, acetylcysteine, potassium iodide) may worsen cough or airflow obstruction. Anxiolytic and hypnotic drugs are generally contraindicated in severe asthma exacerbations because of their potential respiratory depressant effects.

Multiple studies suggest that infections with viruses (rhinovirus) and bacteria (*Mycoplasma pneumoniae, Chlamydophila pneumoniae*) predispose to acute exacerbations of asthma and may underlie chronic, severe asthma. The use of empiric antibiotics is, however, not recommended in routine asthma exacerbations since there is no consistent evidence to show improved clinical outcomes. **Antibiotics** should be considered when there is a high likelihood of acute bacterial respiratory tract infection, such as when patients have fever or purulent sputum and evidence of pneumonia or bacterial sinusitis.

In the **emergency department setting**, repeat assessment of patients with severe exacerbations should be done after the initial dose of an inhaled SABA and again after three doses of an inhaled SABA (60–90 minutes after initiating treatment). The response to initial treatment is a better predictor of the need for hospitalization than is the severity of the exacerbation on presentation. The decision to hospitalize a patient should be based on the duration and severity of symptoms, severity of airflow obstruction, ABG results (if available), course and severity of prior exacerbations, medication use at the time of the exacerbation, access to medical care and medications, adequacy of social support and home conditions, and presence of



Patient with worsening asthma symptoms
Persistent mild or moderate exacerbation per Asthma Action Plan
PCP/Office setup
Assess for:
• Severity of exacerbation
• Risks for asthma-related death (eg, prior intubations, poor adherence, frequent health care presentations)
Mild/Moderate
• Mild distress on exam
• No hypoxia
• PEF > 50% predicted
Severe
• Increased respiratory distress
• Hypoxia
• PEF ≤ 50% predicted
Respiratory Failure
Treat with:
• SABA 4–10 puffs MDI with spacer, may repeat up to 3 times in first hour
• Prednisolone
• Oxygen with goal SpO2 93–95%
Transfer to emergency care
Interval management:
• Treat with SABA, ipratropium, oxygen, and systemic corticosteroid
If improved:
• Discharge with plan for prednisolone course
• Short-term follow-up
Persistent or worsening

▲ **Figure 9–1.** Management of mild or moderate asthma exacerbations in primary care. SABA, short-acting β_2-agonist (doses are for salbutamol).

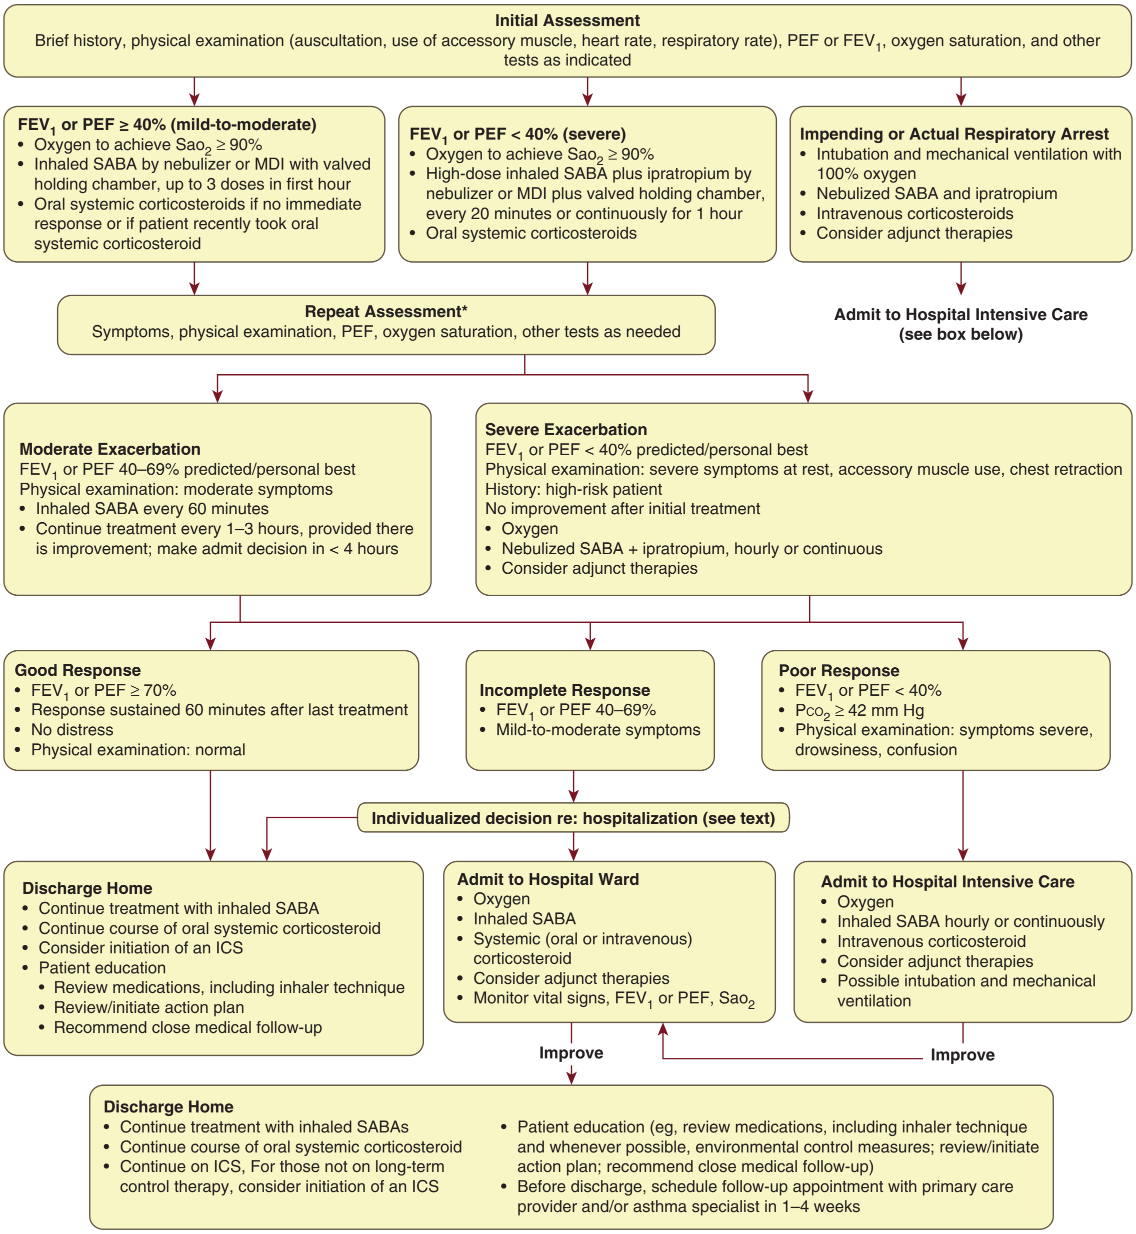
psychiatric illness. In general, discharge to home is appropriate if the PEF or FEV_1 has returned to 60% or more of predicted or personal best and if symptoms are minimal or absent. Patients with a rapid response to treatment should be observed for 30 minutes after the most recent dose of bronchodilator to ensure stability of response before discharge.

In the **intensive care setting**, a small subset of patients will not respond to treatment and will progress to impending respiratory failure due to a combination of worsening airflow obstruction and respiratory muscle fatigue (see Figure 9–2 and Table 9–6). Since such patients can deteriorate rapidly, they must be monitored in a critical care setting. Intubation of an acutely ill asthma patient is technically difficult and is best done semi-electively before the crisis of a respiratory arrest. At the time of intubation, the patient's intravascular volume should be closely monitored because hypotension commonly follows the administration of sedative medications and the initiation of positive-pressure ventilation; these patients are often dehydrated due to poor recent oral intake and high insensible losses.

The main goals of **mechanical ventilation** are to ensure adequate oxygenation and to avoid barotrauma. Controlled hypoventilation with permissive hypercapnia is often required to limit airway pressures. Frequent high-dose delivery of inhaled SABAs should be continued along with anti-inflammatory agents as discussed above.

When to Refer

- Atypical presentation or uncertain diagnosis of asthma, particularly if additional diagnostic testing is required (bronchoprovocation challenge, allergy skin testing, rhinoscopy, consideration of occupational exposure).



Initial Assessment
Brief history, physical examination (auscultation, use of accessory muscle, heart rate, respiratory rate), PEF or FEV_1, oxygen saturation, and other tests as indicated
FEV_1 or PEF ≥ 40% (mild-to-moderate)
• Oxygen to achieve Sao_2 ≥ 90%
• Inhaled SABA by nebulizer or MDI with valved holding chamber, up to 3 doses in first hour
• Oral systemic corticosteroids if no immediate response or if patient recently took oral systemic corticosteroid
FEV_1 or PEF < 40% (severe)
• Oxygen to achieve Sao_2 ≥ 90%
• High-dose inhaled SABA plus ipratropium by nebulizer or MDI plus valved holding chamber, every 20 minutes or continuously for 1 hour
• Oral systemic corticosteroids
Impending or Actual Respiratory Arrest
• Intubation and mechanical ventilation with 100% oxygen
• Nebulized SABA and ipratropium
• Intravenous corticosteroids
• Consider adjunct therapies
Repeat Assessment*
Symptoms, physical examination, PEF, oxygen saturation, other tests as needed
Admit to Hospital Intensive Care (see box below)
Moderate Exacerbation
FEV_1 or PEF 40–69% predicted/personal best
Physical examination: moderate symptoms
• Inhaled SABA every 60 minutes
• Continue treatment every 1–3 hours, provided there is improvement; make admit decision in < 4 hours
Severe Exacerbation
FEV_1 or PEF < 40% predicted/personal best
Physical examination: severe symptoms at rest, accessory muscle use, chest retraction
History: high-risk patient
No improvement after initial treatment
• Oxygen
• Nebulized SABA + ipratropium, hourly or continuous
• Consider adjunct therapies
Good Response
• FEV_1 or PEF ≥ 70%
• Response sustained 60 minutes after last treatment
• No distress
• Physical examination: normal
Incomplete Response
• FEV_1 or PEF 40–69%
• Mild-to-moderate symptoms
Poor Response
• FEV_1 or PEF < 40%
• Pco_2 ≥ 42 mm Hg
• Physical examination: symptoms severe, drowsiness, confusion
Individualized decision re: hospitalization (see text)
Discharge Home
• Continue treatment with inhaled SABA
• Continue course of oral systemic corticosteroid
• Consider initiation of an ICS
• Patient education
• Review medications, including inhaler technique
• Review/initiate action plan
• Recommend close medical follow-up
Admit to Hospital Ward
• Oxygen
• Inhaled SABA
• Systemic (oral or intravenous) corticosteroid
• Consider adjunct therapies
• Monitor vital signs, FEV_1 or PEF, Sao_2
Admit to Hospital Intensive Care
• Oxygen
• Inhaled SABA hourly or continuously
• Intravenous corticosteroid
• Consider adjunct therapies
• Possible intubation and mechanical ventilation
Improve
Improve
Discharge Home
• Continue treatment with inhaled SABAs
• Continue course of oral systemic corticosteroid
• Continue on ICS, For those not on long-term control therapy, consider initiation of an ICS
• Patient education (eg, review medications, including inhaler technique and whenever possible, environmental control measures; review/initiate action plan; recommend close medical follow-up)
• Before discharge, schedule follow-up appointment with primary care provider and/or asthma specialist in 1–4 weeks

*Patients who have achieved ≥ 70% PEF or FEV_1 should go to the "Good Response" category.

▲ **Figure 9–2.** Management of asthma exacerbations in acute care facility (eg, emergency department). - Complicating comorbid problems, such as rhinosinusitis, multiple environmental allergies, suspected allergic bronchopulmonary aspergillosis.
- Occupational asthma.
- Uncontrolled symptoms despite a moderate-dose ICS and a LABA.
- Patient not meeting goals of asthma therapy after 3–6 months of treatment.
- Frequent asthma-related health care utilization.
- More than two courses of oral corticosteroid therapy in the past 12 months.
- Any life-threatening asthma exacerbation or exacerbation requiring hospitalization in the past 12 months.
- Presence of social or psychological issues interfering with asthma management.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

ESSENTIALS OF DIAGNOSIS

- History of cigarette smoking or other chronic inhalational exposure.
- Chronic cough, dyspnea, and sputum production.
- Rhonchi, decreased intensity of breath sounds, and prolonged expiration on physical examination.
- Airflow limitation on PFT that is not fully reversible and most often progressive.

General Considerations

The Global Initiative for Chronic Obstructive Lung Disease (GOLD) defines COPD as a heterogeneous lung condition characterized by chronic respiratory symptoms and airflow limitation due to airway and alveolar abnormalities usually caused by significant exposure to noxious particles or gases. The term "COPD" has evolved from an umbrella term for chronic bronchitis and emphysema to one that refers to a clinical syndrome of chronic respiratory symptoms, structural pulmonary abnormalities (airways or alveoli), and impaired lung function arising from multiple causes that result in airflow limitation that is not fully reversible and is often progressive. Symptoms include cough, dyspnea, and sputum production. COPD is a major cause of chronic morbidity and is the third leading cause of death worldwide.

The most important causes of COPD are cigarette smoking in the developed world and biomass fuel cooking in the developing world. Most smokers suffer an accelerated decline in lung function that is dose- and duration-dependent. One major study of active smokers reported yearly decreases in FEV_1 of 66 mL per year in men and 54 mL per year in women compared to 30 mL per year in men and 22 mL per year in women who sustained smoking cessation. Fifteen percent of smokers develop progressively disabling symptoms in their 40s and 50s. Approximately two-thirds of patients seen for COPD have significant exposure to tobacco smoke. The remaining one-third may have a combination of exposures to environmental tobacco smoke, occupational dusts and chemicals, and indoor air pollution from biomass fuel used for cooking and heating in poorly ventilated buildings. Outdoor air pollution, airway infection, environmental factors, and allergy have also been implicated, along with hereditary factors (most notably, deficiency of α_1-antitrypsin [α_1-antiprotease]). Atopy and bronchoconstriction in response to nonspecific airway stimuli may be important risk factors. There is evidence that lung exposures to pollution and allergens early in life, including antenatal and early childhood exposure, can lead to poor lung growth in childhood and expiratory airflow limitation, resulting in lower than predicted spirometric values in midlife.

Clinical Findings

A. Symptoms and Signs

Patients with COPD characteristically present in the fifth or sixth decade of life reporting excessive cough, sputum production, shortness of breath, or a combination thereof. Symptoms have often been present for 10 years or more, yet if diagnosed early, smoking cessation can reduce lung function decline. Dyspnea is noted initially on heavy exertion, but as the condition progresses it occurs with mild activity. In severe disease, dyspnea occurs at rest. As the disease progresses, two symptom patterns tend to emerge, historically referred to as "pink puffers" and "blue bloaters" (Table 9–7). Most COPD patients have features of both disorders, and their clinical course and severity may involve other factors, such as central control of ventilation and concomitant sleep-disordered breathing.

A hallmark of COPD is the acute exacerbation of symptoms beyond normal day-to-day variation, often including increased dyspnea, an increased frequency or severity of cough, and increased sputum volume or change in sputum character. These exacerbations are commonly precipitated by infection (more often viral than bacterial) or environmental factors. Pneumonia, pulmonary hypertension, right-sided HF, and chronic respiratory failure characterize the late stage of COPD.

B. Diagnostic Tests

Spirometry is critical to the diagnosis and severity assessment of COPD. PFTs early in the course of COPD may reveal only abnormal closing volume and reduced mid-expiratory flow rates. Reduction in FEV_1 establishes the presence of airflow obstruction and reduction in the ratio of FEV_1 to vital capacity (FEV_1% or FEV_1/FVC ratio) establishes the severity of obstruction. Lung volume measurements reveal an increase in RV and in TLC, and an elevation of the RV/TLC ratio, indicative of air trapping and hyperinflation, common in patients with emphysema. In the setting of airflow obstruction, a reduction in the

Table 9–7. Patterns of disease in advanced COPD.

	Type A: Pink Puffer (Emphysema Predominant)	Type B: Blue Bloater (Bronchitis Predominant)
History and physical examination	Major symptom is dyspnea, often severe, usually presenting after age 50. Cough is rare, with scant clear, mucoid sputum. Patients are thin, with recent weight loss common. They appear uncomfortable, with evident use of accessory muscles of respiration. Chest is very quiet without adventitious sounds. No peripheral edema.	Major symptom is chronic cough, productive of mucopurulent sputum, with frequent exacerbations due to chest infections. Often presents in late 30s and 40s. Dyspnea usually mild, though patients may note limitations to exercise. Patients frequently overweight and cyanotic but seem comfortable at rest. Peripheral edema is common. Chest is noisy, with rhonchi invariably present; wheezes are common.
Laboratory studies	Hemoglobin usually normal (12–15 g/dL). Pao_2 normal to slightly reduced (65–75 mm Hg) but Sao_2 normal at rest. Paco_2 normal to slightly reduced (35–40 mm Hg). CXR shows hyperinflation with flattened diaphragms. Vascular markings are diminished, particularly at the apices.	Hemoglobin usually elevated (15–18 g/dL). Pao_2 reduced (45–60 mm Hg) and Paco_2 slightly to markedly elevated (50–60 mm Hg). CXR shows increased interstitial markings ("dirty lungs"), especially at bases. Diaphragms are not flattened.
Pulmonary function tests	Airflow obstruction ubiquitous. TLC increased, sometimes markedly so. DLCO reduced. Static lung compliance increased.	Airflow obstruction ubiquitous. TLC generally normal but may be slightly increased. DLCO normal. Static lung compliance normal.
Special Evaluations		
Ventilation-perfusion testing	Increased ventilation to high $\dot{V}/\dot{Q}$ areas, ie, high dead space ventilation.	Increased perfusion to low $\dot{V}/\dot{Q}$ areas.
Hemodynamics	Cardiac output normal to slightly low. Pulmonary artery pressures mildly elevated and increase with exercise.	Cardiac output normal. Pulmonary artery pressures elevated, sometimes markedly so, and worsen with exercise.
Nocturnal ventilation	Mild to moderate degree of oxygen desaturation not usually associated with obstructive sleep apnea.	Severe oxygen desaturation, frequently associated with obstructive sleep apnea.
Exercise ventilation	Increased minute ventilation for level of oxygen consumption; Pao_2 tends to fall; Paco_2 rises slightly.	Decreased minute ventilation for level of oxygen consumption. Pao_2 may rise; Paco_2 may rise significantly.

$\dot{V}/\dot{Q}$, ventilation-perfusion.

single-breath DLCO predicts anatomic emphysema. A severely reduced DLCO predicts exertional oxyhemoglobin desaturation and is associated with coexisting pulmonary hypertension. A 6-minute walking distance of < 350 m is associated with increased mortality.

ABG measurement characteristically shows no abnormalities early in COPD other than an increased A–a–DO_2. Indeed, ABG measurement is unnecessary unless (1) hypoxemia or hypercapnia is suspected or (2) the FEV_1 or DLCO is < 40% of predicted. Hypoxemia occurs earlier in disease in which chronic bronchitis predominates. Hypercapnia and compensated respiratory acidosis occur as disease progresses, which may worsen with sleep and exercise, and during acute exacerbations.

Positive sputum bacterial cultures are poorly correlated with acute exacerbations, which more commonly are preceded by viral infections. The ECG may show sinus tachycardia, and in advanced disease there may be ECG abnormalities typical of right-sided HF. Supraventricular arrhythmias (multifocal atrial tachycardia, atrial flutter, and atrial fibrillation) and ventricular irritability also occur.

C. Imaging

Radiographs of patients with chronic bronchitis typically show only nonspecific peribronchial and perivascular markings. Plain radiographs are insensitive for the diagnosis of emphysema; hyperinflation with flattening of the diaphragm or peripheral arterial deficiency is seen in half of cases. Chest CT can identify and quantify the emphysema phenotype and detects airway narrowing and wall thickening characteristic of the bronchitic phenotype. In advanced disease, pulmonary hypertension may be suggested by enlargement of central pulmonary arteries on CXRs or chest CTs, and Doppler echocardiography provides an estimate of pulmonary artery pressure. CT provides information in patients being considered for lung volume reduction surgery or endobronchial valve placement for underlying severe hyperinflation.

▶ Differential Diagnosis

Clinical, imaging, and laboratory findings should enable the clinician to distinguish COPD from other obstructive pulmonary disorders, such as asthma, bronchiectasis, cystic fibrosis, bronchopulmonary aspergillosis, and central airflow obstruction. Asthma is characterized by complete or near-complete reversibility of airflow obstruction. Bronchiectasis is distinguished from COPD by recurrent pneumonia and hemoptysis, digital clubbing, and characteristic imaging abnormalities. Cystic fibrosis occurs in children, adolescents, and young adults and has characteristic imaging as well as endocrine and hepatic abnormalities. Bronchopulmonary aspergillosis is characterized by eosinophilia; elevated levels of immunoglobulin E; and episodic worsening marked by fever, malaise, productive cough, and radiographic infiltrates. Mechanical obstruction of the central airways can be distinguished from COPD by flow-volume loops.

Complications

Acute bronchitis, pneumonia, pulmonary thromboembolism, atrial dysrhythmias (eg, atrial fibrillation, atrial flutter, multifocal atrial tachycardia), and concomitant LV failure may worsen otherwise stable COPD. Pulmonary hypertension, right-sided HF, and chronic respiratory failure are common in advanced COPD. Spontaneous pneumothorax occurs in a small fraction of patients with emphysema. Hemoptysis may result from chronic bronchitis or may signal bronchogenic carcinoma.

Prevention

COPD is largely preventable by eliminating long-term exposure to tobacco smoke, products of biomass fuels combustion, or other inhaled toxins. Smokers with early evidence of airflow limitation can significantly alter the course of their disease by smoking cessation. Influenza vaccination reduces the frequency and severity of influenza-like illness as well as the number of COPD exacerbations. Pneumococcal vaccination appears to reduce both the frequency of community-acquired pneumonia and the number of COPD exacerbations. COVID-19 vaccination reduces mortality and rate of COPD exacerbations. In patients with COPD and diabetes, there is emerging evidence for possible benefit from GLP-1 receptor agonists and SGLT-2 inhibitors in reducing exacerbation rates.

Treatment

The treatment of COPD is guided by the severity of symptoms or the presence of an exacerbation of stable symptoms. Standards for the management of patients with stable COPD and COPD exacerbations from the American Thoracic Society and GOLD, a joint expert committee of the National Heart, Lung, and Blood Institute and the WHO, are incorporated in the recommendations below. There are three commonly used ways to identify high-risk COPD patients who may require more intense treatment: (1) FEV_1 < 50% predicted, (2) more than two exacerbations in the previous year, and (3) one or more hospitalizations for COPD exacerbation in the previous year.

A. Ambulatory Patients

1. Smoking cessation—The single most important intervention in smokers with COPD is to facilitate smoking cessation (see Chapter 1), which slows the accelerated decline in lung function caused by smoking. Simply telling a patient to quit succeeds 5% of the time. Behavioral approaches, ranging from clinician advice to intensive group programs, may improve cessation rates. Pharmacologic therapy includes bupropion, nicotine replacement (transdermal patch, gum, lozenge, inhaler, or nasal spray), and varenicline (a partial agonist of nicotinic acetylcholine receptors). Combined pharmacotherapies (two forms of nicotine replacement, or nicotine replacement and bupropion), with or without behavioral approaches, have been recommended. Varenicline is effective but use has been limited by concerns about neuropsychiatric side effects. Electronic cigarettes are not recommended as a smoking cessation aid, due in part to concern for e-cigarette and vaping-associated lung injury (EVALI) (see below).

2. Oxygen therapy—Supplemental oxygen for patients with resting hypoxemia (PaO_2 < 56 mm Hg or pulse oxygen saturation [SpO_2] ≤ 88%) is the only therapy with evidence of improvement in the natural history of COPD. Proven benefits of home oxygen therapy in hypoxemic patients include longer survival, reduced hospitalizations, and better quality of life. Survival in hypoxemic patients with COPD treated with supplemental oxygen therapy is directly proportional to the number of hours per day oxygen is administered: in hypoxemic COPD patients treated with continuous oxygen for 24 hours daily, the survival after 36 months is about 65%—significantly better than the survival rate of about 45% in those treated with only nocturnal oxygen. Oxygen by nasal prongs must be given for at least 15 hours a day unless therapy is specifically intended only for exercise or sleep. However, several studies of supplemental oxygen therapy showed no survival benefit in COPD patients with borderline low-normal resting oxygen levels (PaO_2 56–69 mm Hg). In a study of patients with stable COPD and resting or exercise-induced moderate desaturation, the prescription of long-term supplemental oxygen did not result in a longer time to first hospitalization or death than no long-term supplemental oxygen, nor did it provide sustained benefit in any other measured outcomes. Requirements for US Medicare coverage for a patient's home use of oxygen and oxygen equipment are listed in Table 9–8. ABG analysis is preferred over oximetry to guide initial oxygen therapy. Hypoxemic patients with pulmonary hypertension, chronic right-sided HF, erythrocytosis, impaired cognitive function, exercise intolerance, nocturnal restlessness, or morning headache are likely to benefit from home oxygen therapy.

Home oxygen may be supplied by liquid oxygen systems, compressed gas cylinders, or oxygen concentrators. Most patients benefit from having both stationary and portable systems. For most patients, a flow rate of 1–3 L/min achieves a PaO_2 > 55 mm Hg. Reservoir nasal cannulas or "pendants" and demand (pulse) oxygen delivery systems are available to conserve oxygen.

3. Inhaled bronchodilators—Bronchodilators do not alter the inexorable decline in lung function that is a hallmark of COPD, but they improve symptoms, exercise tolerance, FEV_1, and overall health status. The bronchodilator regimen should be tailored to the clinical severity of the patient's disease. In patients who experience no symptomatic improvement, bronchodilators should be discontinued.

The most commonly prescribed short-acting bronchodilators are the SAMA **ipratropium bromide** and the SABAs (eg, albuterol/salbutamol), delivered by MDI or as

Table 9–8. Home oxygen therapy: requirements for Medicare coverage.[1]

Group I (any of the following):

$\text{Pao}_2 \le 55$ mm Hg or $\text{Sao}_2 \le 88\%$ taken while awake, at rest, breathing room air.

1. During sleep (prescription for nocturnal oxygen use only): $\text{Pao}_2 \le 55$ mm Hg or $\text{Sao}_2 \le 88\%$ for a patient who is awake, resting, room air Pao_2 is ≥ 56 mm Hg or $\text{Sao}_2 \ge 89\%$, *or* Decrease in $\text{Pao}_2 > 10$ mm Hg or decrease in $\text{Sao}_2 > 5\%$ associated with symptoms or signs reasonably attributed to hypoxemia (eg, impaired cognitive processes, nocturnal restlessness, insomnia).
2. During exercise (prescription for oxygen use only during exercise): $\text{Pao}_2 \le 55$ mg Hg or $\text{Sao}_2 \le 88\%$ taken during exercise for a patient who is awake, resting, room air Pao_2 is ≥ 56 mm Hg or $\text{Sao}_2 \ge 89\%$, *and* there is evidence that the use of supplemental oxygen during exercise improves the hypoxemia that was demonstrated during exercise while breathing room air.

Group II[2]:

$\text{Pao}_2 = 56–59$ mm Hg or $\text{Sao}_2 = 89\%$ if there is evidence of any of the following:

1. Dependent edema suggesting HF.
2. P pulmonale on ECG (P wave > 3 mm in standard leads II, III, or aVF).
3. Hematocrit > 56%.

[1] Centers for Medicare and Medicaid Services, 2003.

[2] Patients in this group must have a second oxygen test 3 months after the initial oxygen setup.

an inhalation solution by nebulizer. Some clinicians prefer ipratropium as a first-line agent because of its longer duration of action and absence of sympathomimetic side effects. Some studies have suggested that ipratropium achieves superior bronchodilation in COPD patients. Typical doses are 2–4 puffs (36–72 mcg) every 6 hours. Other clinicians prefer SABAs because they are less expensive and have a more rapid onset of action, commonly leading to greater patient satisfaction. There has been no consistent difference in efficacy demonstrated between SABAs and SAMAs.

LAMAs (eg, **tiotropium, aclidinium, umeclidinium, glycopyrrolate**) and LABAs (eg, **formoterol, salmeterol, indacaterol, arformoterol, vilanterol, olodaterol**) appear to achieve bronchodilation that is equivalent or superior to ipratropium, in addition to similar improvements in health status. Although more expensive than short-acting agents, long-acting bronchodilators may have superior clinical efficacy in persons with advanced disease. One RCT of long-term administration of **tiotropium** added to standard therapy reported fewer exacerbations or hospitalizations and improved dyspnea scores in the tiotropium group but no long-term effect on lung function. The initial drug of choice for patients with very mild disease and no exacerbations is a LAMA. If the patient has more significant dyspnea and airflow obstruction, the 2024 GOLD update recommends early initiation of treatment with LAMA plus LABA for stable COPD management, rather than LAMA alone, which leads to improved FEV_1 and reduced dyspnea burden.

The symptomatic benefits of long-acting bronchodilators are firmly established. The increased exacerbations and mortality reported in some patients with asthma treated with salmeterol have not been observed in COPD patients, and studies report a trend toward lower mortality with salmeterol alone, compared with placebo. In addition, a 4-year tiotropium trial reported fewer cardiovascular events in the intervention group. Subsequent meta-analyses of long-acting LAMA that include the 4-year tiotropium trial did not find an increase in cardiovascular events. Most practitioners believe that the documented benefits of anticholinergic therapy outweigh any potential risks.

4. Corticosteroids—Multiple large clinical trials have reported a reduction in the frequency of COPD exacerbations and an increase in self-reported functional status in COPD patients treated with inhaled corticosteroids. These same trials demonstrate no effect of ICS on mortality or the characteristic decline in lung function experienced by COPD patients. The benefits of ICS must be weighed against the increased risk of cataracts, decreased bone densitometry, and bacterial pneumonia, especially in those with severe COPD. For these reasons, the updated 2024 GOLD guidelines do not encourage use of ICS in early stages of COPD and call for judicious use of ICS in patients with more severe COPD with frequent exacerbations, those with blood eosinophilia of ≥ 300 cells/mcL, concomitant asthma, or history of hospitalizations due to COPD exacerbations. Withdrawal of inhaled corticosteroids should be considered when patients have been stable for 2 years.

Apart from acute exacerbations, COPD is not generally responsive to oral corticosteroid therapy. Given the risks of adverse side effects, oral corticosteroids are not recommended for long-term treatment of COPD.

5. Theophylline—Low-dose oral theophylline is a fourth-line agent for treating COPD patients who do not achieve adequate symptom control with inhaled anticholinergic, β_2-agonist, and corticosteroid therapies. Theophylline improves dyspnea ratings, exercise performance, and pulmonary function in many patients with stable COPD. Theophylline toxicity is a significant concern due to the medication's narrow therapeutic window, and long-term administration requires careful monitoring of serum levels. GOLD guidelines recommend theophylline only as a last resort if other bronchodilators are unavailable or unaffordable, with discontinuation if clinical improvement not seen.

6. Antibiotics—Antibiotics are commonly prescribed to outpatients with COPD for the following indications: (1) to treat an acute exacerbation, (2) to treat acute bronchitis, and (3) to prevent acute exacerbations of chronic bronchitis (prophylactic antibiotics). Antibiotics appear to improve outcomes slightly in all three situations, but those with a COPD exacerbation associated with increased sputum purulence accompanied by dyspnea or an increase in the quantity of sputum are thought to benefit most. The choice of antibiotic depends on local bacterial resistance patterns and individual risk of *Pseudomonas aeruginosa* infection (history of *Pseudomonas* isolation, $\text{FEV}_1 < 50\%$ of predicted, recent hospitalization [2 or more days in the past 3 months], more than three courses of antibiotics within the past year, use of systemic corticosteroids). Oral antibiotic options include doxycycline (100 mg every 12 hours), trimethoprim-sulfamethoxazole (160/800 mg every 12 hours), a cephalosporin (eg, cefpodoxime 200 mg every 12 hours or cefprozil 500 mg every 12 hours), a macrolide (eg, azithromycin 500 mg followed by 250 mg daily for 5 days), a fluoroquinolone (eg, ciprofloxacin 500 mg every 12 hours), and amoxicillin-clavulanate (875/125 mg every 12 hours). Suggested duration of therapy is 3–5 days and depends on response to therapy. There are few controlled trials of antibiotics in severe COPD exacerbations, but prompt administration is appropriate, particularly in persons with risk factors for poor outcomes (eg, age < 65 years, FEV_1 < 50% of predicted, three or more exacerbations in the past year, antibiotic therapy within the past 3 months, comorbid conditions, such as cardiac disease). In COPD patients subject to frequent exacerbations despite optimal medical therapy, azithromycin (250 mg daily or 500 mg three times weekly) or moxifloxacin (a 5-day course 1 week in 8 over 48 weeks) are modestly effective in reducing the frequency of exacerbations; monitoring for hearing loss and QT prolongation is essential.

7. Pulmonary rehabilitation—Graded aerobic physical exercise programs (eg, walking 20 minutes three times weekly or bicycling) are helpful to prevent deterioration of physical condition and to improve patients' ability to carry out daily activities. Training of inspiratory muscles by inspiring against progressively larger resistive loads reduces dyspnea and improves exercise tolerance, health status, and respiratory muscle strength in some patients. Pursed-lip breathing to slow the rate of breathing and abdominal breathing exercises to relieve fatigue of accessory muscles of respiration may reduce dyspnea in some patients. Many patients undergo these exercise and educational interventions in a structured rehabilitation program. Pulmonary rehabilitation has been shown in multiple studies to improve exercise capacity, decrease hospitalizations, and enhance quality of life. Referral to a comprehensive rehabilitation program is recommended in patients who have severe dyspnea, reduced quality of life, or frequent hospitalizations despite optimal medical therapy.

8. Phosphodiesterase type 4 inhibitor—Roflumilast has been shown to reduce exacerbation frequency in patients who have moderate or severe (FEV_1 < 50% of predicted) COPD and chronic bronchitis, with frequent exacerbations, and who are taking LABA/ICS with or without a LAMA, or LAMA alone.

9. Other measures—In patients with chronic bronchitis, increased mobilization of secretions may be accomplished through adequate systemic hydration, effective cough training methods, or the use of a handheld flutter device and postural drainage, sometimes with chest percussion or vibration. Postural drainage and chest percussion should be used only in selected patients with excessive amounts of retained secretions that cannot be cleared by coughing and other methods; these measures are of no benefit in pure emphysema. Expectorant-mucolytic therapy has generally been regarded as unhelpful in patients with chronic bronchitis. Cough suppressants and sedatives should be avoided.

Human α_1-antitrypsin is available for replacement therapy in emphysema due to congenital deficiency (PiZZ or null genotype) of α_1-antitrypsin (α_1-antiprotease). Patients over 18 years of age with airflow obstruction by spirometry and serum levels < 11 mmol/L (~50 mg/dL) are potential candidates for replacement therapy. α_1-Antitrypsin is administered intravenously in a dose of 60 mg/kg body weight once weekly.

Severe dyspnea despite optimal medical management may warrant a clinical trial of an **opioid** (eg, morphine 5–10 mg orally every 3–4 hours, oxycodone 5–10 mg orally every 4–6 hours, sustained-release morphine 10 mg orally once daily). Sedative-hypnotic drugs (eg, diazepam, 5 mg three times daily) marginally improve intractable dyspnea but cause significant drowsiness; they may benefit very anxious patients. Transnasal positive-pressure ventilation at home to rest the respiratory muscles is an approach to improve respiratory muscle function and reduce dyspnea in patients with severe COPD.

See Chapter 42 for a discussion of air travel in patients with lung disease.

B. Hospitalized Patients

Management of patients hospitalized with an acute exacerbation of COPD includes (1) supplemental oxygen (titrated to maintain Sao_2 at 90–94% or Pao_2 at 60–70 mm Hg); (2) inhaled β_2-agonists (eg, albuterol 2.5 mg diluted with saline to a total of 3 mL by nebulizer, or MDI, 90 mcg per puff, four to eight puffs via spacer, every 1–4 hours as needed) with or without inhaled ipratropium bromide (500 mcg by nebulizer, or 36 mcg by MDI with spacer, every 4 hours as needed); (3) corticosteroids (prednisone 0.5 mg/kg/day orally for 7–10 days is usually sufficient, and even 5 days may be adequate); (4) broad-spectrum antibiotics; and (5) in selected cases, chest physiotherapy.

For patients without risk factors for *Pseudomonas*, management options include a fluoroquinolone (eg, levofloxacin 750 mg orally or intravenously per day, or moxifloxacin 400 mg orally or intravenously every 24 hours) or a third-generation cephalosporin (eg, ceftriaxone 1 g intravenously per day, or cefotaxime 1 g intravenously every 8 hours).

For patients with risk factors for *Pseudomonas*, therapeutic options include piperacillin-tazobactam (4.5 g intravenously every 6 hours), ceftazidime (1 g intravenously every 8 hours), cefepime (1 g intravenously every 12 hours), or levofloxacin (750 mg orally or intravenously per day for 3–7 days).

Oxygen therapy should *not* be withheld for fear of worsening respiratory acidemia; hypoxemia is more detrimental than hypercapnia. Right-sided HF usually responds to measures that reduce pulmonary artery pressure, such as supplemental oxygen and correction of acidemia; bed rest, salt restriction, and diuretics may add some benefit. Cardiac dysrhythmias, particularly multifocal atrial tachycardia, usually respond to aggressive treatment of COPD itself. Atrial fibrillation and flutter may require DC cardioversion after initiation of the above therapy. Theophylline should not be initiated in the acute setting, but patients taking theophylline before acute hospitalization should have their theophylline serum levels measured and maintained in the therapeutic range. If progressive respiratory failure ensues, tracheal intubation and mechanical ventilation are necessary. In clinical trials of COPD patients with hypercapnic acute respiratory failure, **noninvasive positive-pressure ventilation (NIPPV)** delivered via face mask reduced the need for intubation and shortened lengths of stay in the ICU. Other studies have suggested a lower risk of nosocomial infections and less use of antibiotics in COPD patients treated with NIPPV.

C. Procedures for COPD

1. Lung transplantation—Requirements for lung transplantation are severe lung disease, limited activities of daily living, exhaustion of medical therapy, ambulatory status, potential for pulmonary rehabilitation, limited life expectancy without transplantation, adequate function of other organ systems, and a good social support system. Two-year survival rate after lung transplantation for COPD is 75%. Complications include acute rejection, opportunistic infection, and obliterative bronchiolitis. Substantial improvements in pulmonary function and exercise performance have been noted after transplantation.

2. Lung volume reduction surgery—Lung volume reduction surgery, or reduction pneumoplasty, is a surgical approach to relieve dyspnea and improve exercise tolerance in patients with advanced diffuse emphysema and lung hyperinflation. Bilateral resection of 20–30% of lung volume in selected patients results in modest improvements in pulmonary function, exercise performance, and dyspnea. The duration of improvement as well as any mortality benefit remains uncertain. Prolonged air leaks occur in up to 50% of patients postoperatively. Mortality rates in centers with the largest experience with lung volume reduction surgery range from 4% to 10%.

The National Emphysema Treatment Trial compared lung volume reduction surgery with medical treatment in a randomized, multicenter clinical trial of 1218 patients with severe emphysema. Overall, surgery improved exercise capacity but not mortality when compared with medical therapy.

3. Bullectomy—Bullectomy is an older surgical procedure for palliation of dyspnea in patients with severe bullous emphysema. Bullectomy is most commonly pursued when a single bulla occupies at least 30–50% of the hemithorax.

4. Endobronchial valves—In some patients with advanced heterogeneous emphysema and very severe air trapping, one-way valves may allow for flow out hyperinflated lung areas and thereby reduce hyperinflation. The US FDA has approved two endobronchial valves (Zephyr and Spiration) duckbill based on trials showing significant improvements in FEV_1, 6-minute walk distance, and respiratory symptoms in the treatment group compared with controls.

Prognosis

The outlook for patients with clinically significant COPD is poor. The degree of pulmonary dysfunction at the time the patient is first seen is an important predictor of survival: median survival of patients with FEV_1 of 1 L or less is about 4 years. A multidimensional index (the BODE index), which includes **B**MI, airway **O**bstruction (FEV_1), **D**yspnea (modified Medical Research Council dyspnea score), and **E**xercise capacity, is a tool that predicts death and hospitalization better than FEV_1 alone. Comprehensive care programs, cessation of smoking, and supplemental oxygen may reduce the rate of decline of pulmonary function, but therapy with bronchodilators and other approaches probably have little, if any, impact on the natural course of COPD.

Dyspnea at the end of life can be extremely uncomfortable and distressing to the patient and family. As patients near the end of life, meticulous attention to palliative care is essential to effectively manage dyspnea (see Chapter 5).

When to Refer

- COPD onset before the age of 40.
- Frequent exacerbations (two or more a year) despite optimal treatment.
- Severe or rapidly progressive COPD.
- Symptoms disproportionate to the severity of airflow obstruction.
- Need for long-term oxygen therapy.
- Onset of comorbid illnesses (eg, bronchiectasis, HF, or lung cancer).

When to Admit

- Severe symptoms or acute worsening that fails to respond to outpatient management.
- Acute or worsening hypoxemia, hypercapnia, peripheral edema, or change in mental status.
- Inadequate home care, or inability to sleep or maintain nutrition/hydration due to symptoms.
- The presence of high-risk comorbid conditions.

BRONCHIECTASIS

ESSENTIALS OF DIAGNOSIS

- Chronic productive cough with dyspnea and wheezing.
- Radiographic findings of dilated, thickened airways and scattered, irregular opacities.

General Considerations

Bronchiectasis is a congenital or acquired disorder of the large bronchi characterized by permanent, abnormal dilation and destruction of bronchial walls. It may be caused by recurrent inflammation or infection of the airways and may be localized or diffuse. Causes include cystic fibrosis, infections (tuberculosis and nontuberculous mycobacteria, fungal infections, lung abscess, recurrent pneumonia, including aspiration pneumonia), immunodeficiencies (congenital or acquired hypogammaglobulinemia; common variable immunodeficiency; selective IgA, IgM, and IgG subclass deficiencies; AIDS; lymphoma; plasma cell myeloma; leukemia), α_1-antitrypsin deficiency, primary ciliary dyskinesia, rheumatic diseases (rheumatoid arthritis, Sjögren syndrome), allergic bronchopulmonary aspergillosis (ABPA), and localized airway obstruction (foreign body aspiration, tumor, mucoid impaction).

Clinical Findings

A. Symptoms and Signs

Symptoms of bronchiectasis include chronic cough with production of copious amounts of purulent sputum, hemoptysis, pleuritic chest pain, dyspnea, and weight loss. Physical findings may include crackles at the lung bases and wheezing.

B. Laboratory Findings and Imaging

Laboratory tests include CBC with differential, immunoglobulin quantification (IgG, IgM, IgA); testing for cystic fibrosis with sweat chloride level, mutation analysis of *CFTR* gene, or both; and sputum culture for bacteria, nontuberculous mycobacteria, and fungi. Additional testing, if appropriate, may include aspergillus antibodies, IgE, α_1-antitrypsin level, and genotype, ciliary testing, autoimmune serologies, and swallow assessment. Obstructive lung disease is the most common finding on PFTs. HRCT is the diagnostic study of choice, which may show dilated and thickened bronchi that may appear as "tram tracks" or as "end-on ring" markings; mucus plugs in the airways, atelectasis, or focal consolidation.

C. Microbiology

Haemophilus influenzae, *Moraxella catarrhalis*, *Pseudomonas aeruginosa*, and *Staphylococcus aureus* are commonly identified. Nontuberculous mycobacteria, *Streptococcus pneumoniae*, and *Stenotrophomonas maltophilia* are seen less commonly. Chronic infection with *Pseudomonas* is a marker for disease severity, frequent exacerbation, accelerated course, and rapid decline in lung function.

Treatment

Treatment of acute exacerbations consists of antibiotics, airway clearance (postural drainage, chest percussion, hypertonic nebulization), and inhaled bronchodilators. Handheld flutter valve devices may be as effective as chest physiotherapy in clearing secretions. Antibiotic therapy should be guided by sputum smears and prior cultures. If a specific bacterial pathogen cannot be isolated, then empiric oral antibiotic therapy with amoxicillin or amoxicillin-clavulanate, ampicillin, a second- or third-generation cephalosporin, doxycycline, azithromycin, or a fluoroquinolone for 10–14 days is appropriate. For recurrent exacerbations, preventive macrolide therapy for 6–12 months has been found to decrease the frequency of exacerbations. Alternatively, inhaled antibiotics or alternating cycles of oral antibiotics may be considered.

Hemoptysis is the most common complication of bronchiectasis. Chest CT angiogram and bronchoscopy may help localize the bleeding site. Massive hemoptysis may require embolization of bronchial arteries, local bronchoscopic hemostasis techniques (balloon tamponade, topical vasoconstrictive agent, laser therapy) or surgical resection.

Following acute exacerbations most patients recover to their baseline, although irreversible worsening may occur. Patients with ≥ 3 exacerbations per year have increased mortality.

O'Donnell AE. Bronchiectasis—a clinical review. N Engl J Med. 2022;387:533. [PMID: 35947710]

ALLERGIC BRONCHOPULMONARY ASPERGILLOSIS

ABPA is a pulmonary hypersensitivity disorder caused by allergy to *Aspergillus* fungal species that colonize the tracheobronchial trees. Criteria for the diagnosis of ABPA include (1) a clinical history of asthma or cystic fibrosis; (2) elevated serum total IgE levels (> 500 IU/mL); (3) elevated serum IgE levels specific to *Aspergillus fumigatus* ≥ 0.35 kU/L (preferred) or *Aspergillus* skin test positivity; and (4) at least two of the following: (a) e elevated serum *Aspergillus* IgG by immunoassay, (b) pulmonary radiographic abnormalities consistent with ABPA, or (c) peripheral blood eosinophil count ≥ 500 cells/mcL (0.5×10^9/L). Symptoms are similar to asthma (dyspnea, wheezing, cough, mucus production); and may include rhinosinusitis. Radiographic abnormalities include transient opacities, mucoid impaction, and proximal or central bronchiectasis. High-dose corticosteroids (eg, prednisone 0.5–1 mg/kg orally per day) for at least 2 weeks with gradual taper is the treatment of choice. Patients with corticosteroid-dependent disease may benefit from itraconazole or voriconazole. Relapses are frequent. For those who have frequent exacerbations or are unable to wean off steroids, the use of biologic agents, such as anti-IL-5 (mepolizumab, benralizumab), anti-IL4 receptor (dupilumab), or anti-IgE (omalizumab), has been shown to improve outcomes. Inhaled steroids and bronchodilators (see Table 9–4) may also be helpful in those with asthma. Complications include hemoptysis, severe bronchiectasis, and pulmonary fibrosis.

CYSTIC FIBROSIS

ESSENTIALS OF DIAGNOSIS

- Autosomal recessive disorder.
- Pulmonary disease: chronic or recurrent productive cough, dyspnea, and wheezing; recurrent infections or chronic colonization of the airways with *H influenzae, P aeruginosa, S aureus*, or *Burkholderia cenocepacia*; bronchiectasis and scarring on CXRs; airflow obstruction on spirometry.
- Extrapulmonary disease: sinuses (chronic sinusitis and nasal polyposis); GI (pancreatic insufficiency, recurrent pancreatitis, hepatobiliary disease, meconium ileus, and distal intestinal obstruction); genitourinary (absent vas deferens and male infertility).

General Considerations

Cystic fibrosis (CF) is the most common chronic lung disease in young adults affecting approximately 40,000 people in the United States. It is an autosomal recessive disorder that is more common in White persons but may affect individuals of all racial and ethnic backgrounds. CF is caused by abnormalities in the cystic fibrosis transmembrane conductance regulator (CFTR) protein that results in altered chloride transport and water flux across the apical surface of epithelial cells. Over 2000 inherited variants of the CFTR gene have been identified with potential to cause disease. The most common mutation is ΔF508. Mutations of the CFTR gene are divided into five different classes: class I (defective protein production), class II (defective protein processing), class III (defective regulation), class IV (defective conduction), and class V (reduced amounts of functional CFTR protein).

Clinical Findings

A. Symptoms and Signs

Due to mandatory newborn screening for CF in many countries, there has been increased number of persons identified before the development of symptoms. In infants and children, CF usually presents with meconium ileus, respiratory symptoms, or failure to thrive. In adults, respiratory symptoms, diabetes, recurrent pancreatitis, or infertility may be seen. Typical symptoms are cough, sputum production, decreased exercise tolerance, recurrent infections, chronic rhinosinusitis symptoms, steatorrhea, diarrhea, and abdominal pain. Patients with cystic fibrosis are often malnourished and have a low BMI. Physical examination findings include digital clubbing (Figure 6–39), increased anteroposterior chest diameter, hyperresonance to percussion, and apical crackles. Nearly all men with CF have congenital bilateral absence of the vas deferens with azoospermia. Biliary cirrhosis and gallstones may occur.

B. Pulmonary Function Testing

Most patients with CF develop an obstructive pattern on PFTs. As the disease progresses, there is continued decline in FEV_1 and FEV_1/FVC, and there may be reduction in FVC and TLC. Air trapping (high ratio of RV to TLC) and reduction in pulmonary diffusing capacity are common.

C. Imaging

Hyperinflation is seen early in the disease process. Lung CT scans commonly reveal peribronchial cuffing, mucus plugging, bronchiectasis (ring shadows and cysts), increased interstitial markings, small, rounded peripheral opacities, and focal atelectasis.

D. Diagnosis

The following two criteria must be present: (1) One of the following: (a) typical symptoms consistent with CF; (b) history of CF in sibling; (c) or a positive newborn screening test; and (2) one of the following: (a) elevated sweat chloride concentration (> 60 mEq/L); (b) presence of two *CFTR* mutations; (c) or abnormal nasal potential difference.

Treatment

Early recognition and comprehensive multidisciplinary therapy at a CF center improve symptom control and survival. Treatment includes CFTR modulator medications, clearance and reduction of lower airway secretions, reversal of bronchoconstriction, treatment of respiratory tract infections and airway bacterial burden, pancreatic enzyme replacement, and nutritional and psychosocial support (including genetic and occupational counseling).

All patients with cystic fibrosis should undergo CFTR genotyping to determine eligibility for CFT modulator therapy. CFTR modulators include: (1) potentiators (increase time that CFTR channel remains open): ivacaftor and elexacaftor; (2) correctors (normalize folding of defective CFTR protein): ivacaftor, tezacaftor, elexacaftor, and lumacaftor; (3) amplifiers (increase expression of CFTR mRNA); or (4) stabilizers (limit removal and degradation of CFTR). Triple modulator therapy with elexacaftor/tezacaftor/ivacaftor is recommended for patients ≥ 2 years of age with two copies of the ΔF508 mutation, or one copy of the ΔF508 regardless of the other CFTR allele. Dual modulator therapy (tezacaftor/ivacaftor) is recommended for children 1 to < 2 years old, and ivacaftor monotherapy for those as young as 1 month old.

Airway clearance can be promoted by postural drainage, chest percussion or vibration techniques, positive expiratory pressure or flutter valve breathing devices, directed cough, inhaled recombinant human deoxyribonuclease (rhDNase, dornase-α) and hypertonic (7%) saline.

Short-term antibiotics are used to treat active exacerbations caused by airway infections based on results of culture and susceptibility testing of sputum. *S aureus* (including methicillin-resistant strains) and *P aeruginosa* are commonly present. *H influenzae*, *Stenotrophomonas maltophilia*, and *B cenocepacia* (a highly drug-resistant organism) are occasionally isolated. **Long-term antibiotic therapy**, such as azithromycin and various inhaled antibiotics (eg, tobramycin, aztreonam, colistin, and levofloxacin), helps slow disease progression and reduce exacerbations in patients with sputum cultures positive for *P aeruginosa*.

Inhaled bronchodilators (eg, albuterol) may be considered in patients who demonstrate an improvement of at least 12% in FEV_1 after an inhaled bronchodilator. An **ICS** should be added to the treatment regimen for patients who have CF with persistent asthma or ABPA.

Lung transplantation may be considered for advanced disease.

Vaccination against pneumococcal and coronavirus infections and annual influenza vaccination are advised.

Prognosis

The longevity of patients with CF is increasing. Death occurs from pulmonary complications (eg, pneumonia, pneumothorax, or hemoptysis) or from terminal chronic respiratory failure and right-sided HF.

Green DM et al. Cystic Fibrosis Foundation evidence-based guideline for the management of CRMS/CFSPID. Pediatrics. 2024 1;153:e2023064657. [PMID: 38577740]

Ong T et al. Cystic fibrosis: a review. JAMA. 2023;329:1859. [PMID: 37278811]

BRONCHIOLITIS

ESSENTIALS OF DIAGNOSIS

- Insidious onset of cough and dyspnea.
- Irreversible airflow obstruction and air trapping on PFTs.
- Minimal findings on CXR; air trapping on chest CT scan.
- Relevant exposure or risk factors: toxic fumes, viral infections, organ transplantation, connective tissue disease.

General Considerations

Bronchiolitis is a generic term applied to varied inflammatory processes that affect the bronchioles, which are small conducting airways < 2 mm in diameter. Although less common in adults than children, bronchiolitis is encountered in multiple clinical settings, such as postinfectious, inhalational injury (eg, vaping), organ transplantation, connective tissue diseases, and hypersensitivity pneumonitis.

The clinical approach to bronchiolitis divides patients into groups based on etiology, but different clinical syndromes may have identical histopathologic findings. As a result, no single classification scheme has been widely accepted, and there is an overlapping array of terms to describe these disorders from the viewpoints of the clinician, the pathologist, and the radiologist.

Clinical Findings

Acute bronchiolitis is rare in adults but may be present following viral infections.

Constrictive bronchiolitis (also referred to as obliterative bronchiolitis or bronchiolitis obliterans) may be caused by inhalation injury (ammonia, welding fumes, and heavy metals); rheumatoid arthritis; medication reactions (busulfan, gold, and penicillamine); and chronic rejection following heart-lung, lung, or hematopoietic stem cell transplantation (*bronchiolitis obliterans syndrome*). PFTs with airflow obstruction and air trapping; unremarkable CXRs, heterogeneous air trapping on chest CT scans.

Proliferative bronchiolitis (organizing pneumonia, previously called idiopathic bronchiolitis obliterans organizing pneumonia [BOOP]) is associated with diverse pulmonary disorders, including infection, aspiration, acute respiratory distress syndrome (ARDS), hypersensitivity pneumonitis, connective tissue diseases, and organ transplantation. PFTs typically reveal a restrictive ventilatory defect. It is more likely to have an abnormal CXR or chest CT scan with patchy consolidation, ground-glass opacities, or nodular appearance.

Follicular bronchiolitis is most commonly associated with connective tissue disease, especially rheumatoid arthritis and Sjögren syndrome, and with immunodeficiency states, such as HIV or common variable immunodeficiency. It may be seen in lymphoid interstitial pneumonia. Chest CT scan may show centrilobular and peribronchial nodules.

Respiratory bronchiolitis is the most common form of bronchiolitis in adults and is usually related to cigarette smoking. It usually occurs without symptoms or physiological evidence of lung impairment, but it may be seen with associated ILD (respiratory bronchiolitis-interstitial lung disease). PFTs may show mixed obstructive-restrictive pattern. Chest CT may show centrilobular nodules, patchy ground-glass opacities, air trapping, and “tree-in-bud” opacities.

Diffuse panbronchiolitis is most frequently diagnosed in Japan. Men are affected about twice as often as women, two-thirds are nonsmokers, and most patients have a history of chronic pansinusitis. PFTs reveal obstructive abnormalities, and the CXR shows a distinct pattern of diffuse, small, nodular shadows with hyperinflation.

Treatment

Constrictive bronchiolitis is relatively unresponsive to corticosteroids and frequently leads to progressive clinical deterioration. Azithromycin may slow progression of bronchiolitis obliterans syndrome in lung transplant recipients. In **proliferative bronchiolitis** corticosteroids are usually effective and provide prompt improvement. Initial therapy is prednisone 1 mg/kg/day orally for 1–3 months following by a slow tapering (as tolerated) to 20–40 mg/day, with weaning over the subsequent 3–6 months, as tolerated. Relapse is common if corticosteroids are stopped prematurely or tapered too quickly. In **follicular bronchiolitis,** treatment of underlying disease is recommended. Systemic steroids and azithromycin may be effective. Systemic steroids also may be utilized in **respiratory bronchiolitis,** although response is variable. Smoking cessation is recommended. Azithromycin is useful in the treatment of **diffuse bronchiolitis**.

Dalziel SR et al. Bronchiolitis. Lancet 2022;400:392. [PMID: 35785792]

PULMONARY INFECTIONS

PNEUMONIA

Pneumonia has classically been considered in terms of the infecting organism (Table 9–9). This approach facilitates discussion of characteristic clinical presentations but is a limited guide to patient management since specific microbiologic information is usually not available at initial presentation. Classification schemes emphasize epidemiologic

Table 9–9. Characteristics of selected pneumonias.

Organism; Appearance on Smear of Sputum	Clinical Setting	Complications
Streptococcus pneumoniae (pneumococcus). Gram-positive diplococci.	Chronic cardiopulmonary disease; follows upper respiratory tract infection	Bacteremia, meningitis, endocarditis, pericarditis, empyema
Haemophilus influenzae. Pleomorphic gram-negative coccobacilli.	Chronic cardiopulmonary disease; follows upper respiratory tract infection	Empyema, endocarditis
Staphylococcus aureus. Plump gram-positive cocci in clumps.	Residence in long-term care facility, hospital-associated, influenza epidemics, cystic fibrosis, bronchiectasis, injection drug use	Empyema, cavitation
Klebsiella pneumoniae. Plump gram-negative encapsulated rods.	Alcohol abuse, diabetes mellitus; hospital-associated	Cavitation, empyema
Escherichia coli. Gram-negative rods.	Hospital-associated; rarely, community-acquired	Empyema
Pseudomonas aeruginosa. Gram-negative rods.	Hospital-associated; cystic fibrosis, bronchiectasis	Cavitation
Anaerobes. Mixed flora.	Aspiration, poor dental hygiene	Necrotizing pneumonia, abscess, empyema
Mycoplasma pneumoniae. PMNs and monocytes; no bacteria.	Young adults; summer and fall	Skin rashes, hemolytic anemia, encephalitis
Legionella species. Few PMNs; no bacteria.	Summer and fall; exposure to contaminated construction site, water source, air conditioner; community-acquired or hospital-associated	Empyema, cavitation, endocarditis, pericarditis
Chlamydophila pneumoniae. Nonspecific.	Clinically similar to *M pneumoniae*, but prodromal symptoms last longer (up to 2 weeks); sore throat with hoarseness common; mild pneumonia in teenagers and young adults	Reinfection in older adults with underlying COPD or HF may be severe or even fatal
Moraxella catarrhalis. Gram-negative diplococci.	Preexisting lung disease; older patients; corticosteroid or immunosuppressive therapy	Rarely, pleural effusions and bacteremia
Pneumocystis jirovecii. Nonspecific.	AIDS, immunosuppressive or cytotoxic drug therapy, cancer	Pneumothorax, respiratory failure, ARDS, death
SARS-CoV-2. Nonspecific.	Pandemic. Milder pneumonia (teenagers, young adults); more severe pneumonia (older, immunocompromised, multiple comorbidly ill adults)	Respiratory failure, ARDS, death

ARDS, acute respiratory distress syndrome; PMN, polymorphonuclear leukocyte; SARS-CoV-2, severe acute respiratory syndrome due to coronavirus-2 (see COVID-19 discussion, Chapter 37, and consult https://www.coronavirus.gov for the latest from the CDC).

factors that predict etiology and guide initial therapy. Pneumonia may be classified as **community-acquired pneumonia (CAP)** or **nosocomial pneumonia** and, within the latter, as **hospital-acquired pneumonia (HAP)** or **ventilator-associated pneumonia (VAP).** These categories are based on differing settings and infectious agents and require different diagnostic and therapeutic interventions. **Anaerobic pneumonia** and **lung abscess** can occur in both hospital and community settings.

This section sets forth the evaluation and management of pulmonary infiltrates in immunocompetent persons separately from the approach to immunocompromised persons—defined as those with HIV disease, absolute neutrophil counts < 1000/mcL (1.0 × 10^9/L), or current or recent exposure to myelosuppressive or immunosuppressive medications.

1. Community-Acquired Pneumonia

ESSENTIALS OF DIAGNOSIS

- Fever or hypothermia, tachypnea, cough with or without sputum, dyspnea, chest discomfort.
- Bronchial breath sounds, rhonchi, or inspiratory crackles on chest auscultation.
- Parenchymal opacity on CXR (occasionally not evident at presentation).
- Occurs outside of the hospital or within 48 hours of hospital admission.

General Considerations

Community-acquired pneumonia (CAP) is a common disorder, with approximately 4–5 million cases diagnosed each year in the United States, at least 25% of which require hospitalization. It is the deadliest infectious disease in the United States and is routinely among the top 10 causes of death. Mortality in milder cases treated as outpatients is < 1%. Among patients hospitalized for CAP, in-hospital mortality is approximately 10–12% and 1-year mortality (in those over age 65) is > 40%. Risk factors for the development of CAP include older age; tobacco use; excessive alcohol use; comorbid medical conditions, especially COPD or other chronic lung disease; immunosuppression; and recent viral upper respiratory tract infection.

The patient's history, physical examination, and imaging studies are essential to establishing a diagnosis of CAP. For the identification of specific pathogen, sputum examination may be helpful, but 40% of patients cannot produce an evaluable sputum sample; additionally, test characteristics of sputum Gram stain and culture vary by organism and lack sensitivity for some of the most common causes of pneumonia. Since patient outcomes improve when the initial antibiotic choice is appropriate for the infecting organism, the American Thoracic Society and the Infectious Diseases Society of America recommend empiric treatment based on epidemiologic data (Table 9–10). Such treatment improves initial antibiotic coverage, reduces unnecessary hospitalization, and improves 30-day survival.

Definition & Pathogenesis

CAP is diagnosed outside of the hospital setting or within the first 48 hours of hospital admission. Pulmonary defense mechanisms (cough reflex, mucociliary clearance system, immune responses) normally prevent the development of lower respiratory tract infections following aspiration of oropharyngeal secretions containing bacteria or inhalation of infected aerosols. CAP occurs when there is a defect in one or more of these normal defense mechanisms or when a large infectious inoculum or a virulent pathogen overwhelms the immune response.

Prospective studies fail to identify the cause of CAP in 30–60% of cases; two or more causes are identified in up to one-third of cases. The most common bacterial pathogen identified in most studies of CAP is *S pneumoniae*, accounting for approximately two-thirds of bacterial isolates. Other common bacterial pathogens include *H influenzae*, *M pneumoniae*, *C pneumoniae*, *S aureus*, *Moraxella catarrhalis*, *Klebsiella pneumoniae*, other gram-negative rods, and *Legionella* species. Common viral causes of CAP include coronaviruses (SARS-CoV-2, MERS), influenza virus, RSV, adenovirus, and parainfluenza virus. A detailed assessment of epidemiologic risk factors may aid in diagnosing pneumonias due to the following uncommon causes: *Chlamydophila psittaci* (psittacosis); *Coxiella burnetii* (Q fever); *Francisella tularensis* (tularemia); *Blastomyces*, *Coccidioides*, *Histoplasma* (endemic fungi); and Sin Nombre virus (hantavirus pulmonary syndrome).

Clinical Findings

A. Symptoms and Signs

Most patients with CAP experience an acute or subacute onset of fever, cough with or without sputum production, and dyspnea. Other common symptoms include chills, rigors, pleurisy, fatigue, myalgias, anorexia, headache, and abdominal pain. Patients aged 80 years or older, however, may have an atypical presentation, including falls, delirium, lethargy, and anorexia.

Common physical findings include fever or hypothermia, tachypnea, and tachycardia. Many patients appear acutely ill. Chest examination often reveals inspiratory crackles, rhonchi, and bronchial breath sounds. Dullness to percussion may be observed if lobar consolidation or a parapneumonic pleural effusion is present. The clinical evaluation is < 50% sensitive compared to chest imaging for the diagnosis of CAP (see Imaging section below). In most patients, therefore, imaging is essential to the evaluation of suspected CAP.

B. Diagnostic Testing

Diagnostic testing for a specific infectious cause of CAP is not generally indicated in outpatients because empiric antibiotic therapy is almost always effective in this population. In ambulatory outpatients whose presentation (travel history, exposure) suggests an etiology not covered by

Table 9–10. Recommended empiric antibiotics for community-acquired bacterial pneumonia.

Outpatient management

1. For previously healthy patients with no risk factors for MRSA or *Pseudomonas*:
    a. Amoxicillin, 1 g orally three times daily, *or*
    b. Doxycycline, 100 mg orally twice a day, *or*
    c. In regions with a low rate (< 25%) of infection with high level (MIC ≥ 16 mcg/mL) macrolide-resistant *Streptococcus pneumoniae*, then a macrolide (clarithromycin, 500 mg orally twice a day; or azithromycin, 500 mg orally as a first dose and then 250 mg orally daily for 4 days, or 500 mg orally daily for 3 days).
2. For patients with comorbid medical conditions such as chronic heart, lung, liver, or kidney disease; diabetes mellitus; alcohol use disorder; malignancy; asplenia; immunosuppressant conditions or use of immunosuppressive drugs; or use of antibiotics within the previous 3 months (in which case an agent from a different antibiotic class should be selected):
    a. A macrolide *or* doxycycline (as above) *plus* an oral β-lactam (amoxicillin/clavulanate 500 mg/125 mg three times daily, amoxicillin/clavulanate 875 mg/125 mg twice daily, amoxicillin/clavulanate 2 g/125 mg twice daily; cefpodoxime, 200 mg twice daily; cefuroxime, 500 mg twice daily).
    b. Monotherapy with an oral fluoroquinolone (moxifloxacin, 400 mg daily; gemifloxacin, 320 mg daily; levofloxacin, 750 mg daily).

Inpatient management of nonsevere pneumonia (typically not requiring intensive care)

1. A respiratory fluoroquinolone. Oral and intravenous doses equivalent: moxifloxacin, 400 mg daily or levofloxacin, 500–750 mg daily *or*
2. A macrolide (see above for oral therapy) *plus* a β-lactam (see above for oral β-lactam therapy). For intravenous therapy: ampicillin/sulbactam, 1.5–3 g every 6 hours; cefotaxime, 1–2 g every 8 hours; ceftriaxone, 1–2 g every 12–24 hours; ceftaroline, 600 mg every 12 hours.
3. For patients with prior respiratory isolation of MRSA, strongly consider adding coverage for MRSA and obtain cultures or nasal PCR to confirm infection or to allow de-escalation of therapy: vancomycin, typically starting at 15 mg/kg intravenously every 12 hours with interval dosing based on kidney function to achieve serum trough concentration 15–20 mcg/mL *or* linezolid, 600 mg orally or intravenously every 12 hours.
4. For patients with prior respiratory isolation of *Pseudomonas aeruginosa*, strongly consider adding coverage for *P aeruginosa* and obtain cultures to confirm infection or to allow de-escalation of therapy. Intravenous therapy only: piperacillin-tazobactam, 3.375–4.5 g every 6 hours; cefepime, 1–2 g every 8 hours; imipenem, 0.5–1 g every 6 hours; meropenem, 1 g every 8 hours; or aztreonam 2 g every 8 hours.

Inpatient management of severe pneumonia (typically requiring intensive care). All agents administered intravenously, except as noted.

1. Azithromycin (500 mg orally as a first dose and then 250 mg orally daily for 4 days, *or* 500 mg orally daily for 3 days) or a respiratory fluoroquinolone (as above) plus an intravenous anti-pneumococcal β-lactam (as above).
2. For patients allergic to β-lactam antibiotics, a fluoroquinolone *plus* aztreonam (2 g every 8 hours).
3. For patients at risk for *P aeruginosa*, add coverage for *P aeruginosa* and obtain cultures to confirm infection or to allow de-escalation of therapy: piperacillin-tazobactam, 3.375–4.5 g every 6 hours; cefepime, 1–2 g every 8 hours; imipenem, 0.5–1 g every 6 hours; meropenem, 1 g every 8 hours; or aztreonam 2 g every 8 hours.
4. For patients at risk for *Pseudomonas* infection AND who are critically ill, at increased risk for drug resistance, or if local incidence of monotherapy-resistant *Pseudomonas* is > 10%, consider adding either an anti-pseudomonal fluoroquinolone (ciprofloxacin 400 mg every 8–12 hours or levofloxacin 750 mg daily) *or* an aminoglycoside (gentamicin, tobramycin, amikacin, all weight-based dosing administered daily adjusted to appropriate trough levels).
5. For patients at risk for MRSA infection, add coverage for MRSA and obtain cultures or nasal PCR, or both, to confirm infection or to allow de-escalation of therapy: vancomycin, typically starting at 15 mg/kg intravenously every 12 hours with interval dosing based on kidney function to achieve serum trough concentration 15–20 mcg/mL or linezolid, 600 mg every 12 hours.

MIC, minimum inhibitory concentration; MRSA, methicillin-resistant *Staphylococcus aureus*.

Recommendations assembled from Metlay JP et al. Diagnosis and treatment of adults with community-acquired pneumonia. An official clinical practice guideline of the American Thoracic Society and Infectious Diseases Society of America. Am J Respir Crit Care Med. 2019;200(7):e45–e67.

standard therapy (eg, *Coccidioides*) or public health concerns (eg, SARS-CoV-2, *Mycobacterium tuberculosis*, influenza), diagnostic testing is appropriate. Diagnostic testing is recommended in hospitalized CAP patients for multiple reasons: the likelihood of an infectious cause unresponsive to standard therapy is higher in more severe illness, the inpatient setting allows narrowing of antibiotic coverage as specific diagnostic information is available, and the yield of testing is higher in more acutely ill patients.

Diagnostic tests are used to adjust empirically chosen therapy and to facilitate epidemiologic analysis. Three widely available diagnostic tests may guide therapy: the sputum Gram stain and culture, tests for viruses such as influenza and SARS-CoV-2 (see COVID-19 discussion, Chapter 37), and urinary antigen tests. The usefulness of a sputum Gram stain lies in broadening initial coverage in patients hospitalized for CAP, most commonly to cover *S aureus* (including community-acquired methicillin-resistant *S aureus* [CA-MRSA] strains) or gram-negative rods (including *P aeruginosa* and Enterobacteriaceae). Urinary antigen assays for *Legionella pneumophila* and *S pneumoniae* are commonly available and do not rely on effective sputum expectoration. Urinary antigen assay for *L pneumophila* should be ordered for patients in an area with an outbreak, with recent travel, with severe disease, or in whom a high clinical index of suspicion exists. The utility of urinary antigen testing for *S pneumoniae* has been questioned due to its low sensitivity and predictive value.

Rapid influenza and SARS-CoV-2 testing have intermediate sensitivity but high specificity, with sensitivity depending on the method of detection (nucleic acid or PCR-based tests have higher sensitivity than antigen-based detection). Positive tests for viruses may direct isolation of hospitalized patients but do not necessarily reduce the need for antibacterial therapy, since coinfection with bacterial pathogens may occur.

Rapid turnaround multiplex-PCR amplification from lower respiratory tract samples is increasingly available. Different commercial products can identify multiple strains of bacteria and viruses, in addition to genes that encode for antibiotic resistance. Early experience with multiplex-PCR shows improved overall diagnostic yield, particularly for viral infections, and a higher incidence of bacterial/viral coinfection than previously recognized. Limitations of multiplex-PCR include cost and availability, in addition to the challenge of interpreting potentially false-positive results from a highly sensitive test, since either viral or bacterial pathogens may colonize the airways. Large scale studies evaluating the impact of rapid molecular diagnostic approaches are in progress and will help inform future utility.

Additional microbiologic testing including pre-antibiotic sputum and blood cultures (at least two sets at separate sites) has been standard practice for patients with CAP who require hospitalization. The yield of blood and sputum cultures is low, as false-positive results are common, and the impact of culture results on patient outcomes is small. As a result, targeted testing is recommended for patients with severe disease and for those treated empirically for MRSA or *P aeruginosa* infection. The role of culture is to allow narrowing of initial empiric antibiotic coverage, adjustment of coverage based on specific antibiotic resistance patterns, to identify unsuspected pathogens not covered by initial therapy, and to provide information for epidemiologic analysis. Patients at risk for or treated empirically for MRSA should have an MRSA nasal screening test performed. A negative nasal screening test may guide de-escalation of empiric MRSA coverage in patients who cannot expectorate a sputum sample.

Apart from microbiologic testing, hospitalized patients should undergo CBC with differential and a chemistry panel (including serum glucose, electrolytes, BUN, creatinine, bilirubin, and liver enzymes). Test results help assess severity of illness and guide evaluation and management. HIV testing should be considered in all adult patients and performed in those with risk factors.

C. Imaging

A pulmonary opacity on CXR or CT scan is required to establish a diagnosis of CAP. Chest CT scan is more sensitive and specific than CXR and may be indicated in selected cases. Radiographic findings range from patchy airspace opacities to lobar consolidation with air bronchograms to diffuse alveolar or interstitial opacities. Additional findings can include pleural effusions and cavitation. Chest imaging cannot identify a specific microbiologic cause of CAP; no pattern of radiographic abnormalities is pathognomonic of any infectious cause. Chest ultrasound, which may be more readily available in resource-constrained settings, has demonstrated variable sensitivity and specificity for pneumonia when compared to CT imaging.

Chest imaging may help assess severity and response to therapy over time. Progression of pulmonary opacities during antibiotic therapy or lack of radiographic improvement over time are poor prognostic signs and raise concerns about secondary or alternative pulmonary processes. Clearing of pulmonary opacities in patients with CAP can take 6 weeks or longer. Clearance is usually quickest in younger patients, nonsmokers, and those with single-lobe involvement.

D. Special Examinations

Patients with CAP who have significant pleural fluid collections may require diagnostic thoracentesis (with pleural fluid sent for glucose, LD, and total protein levels; leukocyte count with differential; pH determination; and Gram stain and culture). Positive pleural cultures or features of complex parapneumonic effusion indicate the need for tube thoracostomy drainage.

Patients with cavitary opacities should have sputum fungal and mycobacterial cultures.

Sputum induction or fiberoptic bronchoscopy to obtain samples of lower respiratory secretions are indicated in patients with a worsening clinical course who cannot provide expectorated sputum samples or who may have pneumonia caused by *M tuberculosis* infection or certain opportunistic infections, including *Pneumocystis jirovecii*.

Differential Diagnosis

The differential diagnosis of lower respiratory tract infection is extensive and includes upper respiratory tract infections, reactive airway diseases, HF, interstitial pneumonias, lung cancer, pulmonary vasculitis, pulmonary thromboembolic disease, and atelectasis.

Treatment

Two general principles guide antibiotic therapy once the diagnosis of CAP is established: **prompt** initiation of a medication to which the etiologic pathogen is **susceptible.**

In patients who require specific diagnostic evaluation, sputum and blood culture specimens should be obtained before initiation of antibiotics. Since early administration of antibiotics to acutely ill patients is associated with improved outcomes, obtaining other diagnostic specimens or test results should not delay the initial dose of antibiotics.

Optimal antibiotic therapy would be pathogen directed, but a definitive microbiologic diagnosis is not typically available on presentation. A syndromic approach to therapy, based on clinical presentation and chest imaging, does not reliably predict the microbiology of CAP. Therefore, initial antibiotic choices are empiric, based on acuity (treatment as an outpatient, inpatient, or in the ICU), patient risk factors for specific pathogens, and local antibiotic resistance patterns (see Table 9–10).

Since *S pneumoniae* remains a common cause of CAP in all patient groups, local prevalence of drug-resistant

S pneumoniae significantly affects initial antibiotic choice. Prior treatment with one antibiotic in a pharmacologic class (eg, β-lactam, macrolide, fluoroquinolone) predisposes to the emergence of drug-resistant *S pneumoniae*, with resistance developing against that class of antibiotics to which the pathogen was previously exposed. In vivo efficacy appears to justify maintaining macrolides as first-line therapy except in areas where there is a high prevalence of resistant strains. Macrolide resistance has increased (approximately one-third of *S pneumoniae* isolates show in vitro resistance); however, reported treatment failures remain rare compared to the number of patients treated. *S pneumoniae* resistance to fluoroquinolones is rare in the United States but is increasing.

CA-MRSA is genetically and phenotypically different from hospital-acquired MRSA strains and is more virulent. CA-MRSA is a rare cause of necrotizing pneumonia, empyema, respiratory failure, and shock; it appears to be associated with prior influenza infection. Linezolid may be preferred to vancomycin in treatment of CA-MRSA pulmonary infection due to bacterial toxin inhibition. Daptomycin should **not** be used in any MRSA pneumonia because it does not achieve adequate concentration in the lung. For expanded discussions of specific antibiotics, see Chapter 35.

A. Treatment of Outpatients

See Table 9–10 for specific medication dosages. The most common etiologies of CAP in outpatients who do not require hospitalization are *S pneumoniae*; *M pneumoniae; C pneumoniae;* and respiratory viruses, including influenza. For previously healthy patients with no recent (90 days) use of antibiotics, the recommended treatment is amoxicillin with or without a macrolide (clarithromycin or azithromycin), or doxycycline. In areas with a high incidence of macrolide-resistant *S pneumoniae*, initial therapy in patients with no comorbidities may include the combination of a β-lactam plus a macrolide, or a respiratory fluoroquinolone.

In outpatients with chronic heart, lung, liver, or kidney disease; diabetes mellitus; alcohol use disorder; malignancy; or asplenia or who received antibiotic therapy within the past 90 days, the recommended treatment is a macrolide or doxycycline plus a β-lactam (high-dose amoxicillin and amoxicillin-clavulanate are preferred to cefpodoxime and cefuroxime) or monotherapy with a respiratory fluoroquinolone (moxifloxacin, gemifloxacin, or levofloxacin).

The default duration of antibiotic therapy for CAP should be 5 days; factors that may affect therapy duration are clinical stability, etiology (MRSA and *P aeruginosa* require minimum 7 days of therapy, for example), severity of illness, complications, and comorbid medical problems.

B. Treatment of Hospitalized and ICU Patients

1. Antibiotics—The most common etiologies of CAP in patients who require hospitalization but not intensive care are *S pneumoniae*, *M pneumoniae*, *C pneumoniae*, *H influenzae*, *Legionella* species, and respiratory viruses. Some patients have aspiration as an immediate precipitant to the CAP without a specific bacterial etiology. First-line therapy in hospitalized patients is the combination of a macrolide (clarithromycin or azithromycin) plus a β-lactam (cefotaxime, ceftriaxone, ceftaroline, or ampicillin-sulbactam) or monotherapy with a respiratory fluoroquinolone (eg, moxifloxacin, gemifloxacin, or levofloxacin) (Table 9–10).

Almost all patients admitted to a hospital for treatment of CAP receive intravenous antibiotics. However, no studies in hospitalized patients demonstrated superior outcomes with intravenous antibiotics compared with oral antibiotics, provided patients were able to tolerate oral therapy and the medication was well absorbed. Duration of inpatient antibiotic treatment is the same as for outpatients.

The most common etiologies of CAP in patients who require admission to intensive care are *S pneumoniae*, *Legionella* species, *H influenzae*, Enterobacteriaceae species, *S aureus*, *Pseudomonas* species, and respiratory viruses. First-line antibacterial therapy in ICU patients with CAP is an anti-pneumococcal β-lactam (cefotaxime, ceftriaxone, ceftaroline, or ampicillin-sulbactam) plus either a macrolide or a respiratory fluoroquinolone.

Risk factors for *Pseudomonas*, Enterobacteriaceae, or MRSA infection must be considered when choosing empiric antibiotic therapy for inpatients with CAP. Specific risk factors for these organisms include (1) prior isolation of the pathogen, (2) inpatient hospitalization within the last 90 days, or (3) exposure to intravenous antibiotics within the last 90 days. In patients with specific risk factors for *Pseudomonas* infection, combine an anti-pneumococcal, anti-pseudomonal β-lactam (piperacillin-tazobactam, cefepime, imipenem, meropenem) with either azithromycin or a respiratory fluoroquinolone (moxifloxacin, gemifloxacin, or levofloxacin). In critically ill patients, in those at increased risk for drug resistance, or if the unit incidence of monotherapy-resistant *Pseudomonas* is > 10%, consider use of two agents with anti-pseudomonal efficacy: either ciprofloxacin or levofloxacin plus the above anti-pneumococcal, anti-pseudomonal β-lactam or an anti-pneumococcal, anti-pseudomonal β-lactam plus an aminoglycoside (gentamicin, tobramycin, amikacin) plus either azithromycin or a respiratory fluoroquinolone. Patients with specific risk factors for MRSA should be treated with vancomycin or linezolid. Patients with very severe disease (respiratory failure requiring mechanical ventilation or septic shock) should also be strongly considered for MRSA therapy. Provided the patient is clinically improving, negative sputum and blood cultures obtained before initiation of antibiotics can support de-escalation of antibiotic therapy. Additionally, all patients prescribed vancomycin or linezolid should have swabs of the nasal passages for MRSA; if the swab results are negative, MRSA coverage can be safely de-escalated, even when adequate sputum samples have not been obtained.

Patients with CAP in whom influenza is detected should be treated with the antiviral oseltamivir, whether influenza is identified as a single pathogen or as a coinfection along with a bacterial pathogen. Oseltamivir is most effective when begun within 2 days but may still be beneficial within several days after symptom onset, particularly in severe cases of CAP.

2. Adjunctive treatment: Corticosteroids—The role of corticosteroid therapy in the management of CAP has been controversial; however, a 2023 large RCT of adults with severe CAP hospitalized in an ICU identified a lower risk of mortality at 28 days in patients treated with hydrocortisone (200 mg/day for 4–7 days followed by tapering) than patients treated with placebo (6.2% versus 11.9%, respectively) and a lower requirement for mechanical ventilation. While the role of corticosteroids in CAP is being further evaluated, they are recommended in patients with CAP who may also have severe septic shock, acute exacerbation of asthma or COPD, or adrenal insufficiency. Corticosteroid treatment of influenza pneumonia may be associated with higher mortality and should be avoided. Corticosteroid treatment is recommended for SARS-CoV-2 pneumonia when oxygen is required; see Chapter 37 for further discussion.

Prevention

Pneumococcal vaccines prevent or lessen the severity of pneumococcal infections in immunocompetent patients. Two classes of pneumococcal vaccines for adults are available and approved for use in the United States: one containing capsular polysaccharide antigens to 23 common strains of *S pneumoniae* (PPSV23) and several other polyconjugate vaccines, including 13-valent (PCV13), 15-valent (PCV15), 20-valent (PCV20), and 21-valent (PCV21).

Pneumococcal vaccination has historically been recommended for all adults aged 65 and older, and adults aged 19-64 with certain medical comorbidities (diabetes, chronic lung disease, chronic liver disease), increased risk of meningitis (CSF leak, cochlear implant), or immunocompromising condition, including asplenia. In 2024, the CDC Advisory Committee on Immunization Practices issued updated guidance, lowering the recommended age for routine pneumococcal vaccination to age 50. The guidance provided below for choice of vaccine reflects the previous age ranges but can reasonably be extrapolated to all adults aged 50 and older.

Adults 65 years or older: PCV21 or PCV20 alone are recommended for all adults 65 years or older with or without chronic medical or immunocompromising conditions. PCV21, the most recent vaccine, contains the broadest range of serotypes, but does not cover serotype 4, which is more prevalent in Navajo communities and in certain risk groups (people with substance use disorder or homelessness). Alternatively, patients may be given sequential administration of PCV15 followed by PPSV23 injection at least one year later. For adults 65 years or older who have an immunocompromising condition or cochlear implant, PPSV23 should be administered 8 or more weeks following PCV15 injection. Many patients have already received a pneumococcal vaccine or a series of vaccines. Adults (with or without underlying medical conditions) who previously received PPSV23 alone should receive either PCV21 or PCV20 1 year or later after the PPSV23 injection. Adults who previously received PCV13 or PCV10 and are without immunocompromising conditions alone should receive PCV21 or PCV20 at least 1 year later; those with underlying immunosuppression or cochlear implant are recommended to receive the PPSV23 injection 8 or more weeks following the PCV13 or PCV10 injection. Adults 65 years or older who received both PCV13 *and* PPSV23 before age 65 should receive a single dose of PCV21 or PVC20 ≥ 5 years after the last vaccine.

Adults 19 years or older with immunocompromising conditions or medical comorbidities: PCV21 or PCV20 alone are recommended for adults with immunocompromising conditions, chronic renal failure, asplenia, or increased risk of meningitis (CSF leak or cochlear implant). Alternatively, they may receive sequential PCV15/PPSV23, with PPSV23 administered at a shortened interval of 8 or more weeks. Adults 19–64 with high-risk conditions who previously received PPSV23 should receive a single dose of PCV21 or PVC20 1 or more years later, and those who received PCV13 or PCV10 should either receive PCV21 or PCV20 1 or more years later, or, in the case of immunosuppression or cochlear implant, PPSV23 8 or more weeks later. Adults 19–64 years who previously received both PCV13/PCV10 and PPSV23 should receive PCV21 or PCV20 or more years following the last vaccine. PPSV23 is an acceptable alternative if PCV21 or PCV20 is not available.

Subsequent pneumococcal "revaccination" after the first vaccine at or after age 65 remains controversial.

Influenza vaccine is effective in preventing severe disease due to influenza virus with a resulting positive impact on both primary influenza pneumonia and secondary bacterial pneumonias. The seasonal influenza vaccine is recommended annually for all persons older than 6 months without contraindications, with priority given to persons at risk for complications of influenza infection (persons aged 50 years or older, immunocompromised persons, residents of long-term care facilities, patients with pulmonary or cardiovascular disorders, pregnant persons) as well as health care workers and others who may transmit influenza to high-risk patients. Higher dose or adjuvanted vaccination is recommended for adults 65 and older.

SARS-CoV-2 vaccinations are recommended for everyone older than 6 months without contraindications. Vaccinations (including boosters) reduce the likelihood of infection, pneumonia, hospitalization, and mortality (see COVID-19 discussion, Chapter 37).

RSV vaccination was recently approved for adults over age 60, especially those with chronic underlying medical conditions or deemed to be at increased risk for severe disease, using a shared-decision making model. It is recommended for all adults over 75. Pregnant persons who are 32–36 weeks gestation during RSV season and have not previously been vaccinated are recommended to receive the vaccine, as a measure to prevent severe RSV disease in the infant.

When to Admit

Once a diagnosis of CAP is made, the first management decision is to determine the site of care: Is it safe to treat the patient at home or does he or she require hospital or ICU admission? When need for admission is not immediately apparent, there are two widely used clinical prediction rules available to guide admission and triage decisions, the **Pneumonia Severity Index (PSI)** and the **CURB-65.**

A. Hospital Admission Decision

The PSI is a validated prediction model that uses 20 items from demographics, medical history, physical examination, laboratory results, and imaging to stratify patients into five risk groups. In conjunction with clinical judgment, it facilitates safe decisions to treat CAP in the outpatient setting. An online PSI risk calculator is available at https://www.thecalculator.co/health/Pneumonia-Severity-Index-(PSI)-Calculator-977.html. The CURB-65 assesses five simple, independent predictors of increased mortality (**C**onfusion, **U**remia, **R**espiratory rate, **B**lood pressure, and age > **65**) to calculate a 30-day predicted mortality (https://www.mdcalc.com/curb-65-score-pneumonia-severity). Compared with the PSI, the simpler CURB-65 is less discriminating at low mortality but excellent at identifying patients with high mortality who may benefit from ICU-level care. A modified version (CRB-65) dispenses with BUN and eliminates the need for laboratory testing.

Hospital admission decision should also include circumstances of care independent of pneumonia severity, including comorbidities and the patient's ability to care for themselves effectively at home.

B. ICU Admission Decision

Expert opinion has defined major and minor criteria to identify patients at high risk for death. Major criteria are septic shock with need for vasopressor support and respiratory failure with need for mechanical ventilation. Minor criteria are respiratory rate of 30 breaths or more per minute, hypoxemia (defined as $\text{Pao}_2/\text{Fio}_2 \leq 250$), hypothermia (core temperature < 36.0°C), hypotension requiring aggressive fluid resuscitation, confusion/disorientation, multilobar pulmonary opacities, leukopenia due to infection with WBC < 4000/mcL ($< 4.0 \times 10^9$/L), thrombocytopenia with platelet count < 100,000/mcL ($< 100 \times 10^9$/L), uremia with BUN of ≥ 20 mg/dL (≥ 7.1 mmol/L), metabolic acidosis, or elevated serum lactate level. Either one major criterion or three or more minor criteria of illness severity generally require ICU-level care.

2. Nosocomial Pneumonia (Hospital-Acquired & Ventilator-Associated)

ESSENTIALS OF DIAGNOSIS

- **Hospital-acquired pneumonia (HAP)** is diagnosed in patients with clinical features and imaging consistent with pneumonia, occurring > 48 hours after admission to the hospital and excluding any infections present at the time of admission.
- **Ventilator-associated pneumonia (VAP)** requires clinical features concerning for new pneumonia with positive respiratory samples developing > 48 hours following tracheal intubation and mechanical ventilation.

General Considerations

Hospitalized patients carry different flora with different resistance patterns than healthy patients in the community, and their health status may place them at higher risk for more severe infection. The diagnostic approach and antibiotic treatment of patients with HAP is, therefore, different from patients with CAP. Similarly, management of patients in whom VAP develops following tracheal intubation and mechanical ventilation should address issues specific to this group of patients.

Considered together, nosocomial pneumonias (HAP or VAP) represent an important cause of morbidity and mortality despite widespread use of preventive measures, advances in diagnostic testing, and potent antimicrobial agents. HAP is one of the most common causes of infection among hospital inpatients and carries the highest burden of morbidity and mortality. Patients in ICUs and those who are being mechanically ventilated are at the highest risk for HAP (and VAP) and experience higher morbidity and mortality than other inpatients. Definitive identification of the infectious cause of a lower respiratory infection is rarely available on presentation; initial antibiotic treatment is therefore empiric and informed by epidemiologic and patient data rather than pathogen directed.

Definition & Pathogenesis

HAP develops > 48 hours after admission to the hospital, and VAP develops in a mechanically ventilated patient > 48 hours after tracheal intubation. Three factors distinguish nosocomial pneumonia from CAP: (1) different infectious causes; (2) different antibiotic susceptibility patterns, specifically, a higher incidence of drug resistance; and (3) poorer underlying health status of patients, putting them at risk for more severe infections. Since access to the lower respiratory tract occurs primarily through microaspiration, nosocomial pneumonia starts with a change in upper respiratory tract flora. Colonization is promoted by exogenous factors (eg, instrumentation of the upper airway with nasogastric and endotracheal tubes; contact with personnel, equipment, and contaminated aerosols; treatment with broad-spectrum antibiotics that promote the emergence of drug-resistant organisms); and patient factors (eg, malnutrition, advanced age, altered consciousness, swallowing disorders, and underlying pulmonary and systemic diseases). Impaired cellular and mechanical defense mechanisms in the lungs of hospitalized patients raise the risk of infection after aspiration has occurred.

Gastric acid may play a role in protection against nosocomial pneumonias. Observational studies have suggested that elevation of gastric pH due to antacids, H_2-receptor antagonists, PPIs, or enteral feeding is associated with gastric microbial overgrowth, tracheobronchial colonization, and HAP/VAP. Meta-analysis of RCTs suggested an increased risk of HAP among enterally fed patients receiving stress ulcer prophylaxis. The IDSA and other professional organizations recommend that acid-suppressive medications (H_2-receptor antagonists and PPIs) be given only to patients at high risk for stress gastritis.

The microbiology of the nosocomial pneumonias differs from CAP but is substantially the same among HAP and VAP. The most common organisms responsible for HAP and VAP include *S aureus* (both methicillin-sensitive *S aureus* and MRSA), *Streptococcus* species, *P aeruginosa*, other gram-negative rods, including extended spectrum β-lactamase (ESBL)–producing organisms (*Enterobacter* species, *K pneumoniae*, and *Escherichia coli*) and non-ESBL-producing organisms. VAP patients may be infected with *Acinetobacter* species and *S maltophilia*. Anaerobic organisms (*Bacteroides*, anaerobic streptococci, *Fusobacterium*) may also cause pneumonia in hospitalized patients; when these organisms are isolated, they are commonly part of a polymicrobial flora. VAP occurring before hospital day 4 in a previously healthy person with no antibiotic exposure is more likely to involve oral flora with minimal resistance profiles than multidrug-resistant pathogens. However, multidrug-resistant pathogens may complicate early-onset VAP in patients with antibiotic exposure in preceding 90 days, recent hospitalization, or prior colonization with multidrug-resistant pathogens.

Clinical Findings

A. Symptoms and Signs

The symptoms and signs associated with nosocomial pneumonias are nonspecific. However, two or more clinical findings (fever, leukocytosis, purulent sputum, worsening respiratory status) along with new or progressive pulmonary opacities on chest imaging are characteristic features of nosocomial pneumonia. Other findings include those listed above for CAP.

The differential diagnosis of new lower respiratory tract symptoms and signs in hospitalized patients includes HF, atelectasis, aspiration, ARDS, pulmonary thromboembolism, pulmonary hemorrhage, and medication reactions.

B. Laboratory Findings

Diagnostic evaluation for suspected nosocomial pneumonia includes blood cultures from two different sites. Blood cultures can identify the pathogen in 15–20% of patients with nosocomial pneumonias; positivity is associated with increased risk of complications and other sites of infection. Blood counts and clinical chemistry tests do not establish a specific diagnosis; however, they help define the severity of illness and identify complications. Thoracentesis for pleural fluid analysis should be considered in patients with pleural effusions.

Examination of lower respiratory tract secretions is attended by the same disadvantages as in CAP. Gram stains and cultures of sputum are neither sensitive nor specific in the diagnosis of nosocomial pneumonias; sensitivity of sputum decreases following antibiotic therapy, particularly after 72 hours of antibiotics. The identification of a bacterial organism by culture of lower respiratory tract secretions does not prove that the organism is a lower respiratory tract pathogen; however, it can be used to help identify bacterial antibiotic sensitivity patterns and as a guide to adjusting empiric therapy. Nasal swab for PCR detection of MRSA is recommended to guide de-escalation of broad-spectrum antibiotic therapy in patients with HAP and VAP.

C. Imaging

Radiographic findings in HAP/VAP are nonspecific and often confounded by other processes that led to hospitalization or ICU admission. (See CAP above.) Imaging may demonstrate complicating features including effusion, cavitation, or barotrauma.

D. Special Examinations

When HAP is suspected in a patient who subsequently requires mechanical ventilation, secretions may be obtained by spontaneous expectoration, sputum induction, nasotracheal suctioning, and endotracheal aspiration (qualitative or semiquantitative samples), or more invasively via bronchoscopic sampling of the lower airways (quantitative samples). The best approach remains a matter of debate, since qualitative or semiquantitative samples are more likely to return nonpathogenic organisms and are, thus, associated with higher antibiotic exposure (without improvement in mortality), while invasive quantitative sampling increases cost and patient risk. Invasive qualitative sampling is recommended when the patient does not improve during initial therapy directed at expected or isolated pathogens, or in immunocompromised persons in whom an opportunistic pathogen is suspected.

Treatment

The initial treatment of HAP and VAP is based on risk factors for MRSA and multiple drug-resistant pathogens (Table 9–11) as well as local antibiograms and mortality risk and is thus empiric (Table 9–12). The predictive capability of sets of risk factors for drug-resistant organisms in nosocomial pneumonia vary locally; strongest predictive factors include prior isolation of drug-resistant organisms, a high local prevalence of drug-resistant organisms, and antibiotic exposure within prior 90 days. Each hospital should generate antibiograms to guide the optimal choice

Table 9–11. Risk factors for multidrug-resistant (MDR) pathogens, methicillin-resistant *Staphylococcus aureus* (MRSA), and *Pseudomonas* and other gram-negative bacilli in patients with hospital-acquired pneumonia (HAP) and ventilator-associated pneumonia (VAP).

Risk factors for MDR pathogens
- Antibiotic therapy in the preceding 90 days
- Septic shock
- Acute respiratory distress syndrome preceding VAP
- ≥ 5 days in hospital before occurrence of HAP/VAP
- Acute renal replacement therapy before HAP/VAP onset
- Treatment in a unit where > 10% of gram-negative isolates are resistant to an agent being considered for monotherapy
- Treatment in a unit where local antibiotic susceptibility rates are not known

Risk factors for MRSA
- Antibiotic therapy in the preceding 90 days
- Renal replacement therapy in the preceding 30 days
- Use of gastric acid-suppressive agents
- Positive culture or prior MRSA colonization, especially in the preceding 90 days
- Hospitalization in a unit where > 20% of *S aureus* isolates are MRSA
- Hospitalization in a unit where prevalence of MRSA is not known

Risk factors for *Pseudomonas aeruginosa* and other gram-negative bacilli
- Antibiotic therapy in the preceding 90 days
- Structural lung disease (COPD, especially with recurrent exacerbations; bronchiectasis; or cystic fibrosis)
- Recent hospitalizations, especially with manipulation of the aerodigestive tract (nasoenteric nutrition, intubation)
- High-quality Gram stain of respiratory secretions with numerous and predominant gram-negative bacilli
- Positive culture for *P aeruginosa* in the past year

Data from Kalil AC et al. Management of adults with hospital-acquired and ventilator-associated pneumonia: 2016 Clinical Practice Guidelines by the Infectious Diseases Society of America and the American Thoracic Society. Clin Infect Dis. 2016;63:e61.

of antibiotics with the goals of reducing exposure to unnecessary antibiotics and the development of antibiotic resistance. Because of the high mortality rate, therapy should be started as soon as HAP or VAP is suspected. After results of cultures are available, it may be possible to narrow initially broad therapy to more specific agents. Endotracheal aspiration cultures have significant negative predictive value but limited positive predictive value in the diagnosis of specific infectious causes of HAP/VAP. If an invasive diagnostic approach to suspected VAP using quantitative culture of bronchoalveolar lavage (BAL), protected specimen brush (PSB), or blind bronchial sampling (BBS) is used, antibiotics can be withheld when results are below a diagnostic threshold (BAL $< 10^4$ CFU/mL, PSB or BBS $< 10^3$ CFU/mL). Duration of antibiotic therapy is 7 days, consistent with clinical response, but should be individualized based on the pathogen, complications (empyema, necrotizing pneumonia), severity of illness, response to therapy, and comorbid conditions.

For expanded discussions of specific antibiotics, see Chapter 35.

3. Anaerobic Pneumonia & Lung Abscess

ESSENTIALS OF DIAGNOSIS

- History of or predisposition to aspiration.
- Indolent symptoms, including fever, weight loss, and malaise.
- Poor dentition.
- Foul-smelling purulent sputum (in many patients).
- Infiltrate in dependent lung zone, with single or multiple areas of cavitation or pleural effusion.

General Considerations

Aspiration of small amounts of oropharyngeal secretions occurs during sleep in normal individuals but rarely causes disease. Sequelae of aspiration of larger amounts of material include nocturnal asthma, chemical pneumonitis, mechanical obstruction of airways by particulate matter, bronchiectasis, and pleuropulmonary infection. Individuals predisposed to disease induced by aspiration include those with depressed levels of consciousness due to drug or alcohol use, seizures, general anesthesia, or CNS disease; those with impaired deglutition due to esophageal disease or neurologic disorders; and those with tracheal or nasogastric tubes, which disrupt the mechanical defenses of the airways.

Periodontal disease and poor dental hygiene, which increase the number of anaerobic bacteria in aspirated material, are associated with a greater likelihood of anaerobic pleuropulmonary infection. Aspiration of infected oropharyngeal contents initially leads to pneumonia in dependent lung zones. The onset of symptoms is insidious. By the time the patient seeks medical attention, necrotizing pneumonia, lung abscess, or empyema may be apparent.

In most cases of aspiration and necrotizing pneumonia, lung abscess, and empyema, multiple species of anaerobic bacteria are causing the infection. Most of the remaining cases are caused by infection with both anaerobic and aerobic bacteria. *Prevotella melaninogenica*, *Peptostreptococcus*, *Fusobacterium nucleatum*, and *Bacteroides* species are commonly isolated anaerobic bacteria. Lung abscess may occur independent of aspiration in syndromes including endovascular disease with septic embolization. In such cases, the organisms reflect those associated with the endovascular infection.

Table 9–12. Recommended initial empiric antibiotics for hospital-acquired pneumonia (HAP) and ventilator-associated pneumonia (VAP).

HAP not at high risk for mortality, or VAP with no risk factors for MRSA, MDR, or *Pseudomonas* and other gram-negative bacilli

- USE **one** of the following:
  - Piperacillin-tazobactam, 4.5 g intravenously every 6 hours[1]
  - Cefepime, 2 g intravenously every 8 hours[1]
  - Levofloxacin, 750 mg intravenously daily
  - Imipenem, 500 mg intravenously every 6 hours[1]
  - Meropenem, 1 g intravenously every 8 hours[1]

HAP or VAP with risk factors for MRSA but no risk factors for MDR, *Pseudomonas*, and other gram-negative bacilli

- USE **one** of the following:
  - Piperacillin-tazobactam, 4.5 g intravenously every 6 hours[1]
  - Cefepime, 2 g intravenously every 8 hours[1]
  - Ceftazidime, 2 g intravenously every 8 hours
  - Levofloxacin, 750 mg intravenously daily
  - Ciprofloxacin, 400 mg intravenously every 8 hours
  - Imipenem, 500 mg intravenously every 6 hours[1]
  - Meropenem, 1 g intravenously every 8 hours[1]
  - Aztreonam, 2 g intravenously every 8 hours
- PLUS **one** of the following:
  - Vancomycin, 15 mg/kg intravenously every 8–12 hours with goal to target trough level = 15–20 mg/mL (consider a loading dose of 25–30 mg/kg once for severe illness)[2]
  - Linezolid, 600 mg intravenously every 12 hours

HAP with risk factors for *Pseudomonas* and other gram-negative bacilli, but no risk factors for MRSA and not at high risk for mortality

- USE **one** of the following:
  - Piperacillin-tazobactam, 4.5 g intravenously every 6 hours[1]
  - Cefepime, 2 g intravenously every 8 hours[1]
  - Ceftazidime, 2 g intravenously every 8 hours
  - Imipenem, 500 mg intravenously every 6 hours[1]
  - Meropenem, 1 g intravenously every 8 hours[1]
  - Aztreonam, 2 g intravenously every 8 hours
- PLUS **one** of the following:
  - Levofloxacin, 750 mg intravenously daily
  - Ciprofloxacin, 400 mg intravenously every 8 hours
  - Gentamicin, 5–7 mg/kg intravenously daily[2]
  - Tobramycin, 5–7 mg/kg intravenously daily[2]
  - Aztreonam, 2 g intravenously every 8 hours

HAP at high risk for mortality or VAP with risk factors for MRSA *and* risk factors for MDR, *Pseudomonas*, and other gram-negative bacilli

- USE **one** of the following:
  - Piperacillin-tazobactam, 4.5 g intravenously every 6 hours[1]
  - Cefepime, 2 g intravenously every 8 hours[1]
  - Ceftazidime, 2 g intravenously every 8 hours
  - Imipenem, 500 mg intravenously every 6 hours[1]
  - Meropenem, 1 g intravenously every 8 hours[1]
  - Aztreonam, 2 g intravenously every 8 hours
- PLUS **one** of the following:
  - Levofloxacin, 750 mg intravenously daily
  - Ciprofloxacin, 400 mg intravenously every 8 hours
  - Amikacin, 15–20 mg/kg intravenously daily[2]
  - Gentamicin, 5–7 mg/kg intravenously daily[2]
  - Tobramycin, 5–7 mg/kg intravenously daily[2]
  - Meropenem, 1 g intravenously every 8 hours[1]
  - Polymyxin B, 2.5–3.0 mg/kg per day divided in 2 daily intravenous doses
  - Colistin: consult clinical pharmacist for assistance with dosing
- PLUS **one** of the following:
  - Vancomycin, 15 mg/kg intravenously every 8–12 hours with goal to target trough level = 15–20 mg/mL (consider a loading dose of 25–30 mg/kg once for severe illness)[2]
  - Linezolid, 600 mg intravenously every 12 hours

CrCl, creatinine clearance; MDR, multidrug-resistant; MRSA, methicillin-resistant *Staphylococcus aureus*.

[1] Extended infusions may be appropriate.

[2] Drug level monitoring and adjustment of dosing are required.

Data from Kalil AC et al. Management of adults with hospital-acquired and ventilator-associated pneumonia: 2016 Clinical Practice Guidelines by the Infectious Diseases Society of America and the American Thoracic Society. Clin Infect Dis. 2016;63:e61.

Clinical Findings

A. Symptoms and Signs

Patients with anaerobic pleuropulmonary infection usually present with constitutional symptoms, such as fever, weight loss, and malaise. Cough with expectoration of foul-smelling purulent sputum suggests anaerobic infection, though the absence of productive cough does not rule out such an infection. Dentition is often poor. Patients are rarely edentulous; if so, an obstructing bronchial lesion may be present.

B. Laboratory Findings

Expectorated sputum cultures may be difficult to interpret due to contaminating upper respiratory tract flora, but high colony count of a particular microorganism on Gram stain or in culture likely represents a true pathogen. Anaerobes and facultative anaerobes are difficult to recover on any culture, particularly following initiation of antibiotics; pleural fluid from empyema may be revealing.

C. Imaging

The different types of anaerobic pleuropulmonary infection are distinguished by their radiographic appearance. **Lung abscess** appears as a thick-walled solitary cavity surrounded by consolidation. An air-fluid level is usually present. Other causes of cavitary lung disease (tuberculosis, mycosis, cancer, infarction, necrobiotic nodules in rheumatoid arthritis, and pulmonary vasculitides) should be excluded. **Necrotizing pneumonia** is distinguished by multiple areas of cavitation within an area of consolidation. **Empyema** is characterized by the presence of purulent pleural fluid and may accompany either of the other two radiographic findings. Ultrasonography is of value in locating fluid and may also reveal pleural loculations.

Treatment

Medications of choice are directed at anaerobic organisms or facultative anaerobic streptococci and include a β-lactam/lactamase inhibitor combination, or a carbapenem. Second-line therapy includes a combination of third-generation cephalosporin and metronidazole, or a fluoroquinolone. Duration of antibiotic therapy for anaerobic pneumonia is controversial, but it is usually given for a minimum of 3 weeks, with some experts recommending treatment until the abscess cavity has resolved on imaging.

Peripheral lung abscess must be carefully distinguished from empyema because empyema requires tube thoracostomy; if tube thoracostomy is placed inadvertently into an abscess cavity, complications, such as a bronchopleural fistula, may result. Thoracic surgery consultation is recommended for large or nonresolving abscesses or for abscesses that rupture into the pleural space. Rarely, a large abscess requires surgical intervention (percutaneous drainage, segmentectomy, lobectomy, or pneumonectomy).

Pan D et al. Aspiration pneumonia. Semin Respir Crit Care Med. 2024;45:237. [PMID: 38211629]

PULMONARY INFILTRATES IN IMMUNOCOMPROMISED PATIENTS

Pulmonary infiltrates in immunocompromised patients (patients with HIV disease, absolute neutrophil counts < 1000/mcL [$< 1.0 \times 10^9$/L], current or recent exposure to myelosuppressive or immunosuppressive medications, or those taking > 20 mg/day of prednisone or equivalent for > 4 weeks) may arise from infectious or noninfectious causes. Infection may be due to bacterial, mycobacterial, fungal, protozoal, helminthic, or viral pathogens. Noninfectious processes, such as pulmonary edema, alveolar hemorrhage, medication reactions, pulmonary thromboembolic disease, malignancy, and radiation pneumonitis, may mimic infection.

Although almost any pathogen can cause pneumonia in an immunocompromised patient, two clinical tools help narrow the differential diagnosis. The first is knowledge of the underlying immunologic defect. Specific immunologic defects are associated with particular infections. Defects in humoral immunity predispose to bacterial infections; defects in cellular immunity lead to infections with viruses, fungi, mycobacteria, and protozoa. Neutropenia and impaired granulocyte function predispose to infections from *S aureus*, *Aspergillus*, gram-negative bacilli, and *Candida*. Second, the time course of infection also provides clues to the etiology of pneumonia in immunocompromised patients. A fulminant pneumonia is often caused by bacterial infection, whereas an insidious pneumonia is more apt to be caused by viral, fungal, protozoal, or mycobacterial infection. Pneumonia occurring within 2–4 weeks after organ transplantation is usually bacterial, whereas several months or more after transplantation, *P jirovecii*, viruses (eg, cytomegalovirus), and fungi (eg, *Aspergillus*) are encountered more often.

Clinical Findings

CXR is rarely helpful in narrowing the differential diagnosis. Examination of expectorated sputum for bacteria, fungi, mycobacteria, *Legionella*, and *P jirovecii* is important and may preclude the need for expensive, invasive diagnostic procedures. Sputum induction is often necessary for diagnosis. The sensitivity of induced sputum for detection of *P jirovecii* depends on institutional expertise, number of specimens analyzed, and detection methods.

Routine evaluation frequently fails to identify a causative organism. The clinician may begin empiric antimicrobial therapy before proceeding to invasive procedures, such as bronchoscopy, transthoracic needle aspiration, or open lung biopsy. The approach to management must be based on the severity of the pulmonary infection, the underlying disease, the risks of empiric therapy, and local expertise and experience with diagnostic procedures. BAL using flexible bronchoscopy is a safe and effective method for obtaining pulmonary secretions for microbiologic studies. It involves less risk of bleeding and other complications than transbronchial biopsy. Surgical lung biopsy, now often performed by video-assisted thoracoscopy, provides a definitive option for diagnosis of pulmonary infiltrates in immunocompromised patients; however, a specific diagnosis is obtained in only about two-thirds of cases, and the information obtained may not affect the outcome.

Senecal J et al. Non-invasive diagnosis of *Pneumocystis jirovecii* pneumonia: a systematic review and meta-analysis. Clin Microbiol Infect. 2022;28:23. [PMID: 34464734]

PULMONARY TUBERCULOSIS

ESSENTIALS OF DIAGNOSIS

- Fatigue, weight loss, fever, night sweats, and productive cough.
- Risk factors for acquisition of infection: household exposure, incarceration, drug use, travel to or residence in endemic area.
- CXR: pulmonary opacities, including nodular or cavitating.
- Acid-fast bacilli on smear of sputum, rapid molecular testing positive, or sputum culture positive for *M tuberculosis*.

General Considerations

Tuberculosis is one of the world's most widespread and deadly illnesses. *M tuberculosis*, the organism that causes tuberculosis infection and disease, infects one-quarter of the world's population, nearly 2 billion people. Based on WHO data, there were 10.8 million new cases of tuberculosis worldwide in 2023 and 1.25 million deaths. The incidence has increased since 2020 after having fallen from 2005 to 2019 due to disruption from the COVID-19 pandemic but started to stabilize in 2023. While most incident cases occur in low- and middle-income countries, tuberculosis is present in all regions of the world. Tuberculosis occurs disproportionately among disadvantaged populations, such as people with malnutrition and those living in overcrowded or substandard housing. There is an increased occurrence of tuberculosis among individuals with HIV.

Infection with *M tuberculosis* begins when a susceptible person inhales airborne droplet nuclei containing viable organisms. Tubercle bacilli that reach the alveoli are ingested by alveolar macrophages. Infection follows if the inoculum escapes alveolar macrophage microbicidal activity. Once infection is established, lymphatic and hematogenous dissemination of tuberculosis typically occurs before the development of an effective immune response. This stage of infection, **primary tuberculosis**, is usually clinically and radiographically silent. In most persons with intact cell-mediated immunity, T cells and macrophages surround the organisms in granulomas that limit their multiplication and spread. The infection is contained but not eradicated, since viable organisms may lie dormant within granulomas for years to decades.

Individuals with **tuberculosis infection** that is **latent** do not have active disease and cannot transmit the organism to others. However, reactivation of disease may occur if the patient's immune defenses are impaired. **Tuberculosis disease** (ie, **active tuberculosis**) will develop in 5–15% of individuals with latent tuberculosis infection who are not given preventive therapy; half of these cases occur in the 2 years following primary infection. Diverse conditions such as gastrectomy, silicosis, diabetes mellitus, and an impaired immune response (eg, HIV infection; therapy with corticosteroids, TNF inhibitors, or other immunosuppressive drugs) are associated with an increased risk of reactivation.

In approximately 5% of cases, the immune response is inadequate to contain the primary infection and **progressive primary tuberculosis** develops, accompanied by both pulmonary and constitutional symptoms. The clinical presentation does not definitively distinguish primary disease from reactivation of latent tuberculosis infection. Standard teaching has held that 90% of tuberculosis in adults represents activation of latent disease; however, as many as one-third of new cases in urban populations are primary infections resulting from person-to-person transmission.

The prevalence of drug-resistant strains is increasing worldwide, though in resourced countries including the United States, the rate of multidrug-resistant isolates has fallen to 1%. Risk factors for drug resistance include emigration from regions with a high prevalence of drug-resistant tuberculosis, close and prolonged contact with individuals with drug-resistant tuberculosis, unsuccessful or inappropriate initial therapy, and nonadherence to treatment. Drug resistance may be single or multiple. **Monoresistant tuberculosis** is resistant to one first-line antituberculous drug, either isoniazid (**isoniazid-resistant TB**) or rifampicin (**rifampicin-resistant TB [RR-TB]**). **Multidrug-resistant tuberculosis (MDR-TB)** is resistant to isoniazid and rifampicin. **Pre-extensively drug-resistant tuberculosis (pre-XDR-TB)** is resistant to rifampicin and any fluoroquinolone. **Extensively drug-resistant tuberculosis (XDR-TB)** is resistant to rifampicin, plus any fluoroquinolone, plus either bedaquiline or linezolid. Outcomes of drug-resistant tuberculosis treatment are worse than drug-sensitive tuberculosis organisms, and outcomes appear to vary with HIV status.

Clinical Findings

A. Symptoms and Signs

The patient with pulmonary tuberculosis typically presents with slowly progressive constitutional symptoms of malaise, anorexia, weight loss, fever, and night sweats. Chronic cough is the most common pulmonary symptom. It may be dry at first but typically becomes productive of purulent sputum as the disease progresses. Blood-streaked sputum is common, but significant hemoptysis is rarely a presenting symptom; life-threatening hemoptysis may occur in advanced disease. Dyspnea is unusual unless there is extensive disease. On physical examination, the patient appears chronically ill and malnourished and often has lymphadenopathy. On chest examination, there are no physical findings specific for tuberculosis infection. The examination may be normal or may reveal classic findings such as posttussive apical rales.

B. Laboratory Findings

Definitive diagnosis depends on recovery of *M tuberculosis* from cultures or identification of the organism by DNA or RNA amplification techniques (in concert with appropriate clinical context). At least three consecutive sputum specimens are advised, which should be collected 8 hours apart and include at least one early-morning sample. Acid-fast staining of a sputum smear is performed initially as a screening method, with sensitivity and negative predictive values that are low (50–80%) with a single smear but may improve to 90% with serial sampling. Smear sensitivity is lower in patients coinfected with HIV. Demonstration of acid-fast bacilli on sputum smear does not establish a diagnosis of *M tuberculosis* since nontuberculous mycobacteria may colonize the airways and are increasingly recognized to cause clinical illness in patients with underlying structural lung disease.

The slow rate of mycobacterial growth; the urgency to provide early, appropriate treatment to patients to improve their outcomes and limit community spread; and concerns about potential drug toxicities in patients treated empirically who do not have tuberculosis infection have fostered the use of rapid diagnostic techniques (Table 9–13). Molecular diagnostics offer multiple options and many advantages, though at increased expense. Nucleic acid amplification testing not only detects *M tuberculosis* (NAAT-TB) but also identifies resistance markers (NAAT-R). NAAT-TB can identify *M tuberculosis* within hours of sputum processing, allowing early isolation and treatment, though the negative predictive value is lower in smear-negative patients. In view of the rapidity of results in concert with rifampicin resistance identification, the WHO recommends initial rapid molecular testing for diagnosis and resistance profiling in persons in whom pulmonary or extrapulmonary tuberculosis is suspected.

In patients who cannot produce satisfactory specimens or when the smear of the spontaneously expectorated sputum is negative for acid-fast bacilli, sputum induction with 3% hypertonic saline should be performed. Flexible bronchoscopy with bronchial washings has similar diagnostic yield to induced sputum; transbronchial lung biopsies do not increase the diagnostic yield but may lead to earlier diagnosis by identifying tissue granulomas. Post-bronchoscopy expectorated sputum specimens should be collected. Positive blood cultures for *M tuberculosis* are uncommon in patients with normal CD4 cell counts, but the organism may be cultured from blood in up to 50% of patients who are HIV seropositive with tuberculosis whose CD4 cell counts are < 100/mcL ($< 0.1 \times 10^9$/L); mycobacterial blood and urine cultures should be obtained in such patients.

Tuberculous pleural effusions may be diagnosed on a clinical basis, without confirmatory testing, in patients with active pulmonary tuberculosis in whom there is no suspicion for an alternative cause. If tuberculous effusion is suspected in a patient without confirmed pulmonary tuberculosis, diagnostic thoracentesis is recommended. Pleural fluid cultures are positive for *M tuberculosis* in 23–58% of cases of pleural tuberculosis. Pleural fluid adenosine deaminase > 70 U/L has a 90% sensitivity and specificity for pleural tuberculosis. If thoracentesis is unrevealing, thoracoscopic or ultrasound-guided needle biopsy of the pleura reveals granulomatous inflammation or AFB with 60–90% sensitivity.

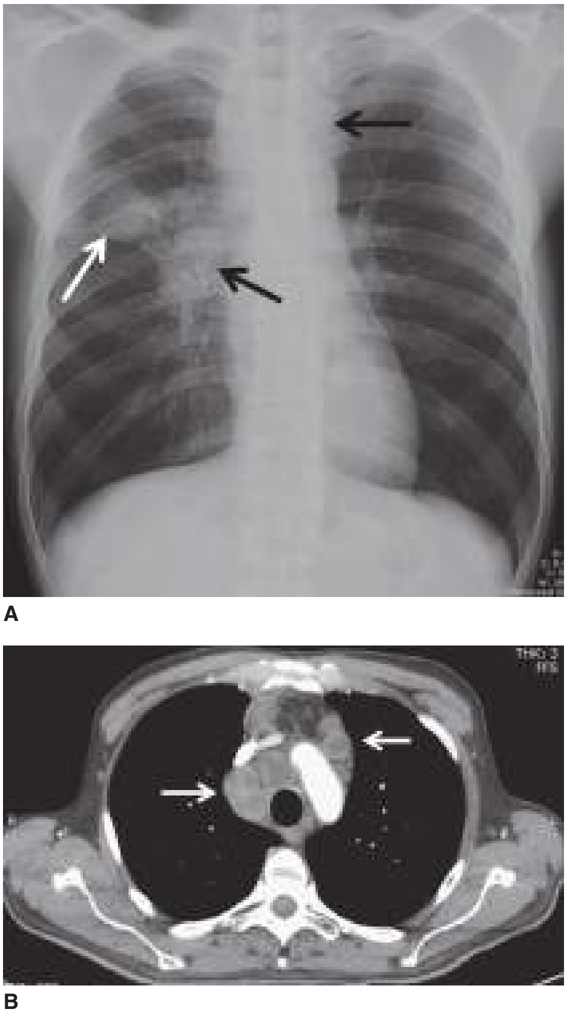
C. Imaging

Radiographic abnormalities in pulmonary tuberculosis do not reliably distinguish primary disease from reactivation of latent tuberculosis (Figure 9–3). The chest imaging pattern traditionally associated with primary disease includes small unilateral infiltrates, hilar and paratracheal lymph

Table 9–13. Essential laboratory tests for the detection of *Mycobacterium tuberculosis*.

Test	Time to Result	Test Characteristics
Acid-fast bacilli light microscopy	1 day	Three morning specimens recommended. Combined sensitivity of 70% (54% for the first specimen, 11% for the second specimen, and 5% for the third specimen). First morning specimen increased yield by 12% compared with spot specimen.
Nucleic acid amplification test, detection (NAAT-TB)	1 day	Sensitivity/specificity high for smear-positive specimens, 85–97% for both; sensitivity falls in smear-negative specimens to ~75–88%. A positive NAAT in smear-negative patients with intermediate to high (> 30%) pretest probability of *M tuberculosis* infection is helpful while a negative NAAT is not.
Nucleic acid amplification test, resistance markers (NAAT-R)	1–2 days	Multiple assays for rifampicin and isoniazid are available. Specificity uniformly high, > 98%. Sensitivity varies from ~84–96%.
Mycobacterial growth detection Liquid (broth based) medium Solid (agar or egg based) medium	Up to 6–8 weeks Avg 10–14 days Avg 3–4 weeks	Liquid culture methods are more sensitive than solid culture methods (~90% and 76%, respectively) with shorter time to detection but higher contamination with bacterial growth. Specificity exceeds 99% for all methods.
First-line drug susceptibility testing (liquid medium)	1–2 weeks[1]	Gold standard. Should be performed routinely on the initial isolate.

[1] Following detection of mycobacterial growth.



▲ **Figure 9–3.** Pulmonary tuberculosis. Primary pulmonary tuberculosis in a 20-year-old man with CXR **(A)** showing right upper lobe consolidation (white arrow) and right hilar and mediastinal lymphadenopathy (black arrows) and contrast-enhanced CT scan **(B)** showing mediastinal lymphadenopathy (arrows). (Used, with permission, from Carlos Santiago Restrepo, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine*, 2nd ed. McGraw-Hill, 2013.)

node enlargement, and segmental atelectasis. Pleural effusion is present in 30–40% of patients, sometimes as the sole radiographic abnormality. Reactivation tuberculosis traditionally has been associated with fibrocavitary apical disease, discrete nodules, and pneumonic infiltrates, usually in the apical or posterior segments of the upper lobes or in the superior segments of the lower lobes. Radiographic evidence of disease in other locations may be present in up to 30% of patients.

Patients with an impaired immune response are more likely to have atypical pattern on CXR—that is, disease that is not cavitary or associated with the upper lobe. In older patients, lower lobe infiltrates with or without pleural effusion are frequently encountered. A "miliary" pattern (diffuse small nodular densities) can be seen with hematologic or lymphatic dissemination of the organism. Immunocompromised patients—particularly those with late-stage HIV infection—often display lower lung zone, diffuse, or miliary infiltrates; pleural effusions; and involvement of hilar and mediastinal lymph nodes.

Resolution of active tuberculosis leaves characteristic radiographic findings. Dense nodules in the pulmonary hila, with or without obvious calcification, upper lobe fibronodular scarring, and bronchiectasis with volume loss are common findings. Ghon (calcified primary focus) and Ranke (calcified primary focus and calcified hilar lymph node) complexes are seen in a minority of patients.

D. Special Examinations

Testing for latent tuberculosis infection is used to evaluate an asymptomatic person in whom *M tuberculosis* infection is suspected (eg, following contact exposure) or to establish the prevalence of tuberculosis infection in a population. Testing may be used in a person with symptoms of active tuberculosis, but a positive test does not distinguish between active and latent infection, and a negative test does not rule out active disease. Routine testing of individuals at low risk for tuberculosis is not recommended. Empiric treatment of latent tuberculosis without testing is considered appropriate in persons with HIV or in young (< 5 years old) household contacts of persons with active tuberculosis in endemic areas.

The traditional approach to testing for latent tuberculosis infection is the **Mantoux tuberculin skin test**. The **transverse width in millimeters of induration** at the skin test site is measured after 48–72 hours. To optimize test performance, criteria for determining a positive reaction vary depending on the likelihood of infection. Table 9–14 summarizes the criteria established by the CDC for test interpretation. Skin test sensitivity and specificity are high: 77% and 97%, respectively. Specificity falls to 59% in populations previously vaccinated with bacillus Calmette-Guérin (BCG, an attenuated form of *Mycobacterium bovis*). False-negative tuberculin skin test reactions may result from improper testing technique; concurrent infections, including fulminant tuberculosis; malnutrition; advanced age; immunologic disorders; malignancy; corticosteroid therapy; CKD; and HIV infection. Some individuals with latent tuberculosis infection may have a negative tuberculin skin test when tested many years after exposure. Anergy testing is not recommended for routine use to distinguish a true-negative result from anergy. Interpretation of the tuberculin skin test in persons who have previously received BCG vaccination is the same as in those who have not had BCG.

Interferon-γ release assays are in vitro assays of CD4+ T-cell–mediated interferon-γ release in response to stimulation by specific *M tuberculosis* antigens. The antigens are absent from all BCG strains and most nontuberculous mycobacteria; therefore, the specificity of interferon-γ release assays is superior to the tuberculin skin test in BCG-vaccinated individuals. Sensitivity is comparable to the tuberculin skin test: 60–90% depending on the specific

Table 9–14. Classification of positive tuberculin skin test reactions.[1]

Induration Size	Group
≥ 5 mm	1. Persons with HIV. 2. Close contacts of a person with active tuberculosis disease 3. Persons with fibrotic changes on CXRs suggestive of prior tuberculosis. 4. Patients with organ transplants and other immunosuppressed patients (receiving the equivalent of > 15 mg/day of prednisone for 1 month or more, or those taking TNF-α antagonists).
≥ 10 mm	1. People born in countries where TB disease is common. 2. Injection drug users without HIV. 3. Mycobacteriology laboratory personnel. 4. Residents of and employees in high-risk congregate settings: correctional institutions; long-term care facilities; hospitals and other health care facilities; residential facilities for patients with HIV/AIDS; and homeless shelters. 5. Persons with medical conditions that increase the risk of progression to tuberculosis disease: gastrectomy, weight loss to ≥ 10% below ideal body weight, jejunoileal bypass, diabetes mellitus, silicosis, advanced CKD, some hematologic disorders (eg, leukemias, lymphomas), and other specific malignancies (eg, carcinoma of the head or neck and lung). 6. Children < 5 years; children and adolescents exposed to adults at high risk.
≥ 15 mm	1. Persons with no known risk factors for tuberculosis.

[1] A tuberculin skin test reaction is considered positive if the transverse diameter of the *indurated* area reaches the size required for the specific group. All other reactions are considered negative.
Adapted from https://www.cdc.gov/tb/publications/factsheets/testing/Tuberculin_Skin_Testing_Information_for_Health_Care_Providers.pdf

assay and study population. Sensitivity is reduced by HIV infection, particularly in patients with low CD4 counts. Specificity is > 95%. Potential advantages of interferon-γ release assay testing include fewer false-positive results from prior BCG vaccination, better discrimination of positive responses due to nontuberculous mycobacteria, and the requirement for only one patient contact. Disadvantages include the need for specialized laboratory equipment and personnel and the substantially increased cost compared to the tuberculin skin test. In endemic areas, interferon-γ release assays are no more sensitive than the tuberculin skin test in active tuberculosis (20–40% false-negative rate) and cannot distinguish active from latent disease.

In the diagnosis of latent infections, CDC guidelines allow interferon-γ release assays to be used interchangeably with the tuberculin skin testing. Interferon-γ release assays are preferred in patients with prior BCG vaccination. In individuals with a positive tuberculin skin test but a low prior probability of latent tuberculosis infection and low-risk for progression to active disease, the interferon-γ release assay may be helpful as a confirmatory test to exclude a false-positive tuberculin skin test.

Treatment

A. General Measures

The goals of therapy are to cure the individual patient, minimize risk of morbidity and mortality related to treatment, reduce transmission of *M tuberculosis* to other persons, and prevent the emergence of clinically significant drug resistance in tubercle bacilli. The basic principles of antituberculous treatment are (1) to administer multiple medications to which the organisms are susceptible; (2) to provide the safest, most effective therapy for the shortest period of time; (3) to ensure adherence to therapy; and (4) to add at least two new antituberculous agents to a regimen when treatment failure is suspected.

All suspected and confirmed cases of tuberculosis should be reported promptly to local and state public health authorities. Patients with tuberculosis should be treated by clinicians who are skilled in the management of this infection. Clinical expertise is especially important in cases of drug-resistant tuberculosis.

Nonadherence to antituberculous treatment is a major cause of treatment failure, continued transmission of tuberculosis, and development of medication resistance. Adherence to treatment can be improved by providing detailed patient education about tuberculosis and its treatment in addition to a case manager who oversees all aspects of an individual patient's care. **Directly observed therapy (DOT)**, which requires that a health care worker physically observe the patient ingest antituberculous medications in the home, clinic, hospital, or elsewhere, also improves adherence to treatment. The CDC recommends DOT for all patients with drug-resistant tuberculosis and for those receiving intermittent (twice- or thrice-weekly) therapy. Video DOT ("vDOT") is promising as a more efficient care model in selected populations, and the CDC recommends it as equivalent to traditional DOT.

Hospitalization for initial therapy of tuberculosis is not necessary for most patients. It should be considered if a patient is incapable of self-care or is likely to expose new, susceptible individuals to tuberculosis. Hospitalized patients with active disease require a private room with appropriate environmental controls, including negative-pressure ventilation where available, until tubercle bacilli are no longer found in their sputum ("smear-negative") on three consecutive smears taken on separate days.

More complete information can be obtained from the CDC's Division of Tuberculosis Elimination website at https://www.cdc.gov/tb/topic/treatment/default.htm or the WHO tuberculosis website at https://www.who.int/health-topics/tuberculosis/.

B. Treatment of Tuberculosis Disease in Persons Without HIV

Most patients with previously untreated pulmonary tuberculosis can be effectively treated with either a 4-, 6-, or 9-month regimen; in 2021, a 4-month regimen was added as an appropriate treatment option for many patients with drug-susceptible pulmonary TB, with certain limitations based on side-effect profile. The 4-month regimen includes 8 weeks of daily treatment with rifapentine, moxifloxacin, isoniazid, and pyrazinamide, followed by 9 weeks of daily rifapentine, moxifloxacin, and isoniazid.

The initial phase of a 6-month regimen consists of 2 months of daily isoniazid, rifampin, pyrazinamide, and ethambutol. Once the isolate is determined to be sensitive to isoniazid, rifampin, and pyrazinamide, ethambutol may be discontinued. If the *M tuberculosis* isolate is susceptible to isoniazid and rifampin, the second (continuation) phase of therapy consists of isoniazid and rifampin for a minimum of 4 additional months, guided by sputum AFB cultures and initial chest imaging. If no fibrocavitary disease was present on initial imaging and sputum AFB culture is negative at 2 months, the sputum AFB should be repeated at monthly intervals. If two consecutive negative cultures are obtained by 4 months, treatment may be considered completed at 6 months. If fibrocavitary disease is present on initial imaging and sputum culture is negative at 2 months, the same applies, but some experts extend the total duration of therapy to 9 months, as tolerated. If the sputum AFB culture remains positive at month 2 (irrespective of imaging at presentation), it should be repeated at month 3. If negative at month 3 and again at month 4, treatment may be completed after a total of 6 months (some experts extend to 9 months). If sputum AFB remains positive at month 3, susceptibility testing should be repeated, and if sputum AFB remains positive at month 4, this should be considered a treatment failure.

Patients who have contraindications to taking pyrazinamide (eg, pregnant persons; people with severe drug side effects such as hepatotoxicity) should receive daily isoniazid and rifampin along with ethambutol for 2 months. If susceptibility to isoniazid and rifampin is demonstrated or drug resistance is unlikely, ethambutol can be discontinued, and isoniazid and rifampin may be given for a total of 9 months of therapy. If drug resistance is a concern, patients should receive isoniazid, rifampin, and ethambutol for 9 months.

C. Treatment of Tuberculosis Disease in Persons with HIV

Management of tuberculosis is complex in patients with concomitant HIV disease. Experts in the management of both tuberculosis and HIV disease should be involved in the care of such patients. The CDC has published detailed recommendations for the treatment of tuberculosis in patients who test positive for HIV (https://www.cdc.gov/tb/topic/treatment/tbhiv.htm).

The basic approach to patients with HIV who have tuberculosis is similar to that detailed above for patients without HIV. Additional considerations in patients who test positive for HIV include (1) longer duration of therapy and (2) drug interactions between rifamycin derivatives such as rifampin and rifabutin used to treat tuberculosis and some of the protease inhibitors and nonnucleoside reverse transcriptase inhibitors (NNRTIs) used to treat HIV. DOT is recommended for all patients with tuberculosis and HIV. Pyridoxine (vitamin B_6) should be given to all patients with HIV being treated with isoniazid to reduce central and peripheral nervous system side effects.

D. Treatment of Drug-Resistant Tuberculosis

Patients with drug-resistant *M tuberculosis* infection require careful supervision and management. Clinicians who are unfamiliar with the treatment of drug-resistant tuberculosis should seek expert advice. Tuberculosis resistant only to isoniazid can be successfully treated with a 6-month regimen of rifampin, pyrazinamide, ethambutol, and a fluoroquinolone or a 9–12-month regimen of rifampin, ethambutol, and a fluoroquinolone (provided susceptible). Tuberculosis resistant only to pyrazinamide can be treated with 9 months of isoniazid and ethambutol.

Rifampin-resistant TB, multidrug-resistant tuberculosis, pre-extensively drug-resistant tuberculosis, and extensively drug-resistant tuberculosis call for an individualized daily DOT plan under the supervision of an experienced clinician. Treatment regimens are based on the patient's overall status and the results of susceptibility studies.

E. Treatment of Extrapulmonary Tuberculosis

In most cases, regimens that are effective for treating pulmonary tuberculosis are also effective for treating extrapulmonary disease. However, many experts recommend 9–12 months of therapy when miliary, meningeal, or bone and joint disease is present. Treatment of skeletal tuberculosis is enhanced by early surgical drainage and debridement of necrotic bone. Corticosteroid therapy has been shown to help prevent constrictive pericarditis from tuberculous pericarditis and to reduce neurologic complications from tuberculous meningitis (Chapter 38).

F. Treatment of Pregnant or Lactating Persons

Tuberculosis in pregnancy is usually treated with isoniazid, rifampin, and ethambutol for 2 months, followed by isoniazid and rifampin for an additional 7 months. Ethambutol can be stopped after the first month if isoniazid and rifampin susceptibility is confirmed. Since the risk of teratogenicity with pyrazinamide has not been clearly defined, pyrazinamide is often excluded from the regimen unless resistance to other drugs is documented. Streptomycin is contraindicated in pregnancy because it may cause congenital deafness. Pregnant persons taking isoniazid should receive pyridoxine to prevent peripheral neuropathy.

Small concentrations of antituberculous drugs are present in breast milk. First-line therapy is not known to be harmful to nursing newborns at these concentrations. Therefore, breastfeeding is not contraindicated while receiving first-line antituberculous therapy. If the regimen includes isoniazid, breastfed infants should receive pyridoxine supplementation. Lactating women receiving other agents should consult a tuberculosis expert.

G. Treatment Monitoring

Monthly follow-up of outpatients is recommended, including sputum smear and culture for *M tuberculosis* at monthly intervals until cultures are negative on two consecutive samples. Patients with negative sputum cultures after 2 months of treatment should have at least one additional sputum smear and culture performed at the end of therapy. Patients with drug-resistant isolates should have sputum cultures performed monthly during the entire course of treatment. A CXR at the end of therapy provides a useful baseline for any future comparison.

Patients whose cultures do not become negative or whose symptoms do not resolve despite 3 months of therapy should be evaluated for nonadherence to the regimen and for drug-resistant organisms. Positive sputum culture after 4 months of therapy should be considered treatment failure, and the addition of at least two drugs not previously given should be considered pending repeat drug susceptibility testing. The clinician should seek expert assistance if drug resistance is newly found, if the patient remains symptomatic, or if smears or cultures remain positive.

Patients with only a clinical diagnosis of pulmonary tuberculosis (smears and cultures negative for *M tuberculosis*) whose symptoms and radiographic abnormalities are unchanged after 3 months of treatment usually either have another process or have had tuberculosis in the past.

H. Treatment of Latent Tuberculosis Infection

Treatment of latent tuberculous infection is essential to controlling and eliminating tuberculosis and substantially reduces the risk that infection will progress to active disease. Targeted testing with the tuberculin skin test or interferon-γ release assays is used to identify persons who are at high risk for tuberculosis and benefit from treatment of latent infection. Table 9–14 gives the tuberculin skin test criteria for treatment of latent tuberculous infection. It is essential that each person who meets the criteria for treatment of latent tuberculous infection undergo a careful assessment to exclude active disease, including chest imaging. A history of past treatment for tuberculosis and contraindications to treatment should be sought. All patients at risk for HIV infection should have an HIV test. Patients suspected of having active tuberculosis disease should receive one of the recommended multidrug regimens for active disease until the diagnosis is confirmed or excluded.

Some close contacts of persons with active tuberculosis should be evaluated for treatment of latent tuberculous infection despite a negative tuberculin skin test reaction (< 5 mm of induration). These include immunosuppressed persons and those in whom disease may develop quickly after tuberculous infection. Close contacts who have a negative tuberculin skin test reaction on initial testing should be retested 10–12 weeks later.

Several treatment regimens for persons with and without HIV are available for the treatment of latent tuberculous infection: (1) **Isoniazid:** a 9-month oral regimen is preferable to 6 months of therapy. Persons at risk for developing isoniazid-associated peripheral neuropathy (those with diabetes mellitus, uremia, malnutrition, alcohol use disorder, HIV infection, pregnancy, or seizure disorder) may be given supplemental pyridoxine. (2) **Isoniazid and rifampin:** a 3-month oral regimen of daily isoniazid 5 mg/kg (maximum 300 mg/day) and rifampin 10 mg/kg (maximum 600 mg/dose). (3) **Isoniazid and rifapentine:** a 3-month oral regimen of once weekly isoniazid at 15 mg/kg (maximum 900 mg/dose) and weight-based rifapentine. (4) **Rifampin:** a 4-month oral regimen of rifampin at 10 mg/kg (maximum 600 mg/day). Patients with HIV receiving protease inhibitors or NNRTIs who are given rifampin or rifapentine require management by experts in both tuberculosis and HIV disease (see Treatment of Tuberculosis in Persons with HIV, above).

Contacts of persons with isoniazid monoresistant tuberculosis should receive a 4-month regimen of daily rifampin. Contacts of persons with RR-TB should be treated with daily isoniazid for 9 months. Contacts of persons with MDR-TB that is sensitive to fluoroquinolones should receive 6 months of levofloxacin; however, if the MDR-TB of the contact is resistant to fluoroquinolone, the regimen should include two drugs to which the infecting organism has demonstrated susceptibility. Contacts who are HIV seronegative in whom the tuberculin skin test or interferon-γ release assay is negative may be observed without treatment or treated for 6 months. Contacts with HIV should be treated for 12 months. All contacts of persons with multidrug-resistant tuberculosis or extensively drug-resistant tuberculosis should have 2 years of follow-up regardless of type of treatment.

Persons with a positive tuberculin skin test (5 mm or more of induration) and fibrotic lesions suggestive of old tuberculosis on CXRs who have no evidence of active disease and no history of treatment for tuberculosis should receive 9 months of isoniazid or 4 months of rifampin (with or without isoniazid). Pregnant or breastfeeding persons with latent tuberculosis infection should receive either daily or twice-weekly isoniazid with pyridoxine.

Baseline laboratory testing is indicated for patients at risk for liver disease, patients with HIV infection, persons who are pregnant or within 3 months of delivery, and persons who use alcohol regularly. Patients receiving treatment for latent tuberculous infection should be evaluated once a month to assess for symptoms and signs of active tuberculosis and hepatitis and for adherence to their treatment regimen. Routine laboratory testing during treatment is indicated for those with abnormal baseline laboratory tests and for those at risk for developing liver disease.

BCG vaccine is an antimycobacterial vaccine developed from an attenuated strain of *M bovis*. Millions of individuals worldwide have been vaccinated with BCG. Vaccination is recommended in endemic areas (infancy) and regions with high prevalence (childhood), except in individuals with HIV infection or other immunodeficiency. The vaccine is not generally recommended in the United States because of the low prevalence of tuberculous infection, the vaccine's interference with the ability to determine latent tuberculous infection using tuberculin skin test reactivity, and its variable effectiveness in prophylaxis of pulmonary tuberculosis. Vaccination of health care workers should be considered on an individual basis in settings in which a high percentage of tuberculosis patients are infected with strains resistant to both isoniazid and rifampin, in which transmission of such drug-resistant *M tuberculosis* and subsequent infection are likely, and in which comprehensive tuberculous infection-control precautions have been implemented but have not been successful. The BCG vaccine is contraindicated in persons with impaired immune responses due to disease or medications.

Prognosis

Almost all properly treated immunocompetent patients with tuberculosis can be cured. Relapse rates are < 5% with current regimens. The main cause of treatment failure is nonadherence to therapy.

PULMONARY DISEASE CAUSED BY NONTUBERCULOUS MYCOBACTERIA

ESSENTIALS OF DIAGNOSIS

- Chronic cough, sputum production, and fatigue; less commonly: malaise, dyspnea, fever, hemoptysis, and weight loss.
- Parenchymal opacities on CXR, most often thin-walled cavities or multiple small nodules associated with bronchiectasis.
- Isolation of nontuberculous mycobacteria in a sputum culture.

General Considerations

Nontuberculous mycobacteria (NTM), sometimes referred to as "atypical" mycobacteria—are ubiquitous in water and soil. Marked geographic variability exists, both in NTM species and in the prevalence of disease. These organisms are not considered communicable from person to person, although healthcare-associated transmissions have occurred in vulnerable patient groups (eg, cystic fibrosis). NTM have distinct laboratory characteristics and are often resistant to antituberculous medications (Chapter 38). Long-term epidemiologic data suggest that NTM disease has been increasing worldwide.

Definition & Pathogenesis

The diagnosis of lung disease caused by NTM is based on a combination of clinical, radiographic, and bacteriologic criteria and the exclusion of other diseases that can resemble the condition. Specific diagnostic criteria are discussed below. Complementary data are important for diagnosis because NTM organisms can colonize the airways without causing clinical disease.

Mycobacterium avium complex (MAC) is the most frequent cause of NTM pulmonary disease in the United States. *M kansasii* is the next most frequent pulmonary pathogen. Other NTM causes of pulmonary disease include *M abscessus*, *M xenopi*, *M chelonae*, *M. fortuitum*, and *M malmoense* and other less common species. Most NTM cause a chronic pulmonary infection that resembles tuberculosis but tends to progress more slowly. Disseminated disease is rare in immunocompetent persons; however, disseminated MAC disease is common in patients with AIDS.

Clinical Findings

A. Symptoms and Signs

NTM infection among immunocompetent persons frequently presents in one of three prototypical patterns: cavitary, upper lobe lesions in older smokers that may mimic *M tuberculosis*; nodular bronchiectasis affecting the mid-lung zones in middle-aged women with chronic cough; and hypersensitivity pneumonitis following environmental exposure. Most patients with NTM infection experience a chronic cough, sputum production, and fatigue. Less common symptoms include malaise, dyspnea, fever, hemoptysis, and weight loss. Symptoms from coexisting lung disease (COPD, bronchiectasis, previous mycobacterial disease, cystic fibrosis, and pneumoconiosis) may confound the evaluation. In patients with bronchiectasis, coinfection with NTM and *Aspergillus* is a negative prognostic factor. New or worsening infiltrates as well as adenopathy or pleural effusion (or both) are described in patients with HIV and NTM infection as part of the immune reconstitution inflammatory syndrome following institution of antiretroviral therapy.

B. Laboratory Findings

The diagnosis of NTM infection rests on recovery of the pathogen from cultures. Sputum cultures positive for atypical mycobacteria do not prove infection, because NTM may colonize the airways or may be environmental contaminants. Bronchial washings are more sensitive than expectorated sputum samples; however, their specificity for clinical disease is not known.

Bacteriologic criteria have been proposed based on studies of patients with cavitary disease with MAC or *M kansasii*. Diagnostic criteria in immunocompetent persons include the following: positive culture results from at least two separate expectorated sputum samples; or positive culture from at least one bronchial wash or biopsy; or a positive culture from pleural fluid or any other normally sterile site. The diagnosis can also be established by demonstrating NTM cultured from a lung biopsy, bronchial wash, or sputum plus histopathologic changes, such as granulomatous inflammation in a lung biopsy. Rapid species identification of some NTM is possible using NAAT or a specialized mass spectrometry.

Diagnostic criteria are less stringent for patients with severe immunosuppression. Patients with HIV may show significant MAC growth on culture of bronchial washings without clinical infection; therefore, patients with HIV being evaluated for MAC infection must be considered individually.

Medication susceptibility testing on cultures of NTM is recommended for the following NTM: (1) *Mycobacterium avium intracellulare* to macrolides only (clarithromycin and azithromycin); (2) *M kansasii* to rifampin; and (3) rapid growers (such as *M fortuitum*, *M chelonae*, *and M abscessus*) to amikacin, doxycycline, imipenem, fluoroquinolones, clarithromycin, cefoxitin, and sulfonamides.

C. Imaging

CXR findings include infiltrates that are progressive or persist for at least 2 months, cavitary lesions, and multiple nodular densities. The cavities are often thin-walled and have less surrounding parenchymal infiltrate than is commonly seen with MTB infections. Evidence of contiguous spread and pleural involvement is often present. HRCT of the chest may show multiple small nodules with or without multifocal bronchiectasis. Progression of pulmonary infiltrates during therapy or lack of radiographic improvement over time are poor prognostic signs and also raise concerns about secondary or alternative pulmonary processes. Clearing of pulmonary infiltrates due to NTM is slow.

▶ Treatment

NTM infection does not mandate treatment in all cases, for two reasons. First, clinical disease may never develop in some patients, particularly asymptomatic patients with few organisms isolated from single specimens. Second, the spectrum of clinical disease severity is very wide; in patients with mild or slowly progressive symptoms, traditional antimicrobial regimens using a combination of agents may lead to drug-induced side effects worse than the disease itself. These features at least partly explain variability of adherence to treatment guidelines in practice.

Specific treatment regimens and responses to therapy vary with the species of NTM. Patients who are HIV seronegative with MAC pulmonary disease usually receive a combination of daily clarithromycin or azithromycin, rifampin or rifabutin, and ethambutol. For patients with severe fibrocavitary disease, streptomycin or amikacin is added for the first 2 months. The optimal duration of treatment is unknown, but therapy should be continued for 12 months after sputum conversion. Medical treatment is initially successful in about two-thirds of cases, but relapses after treatment are common; long-term benefit is demonstrated in about half of all patients. Those who do not respond favorably generally have active but stable disease. Surgical resection is an alternative for the patient with progressive disease that responds poorly to antimicrobials. Disease caused by *M kansasii* responds well to drug therapy. A daily regimen of rifampin, isoniazid, and ethambutol for at least 18 months with a minimum of 12 months of negative cultures is usually successful. Rapidly growing mycobacteria (*M abscessus*, *M fortuitum*, *M chelonae*) are generally resistant to standard antituberculous therapy.

Treatment recommendations for less common NTM (including *M chelonae*, *M fortuitum*, *M genavense*, *M gordonae*, *M malmoense*, *M simiae*, and *M szulgai*) are based primarily on case reports and case series; expert consultation should be sought to determine need for treatment.

▶ When to Refer

Patients with rapidly growing mycobacteria or uncommon NTM should be referred for expert management.

PULMONARY NEOPLASMS

See Chapter 44 for discussions of Lung Cancer, Secondary Lung Cancer, and Mesothelioma.

SCREENING FOR LUNG CANCER

Lung cancer remains the leading cause of cancer-related mortality, in large part secondary to advanced stage at diagnosis (Chapter 44). Annual low-dose CT (LDCT) screening is recommended for those at high risk by multiple organizations, including the USPSTF, the American Cancer Society, the American College of Chest Physicians, and the National Comprehensive Cancer Network. High-risk criteria include age 50–80 years, at least a 20-pack-year smoking history, and either current smoking or quit date within past 15 years. Screening should be stopped once 15 years have elapsed since quitting smoking or if a comorbid condition renders the benefits of screening null. Simulation models have found yearly screening using these parameters to be the most efficient in reducing lung cancer-related deaths, though more false-positive test results are expected.

Annual CXRs are not recommended for lung cancer screening in current or former smokers as no mortality benefit has been demonstrated with serial exams in two large RCTs: the Prostate, Lung, Colorectal and Ovarian Randomized Trial (PLCO) and the National Lung Cancer Screening Trial (NLST). The NLST enrolled 53,454 current or former smokers who were randomly assigned to three annual posterior-anterior CXRs or three LDCT scans and monitored for an additional 6.5 years. Compared with CXR, LDCT detected more early-stage lung cancers and fewer advanced-stage lung cancers, indicating that LDCT screening systematically shifted the time of diagnosis to earlier stages, thereby providing more persons the opportunity for effective treatment. Furthermore, the cohort that received three annual LDCT scans had a significant mortality benefit, with reductions in both lung cancer deaths (20.0%) and all-cause mortality (6.7%).

Potential harms of LDCT screening include false-positive findings, overdiagnosis, radiation, and patient anxiety and distress, all of which should be discussed before the patient's referral for screening. Other concerns include **(1) Generalizability to practice:** NLST-participating institutions demonstrated a high level of expertise in imaging interpretation and diagnostic evaluation. Ninety-six percent of findings on CT were false-positives, but most patients were monitored with serial imaging. Invasive diagnostic evaluations were uncommon and were associated with a low complication rate (1.4%). **(2) Duration of screening:** The rate of detection of new lung cancers did not fall with subsequent annual screening over the 3-year trial. Since new lung cancers become detectable during each year-long screening interval, the optimal number of annual CT scans is unknown as is the optimal screening interval. **(3) Overdiagnosis:** After 6.4 years of post-screening observation, there were more lung cancers in the NLST CT cohort than the CXR cohort (1089 and 969, respectively). Since the groups were randomized and well matched, lung cancer incidence should have been identical. Therefore, 18.5% of the lung cancers detected by CT remained clinically silent and invisible on CXR for 6.4 years. Many, perhaps most, of these lung cancers would never cause clinical disease and represent overdiagnosis. **(4) Cost effectiveness:** Studies in the United States, Canada, and Europe suggest screening for lung cancer is cost effective; however, whether it is cost effective in all countries has not been determined. All patients participating in a screening program who still smoke should receive smoking cessation interventions.

SOLITARY PULMONARY NODULE

A solitary pulmonary nodule, sometimes referred to as a "coin lesion," is a less-than-3-cm isolated, rounded opacity on chest imaging outlined by normal lung. Pulmonary nodules may be solid or subsolid with ground glass or mixed consistency. Most are asymptomatic and represent an incidental finding on CXR or CT scanning. Solitary nodules may be benign or malignant; the risk of malignancy varies depending on the patient population under study. Most benign nodules are infectious granulomas. Benign neoplasms, such as hamartomas, account for < 5% of solitary nodules. The probability of cancer in pulmonary nodules detected by LDCT is estimated at 1% of nodules. Malignant nodules are rare in persons under age 30. Above age 30, the likelihood of malignancy increases with age and smoking history. Patients with a prior malignancy have a higher likelihood of having a malignant solitary nodule.

The goals of evaluation are to identify and resect malignant tumors in patients who will benefit from resection while avoiding invasive procedures in benign disease. The task is to identify nodules with a sufficiently high probability of malignancy to warrant biopsy or resection or a sufficiently low probability of malignancy to justify observation.

Clinical and imaging data can be used to assess the probability of malignancy. Comparison of prior and current imaging studies allows estimation of doubling time, which is an important marker for malignancy. Rapid progression (doubling time < 30 days) suggests infection, while long-term stability (doubling time > 465 days) suggests benignity. Radiographic features including size help in estimating the probability of malignancy. Chest CT is indicated for any suspicious solitary pulmonary nodule. Solitary nodules identified by CT scan showed a 1% malignancy rate in those measuring 2–5 mm, 24% in 6–10 mm, 33% in 11–20 mm, and 80% in 21–45 mm nodules. The appearance of a smooth, well-defined edge is characteristic of a benign process. Ill-defined margins or a lobular appearance suggest malignancy. A HRCT finding of spiculated margins and a peripheral halo are both highly associated with malignancy. Calcification and its pattern are also helpful clues. Benign lesions tend to have dense calcification in a central or laminated pattern. Malignant lesions are associated with sparser calcification that is typically stippled or eccentric. Cavitary lesions with thick (> 16 mm) walls are more likely to be malignant. HRCT offers better resolution of these characteristics than CXR and is more likely to detect lymphadenopathy or the presence of multiple lesions.

▶ Treatment

Based on clinical and radiologic data, the clinician should assign a specific probability of malignancy to the lesion. The decision whether to recommend a biopsy or surgical excision depends on the probability of cancer, biopsy and surgical risk, and patient wishes and adherence to follow-up. Quantitative prediction models (Brock model, VA Cooperative model) are available to assess risk of malignancy. The probabilities in parentheses below represent guidelines only and should not be interpreted as definitive.

In the case of solitary pulmonary nodules, a continuous probability function may be grouped into three categories.

In patients with a **low probability (< 5%) of malignancy** (eg, age under 30, lesions stable for > 2 years, characteristic pattern of benign calcification), watchful waiting is appropriate. Management consists of serial imaging studies at intervals that could identify growth suggestive of malignancy. Three-dimensional reconstruction of HRCT images provides a more sensitive test for growth.

Patients with a **high probability (> 60%) of malignancy** should proceed directly to resection following staging, provided the surgical risk is acceptable. Biopsies rarely yield a specific benign diagnosis and are not indicated.

Optimal management of patients with an **intermediate probability of malignancy (5–60%)** remains controversial. The traditional approach is to obtain a diagnostic biopsy, either through bronchoscopy or transthoracic needle aspiration (TTNA). Bronchoscopy yields a diagnosis in 10–80% of procedures depending on the size of the nodule and its location. In general, the bronchoscopic yield for nodules that are < 2 cm and peripheral is low, although complications are generally rare. Newer bronchoscopic modalities, such as electromagnetic navigation and ultrathin bronchoscopy are available, although their impact upon diagnostic yield remains uncertain. TTNA has a diagnostic yield between 50% and 97%. The yield is strongly operator-dependent, however, and is affected by the location and size of the lesion. Complications are higher than bronchoscopy, with pneumothorax occurring in up to 30% of patients, possibly requiring chest tube placement.

Disappointing diagnostic yields and a high false-negative rate (up to 20–30% in TTNA) have prompted alternative approaches. **PET** has a high sensitivity (85–97%) and specificity (70–85%) for malignant lesions and may be useful in the assessment of patients with inconclusive HRCT findings. A positive PET increases the likelihood of malignancy, and a negative PET excludes most cancers. False-negative PET scans can occur with tumors with low metabolic activity (most notably, carcinoid tumors and adenocarcinomas, particularly minimally invasive or in situ adenocarcinomas), so follow-up CT imaging is typically performed at discrete intervals to ensure absence of growth. PET has several other drawbacks: resolution below 1 cm is poor, the test is expensive, and availability remains limited.

Sputum cytology is highly specific but lacks sensitivity. It is used in central lesions and in patients who are poor candidates for invasive diagnostic procedures.

Some centers recommend **video-assisted thoracoscopic surgery (VATS)** resection of all solitary pulmonary nodules with intermediate probability of malignancy. In some cases, the surgeon will remove the nodule and evaluate it in the operating room with frozen section. If the nodule is malignant, he or she will proceed to lobectomy and lymph node sampling, either thoracoscopically or through conversion to standard thoracotomy. This approach is less common when preoperative PET scanning is available.

All patients should be provided with an estimate of the likelihood of malignancy and their preferences used to guide diagnostic and therapeutic decisions. A strategy that recommends observation may not be preferred by a patient who desires a definitive diagnosis. Similarly, a surgical approach may not be agreeable to all patients unless the presence of cancer is definitive. Patient preferences should be elicited, and patients should be well informed regarding the specific risks and benefits associated with the recommended approach as well as the alternative strategies.

Zhong D et al. Lung module Management in low-dose CT screening for lung cancer: lessons from the NELSON trial. Radiology. 2024;313:e240535. [PMID: 39436294]

RIGHT MIDDLE LOBE SYNDROME

Right middle lobe syndrome is recurrent or persistent atelectasis of the right middle lobe. This collapse is related to the relatively long length and narrow diameter of the right middle lobe bronchus and the oval (“fish mouth”) opening to the lobe, in the setting of impaired collateral ventilation. Fiberoptic bronchoscopy or CT scan is often necessary to rule out obstructing tumor. Foreign body or other benign causes are common.

BRONCHIAL CARCINOID TUMORS

Bronchial carcinoid tumors are malignant low- and intermediate-grade neuroendocrine tumors of the lung, with a favorable prognosis compared to high-grade neuroendocrine tumors such as small-cell lung cancer. Bronchial carcinoids typically occur as pedunculated or sessile growths in central bronchi. Common symptoms are hemoptysis, cough, focal wheezing, and recurrent postobstructive pneumonia. Peripherally located tumors are rare and present as asymptomatic solitary pulmonary nodules. **Carcinoid syndrome** (flushing, diarrhea, wheezing, hypotension) and paraneoplastic Cushing syndrome are rare. Fiberoptic bronchoscopy may reveal a pink or purple tumor in a central airway. These lesions have a well-vascularized stroma, and biopsy may be complicated by significant bleeding. CT scanning is helpful to localize the lesion and to follow its growth over time. Octreotide scintigraphy is also available for localization of these tumors.

Bronchial carcinoid tumors grow slowly; the aggressiveness is determined by the cell histology, with “typical carcinoid,” a low-grade tumor, demonstrating a more indolent and favorable course than “atypical carcinoid,” an intermediate-grade tumor. Bronchial carcinoid tumor staging follows the same TNM classification as other lung cancers. Surgical excision, including lymph node dissection and resection, is recommended for localized disease, and the prognosis is generally favorable. Most bronchial carcinoid tumors respond poorly to radiation and chemotherapy (see Chapter 44).

Adenomas, carcinomas, and other malignancies may rarely metastasize to the bronchi and present with endobronchial lesions. Hamartomas, myxomas, and amyloid are other rarer entities in the differential diagnosis of endobronchial mass lesions.

MEDIASTINAL MASSES

Various developmental, neoplastic, infectious, traumatic, and cardiovascular disorders may cause mediastinal masses. A useful convention arbitrarily divides the mediastinum into three compartments—anterior, middle, and posterior—in order to classify mediastinal masses and assist in differential diagnosis based on contents of these anatomic regions. The anterior compartment is bounded by the sternum anteriorly and the surface of the great vessels and pericardium posteriorly. The middle compartment extends from the anterior pericardium to the anterior surface of the thoracic spine. The posterior compartment is paravertebral. Specific mediastinal masses have a predilection for one or more of these compartments; most are located in the anterior or middle compartment.

The differential diagnosis of an **anterior mediastinal mass** includes tumors of the thymus, including thymoma and thymic carcinoma; teratoma; thyroid lesions; lymphoma; and mesenchymal tumors (lipoma, fibroma). The differential diagnosis of a **middle mediastinal mass** includes lymphadenopathy, pulmonary artery enlargement, aneurysm of the aorta or innominate artery, developmental cyst (bronchogenic, enteric, pleuropericardial), dilated azygous or hemiazygous vein, and foramen of Morgagni hernia. The differential diagnosis of a **posterior mediastinal mass** includes hiatal hernia, neurogenic tumor, meningocele, esophageal tumor, foramen of Bochdalek hernia, thoracic spine disease, and extramedullary hematopoiesis. The neurogenic tumor group includes neurilemmoma, neurofibroma, neurosarcoma, ganglioneuroma, and pheochromocytoma.

Symptoms and signs of mediastinal masses are nonspecific and are usually caused by the effects of the mass on surrounding structures. Insidious onset of retrosternal chest pain, dysphagia, or dyspnea is often an important clue to the presence of a mediastinal mass. In about half of cases, symptoms are absent, and the mass is detected on routine CXR. Physical findings vary depending on the nature and location of the mass.

CT scanning is helpful in management; additional radiographic studies of benefit include upper endoscopy if esophageal disease is suspected, Doppler sonography or venography of brachiocephalic veins and the superior vena cava, and angiography. MRI provides better delineation of hilar structures and distinction between vessels and masses. Tissue diagnosis via either needle or excisional biopsy is generally necessary when a neoplastic process is considered. Treatment and prognosis depend on the underlying cause of the mediastinal mass.

INTERSTITIAL LUNG DISEASE (Diffuse Parenchymal Lung Disease)

ESSENTIALS OF DIAGNOSIS

- Insidious onset of progressive dyspnea and nonproductive chronic cough.
- Tachypnea, bibasilar dry rales; digital clubbing and right HF with advanced disease.
- Lung CT scan with patchy distribution of ground glass, reticular, nodular, reticulonodular, or cystic opacities.
- PFTs with restrictive pattern with reduced lung volumes and diffusing capacity.
- Hypoxemia with exercise.

General Considerations

Interstitial lung disease (ILD) comprises a heterogeneous group of disorders that share common presentations (dyspnea), physical findings (late inspiratory crackles), and CXR findings (septal thickening and reticulonodular changes). Table 9–15 provides the extensive differential diagnosis of interstitial lung disease, which includes disorders of known causes (eg, medications, environmental, infection, systemic disorders) and unknown causes (eg, idiopathic interstitial pneumonias).

Clinical Findings

The history—particularly the occupational and medication history—may provide evidence of a specific cause. Laboratory evaluation includes renal and liver function, CBC with differential to evaluate for anemia or eosinophilia, UA, creatine kinase for myositis, and serology for connective tissue diseases. Imaging commonly includes a HRCT, which may show reticular or linear opacities, airspace opacities, ground-glass opacities, honeycombing, or cysts. Typical PFTs show a normal or increased FEV_1/FVC ratio, with decreased TLC.

Bronchoscopy with BAL may be indicated to diagnose (or rule out) cases of infection, particularly with *P jirovecii* or mycobacteria, or malignancy. BAL may be diagnostic of eosinophilic pneumonia, Langerhans cell histiocytosis, or alveolar proteinosis. Lung biopsy (by flexible bronchoscopy, video-assisted thoracoscopic [VATS] or thoracotomy) may be considered in those with atypical radiographic features. Transbronchial biopsy through the flexible bronchoscope can make a definitive diagnosis of sarcoidosis, lymphangitic spread of carcinoma, pulmonary alveolar proteinosis, miliary tuberculosis, and Langerhans cell histiocytosis.

Table 9–15. Differential diagnosis of interstitial lung disease (listed alphabetically within category).

Medication-related
- Antiarrhythmic agents (amiodarone)
- Antibacterial agents (nitrofurantoin, sulfonamides)
- Antineoplastic agents (bleomycin, cyclophosphamide, methotrexate, nitrosoureas)
- Antirheumatic agents (gold salts, penicillamine)
- Phenytoin

Environmental and occupational (inhalation exposures)
- Dust, inorganic (asbestos, beryllium, hard metals, silica)
- Dust, organic (thermophilic actinomycetes, avian antigens, *Aspergillus* species)
- Gases, fumes, and vapors (chlorine, isocyanates, paraquat, sulfur dioxide)
- Ionizing radiation
- Talc (injection drug users)

Infections
- Fungus, disseminated (*Blastomyces dermatitidis, Coccidioides immitis, Histoplasma capsulatum*)
- Mycobacteria, disseminated
- *Pneumocystis jirovecii*
- Viruses

Primary pulmonary disorders
- Cryptogenic organizing pneumonia
- Idiopathic interstitial pneumonia: acute interstitial pneumonia, desquamative interstitial pneumonia, nonspecific interstitial pneumonia, usual interstitial pneumonia, respiratory bronchiolitis–associated interstitial lung disease
- Pulmonary alveolar proteinosis

Systemic disorders
- Acute respiratory distress syndrome
- Amyloidosis
- Ankylosing spondylitis
- Autoimmune disease: dermatomyositis, polymyositis, rheumatoid arthritis, SLE, systemic sclerosis (scleroderma)
- Chronic eosinophilic pneumonia
- Goodpasture syndrome
- Granulomatosis polyangiitis
- IBD
- Idiopathic pulmonary hemosiderosis
- Langerhans cell histiocytosis (eosinophilic granuloma)
- Lymphangitic spread of cancer (lymphangitic carcinomatosis)
- Lymphangioleiomyomatosis
- Pulmonary edema
- Pulmonary venous hypertension, chronic
- Sarcoidosis

Surgical lung biopsy is the standard for diagnosis of diffuse interstitial lung disease. Two or three biopsies taken from multiple sites in the same lung, including apparently normal tissue, may yield a specific diagnosis as well as prognostic information regarding the extent of fibrosis versus active inflammation. Patients under age 60 without a specific diagnosis based on clinical and radiographic features should undergo surgical lung biopsy. In older and sicker patients, the risks and benefits must be weighed carefully, as (1) the morbidity of the procedure can be significant; (2) a definitive diagnosis may not be possible even with surgical lung biopsy; and (3) when a specific diagnosis is made, there may be no effective treatment. Empiric therapy or no treatment may be preferable to surgical lung biopsy in some patients.

Treatment

Treatment by a pulmonologist is recommended for ILD whenever possible. Treatment varies depending on the cause. Oxygen supplementation in is provided to those with hypoxemia. Pulmonary rehabilitation is recommended to improve exercise capacity. Vaccination against respiratory infections is recommended.

IDIOPATHIC INTERSTITIAL PNEUMONIA

ESSENTIALS OF DIAGNOSIS

- May be associated with connective tissue diseases or be idiopathic.
- Diagnosis commonly is made by HRCT scan with characteristic features or less commonly by lung biopsy.
- Accurate diagnosis identifies patients most likely to benefit from therapy.

General Considerations

Idiopathic interstitial pneumonias (IIP) is one of the categories of interstitial pneumonias. IIP may be further categorized by histopathology and radiographic criteria (Table 9–16). Only a small number of patients undergo surgical lung biopsy for diagnosis. Accurate diagnosis dictates treatment and prognosis.

Table 9–16. Idiopathic interstitial pneumonias.

Name and Clinical Presentation	Histopathology	Radiographic Pattern	Response to Therapy and Prognosis
Usual interstitial pneumonia (UIP) Age 55–60, slight male predominance. Insidious dry cough and dyspnea lasting months to years. Clubbing present at diagnosis in 25–50%. Diffuse fine late inspiratory crackles on lung auscultation. Restrictive ventilatory defect and reduced diffusing capacity on PFTs. ANA and RF positive in ~25% in the absence of documented collagen-vascular disease.	Patchy, temporally and geographically nonuniform distribution of fibrosis, honeycomb change, and normal lung. Type I pneumocytes are lost, and there is proliferation of alveolar type II cells. "Fibroblast foci" of actively proliferating fibroblasts and myofibroblasts. Inflammation is generally mild and consists of small lymphocytes. Intra-alveolar macrophage accumulation is present but is not a prominent feature.	Diminished lung volume. HRCT scanning shows increased linear or reticular bibasilar and subpleural opacities, with associated honeycombing. Unilateral disease is rare. Minimal ground-glass. Areas of normal lung may be adjacent to areas of advanced fibrosis.	No randomized study has demonstrated improved survival compared with untreated patients. Inexorably progressive. Median survival ~3 years, depending on stage at presentation. Nintedanib and pirfenidone reduce rate of decline in lung function. Refer early for lung transplantation evaluation.
Respiratory bronchiolitis–associated interstitial lung disease (RB-ILD)[1] Age 40–45. Presentation like that of UIP though in younger patients. Similar results on PFTs, but less severe abnormalities. Patients with respiratory bronchiolitis are invariably heavy smokers.	Increased numbers of macrophages evenly dispersed within the alveolar spaces. Rare fibroblast foci, little fibrosis, minimal honeycomb change. In RB-ILD the accumulation of macrophages is localized within the peribronchiolar air spaces; in DIP[1], it is diffuse. Alveolar architecture is preserved.	HRCT shows nodular or reticulonodular pattern, more likely to reveal diffuse ground-glass opacities. Honeycombing is rare. May also show upper lobe emphysema.	Spontaneous remission occurs in up to 20% of patients, so natural history unclear. Smoking cessation is essential. Prognosis clearly better than that of UIP: median survival > 10 years. Corticosteroids thought to be effective, but there are no randomized clinical trials to support this view.
Acute interstitial pneumonia (AIP) Clinically known as Hamman-Rich syndrome. Wide age range, many young patients. Acute onset of dyspnea followed by rapid development of respiratory failure. Half of patients report a viral syndrome preceding lung disease. Clinical course indistinguishable from that of idiopathic ARDS.	Pathologic changes reflect acute response to injury within days to weeks. Resembles organizing phase of diffuse alveolar damage. Fibrosis and minimal collagen deposition. May appear like UIP but more homogeneous and there is no honeycomb change—though this may appear if the process persists for > 1 month in a patient on mechanical ventilation.	Diffuse bilateral airspace consolidation with areas of ground-glass attenuation on HRCT scan.	Supportive care (mechanical ventilation) critical but effect of specific therapies unclear. High initial mortality: 50–90% die within 2 months after diagnosis. Not progressive if patient survives. Lung function may return to normal or may be permanently impaired.
Nonspecific interstitial pneumonia (NSIP) Age 45–55. Slight female predominance. Like UIP but onset of cough and dyspnea over months, not years.	Nonspecific in that histopathology does not fit into better-established categories. Varying degrees of inflammation and fibrosis, patchy in distribution but uniform in time, suggesting response to single injury. Most have lymphocytic and plasma cell inflammation without fibrosis. Honeycombing present but scant. Some have advocated division into cellular and fibrotic subtypes.	May be indistinguishable from UIP. Most typical picture is bilateral areas of ground-glass attenuation and fibrosis on HRCT. Honeycombing is rare.	Treatment with corticosteroids thought to be effective, but no prospective clinical studies have been published. Overall prognosis good but depends on the extent of fibrosis at diagnosis. Median survival > 10 years.
Cryptogenic organizing pneumonia (COP) Typically age 50–60 but wide variation. Abrupt onset, frequently weeks to a few months following a flu-like illness. Dyspnea and dry cough prominent, but constitutional symptoms are common: fatigue, fever, and weight loss. PFTs usually show restriction, but up to 25% show concomitant obstruction.	Included in the idiopathic interstitial pneumonias on clinical grounds. Buds of loose connective tissue (Masson bodies) and inflammatory cells fill alveoli and distal bronchioles.	Lung volumes normal. CXR typically shows interstitial and parenchymal disease with discrete, peripheral alveolar and ground-glass infiltrates. Nodular opacities common. HRCT shows subpleural consolidation and bronchial wall thickening and dilation.	Rapid response to corticosteroids in two-thirds of patients. Long-term prognosis generally good for those who respond. Relapses are common.

[1] Includes desquamative interstitial pneumonia (DIP).

ARDS, acute respiratory distress syndrome; RF, rheumatoid factor; UIP, usual interstitial pneumonia.

Clinical Findings

The most common of the IIP is pulmonary fibrosis associated with the histopathologic pattern of **usual interstitial pneumonia (UIP).** Serologic studies should be obtained to rule out rheumatologic diseases associated with UIP, including ANA, RF, CCP, and, in selected cases, Jo1, SSA, SSB, dsDNA, and Scl70. When no associated cause is evident, it is classified as **idiopathic pulmonary fibrosis (IPF).** A diagnosis of IPF can be made in patients who have (1) idiopathic disease by history and inspiratory crackles on physical examination, (2) restrictive physiology on PFTs, and (3) characteristic UIP pattern on high-resolution chest CT (subpleural/peripheral, basilar reticular opacities associated with honeycombing and traction bronchiectasis) (Figure 9–4). Such patients do not need surgical lung biopsy. Assessment of pulmonary hypertension is recommended in advanced disease.

Treatment

There is no known cure for IPF. Corticosteroid therapy is ineffective and not recommended. Nintedanib and pirfenidone are approved for the treatment of IPF based on reduction in rate of decline in lung function and longer time to first exacerbation, but neither agent improves survival. The only definitive treatment for IPF is lung transplantation. Supportive care is recommended with supplemental oxygen, when needed, and pulmonary rehabilitation. Surveillance for pulmonary hypertension is advised.

When to Refer

- Patients with IIP should be referred early to a pulmonologist for expert diagnosis and management.
- Patients with IPF should be referred early to a lung transplant program for evaluation.

SARCOIDOSIS

ESSENTIALS OF DIAGNOSIS

- Symptoms may involve the lung, skin, eyes, peripheral nerves, liver, kidney, heart.
- Diagnosis made by demonstration of noncaseating granulomas in a biopsy specimen.

General Considerations

Sarcoidosis is a systemic disease of unknown etiology characterized by granulomatous inflammation, primarily in the lungs. The incidence is highest in North American Black persons and northern European White persons. Among Black persons, women are more frequently affected than men. Onset of disease is usually in the third or fourth decade.

Clinical Findings

A. Symptoms and Signs

Patients may be asymptomatic. Dyspnea, cough, fatigue or chest pain are the most common symptoms. Lung or thoracic lymph node involvement occurs in > 90% of patients. Other systemic involvement include skin (erythema nodosum, lupus pernio [Figure 9–5]), iritis, peripheral neuropathy, arthritis (Chapter 23), or cardiomyopathy. Physical findings of interstitial lung disease with crackles are uncommon. Other findings may include parotid gland enlargement, hepatosplenomegaly, and lymphadenopathy. *Loffren syndrome* involves sarcoidosis with acute fever onset, hilar adenopathy, erythema nodosum, and/or ankle arthritis.

B. Laboratory Findings

Laboratory tests are nonspecific and may show an elevated ESR, hypercalcemia (5%), or hypercalciuria (20%). ACE levels are elevated in 40–80% of patients with active disease, though this finding is neither sensitive nor specific. Physiologic testing may reveal evidence of airflow obstruction or restriction with decreased lung volumes and diffusing capacity, or both. ECG may show heart block and dysrhythmias.

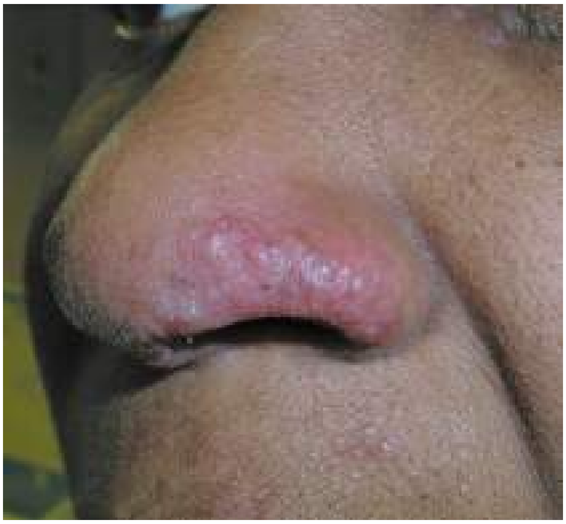

Figure 9–5. Skin involvement in sarcoidosis (lupus pernio), here involving the nasal rim. (Reproduced with permission from Richard P. Usatine, MD, in Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley HS. *The Color Atlas and Synopsis of Family Medicine,* 3rd ed. McGraw-Hill, 2019.)

C. Imaging

Radiographic findings are variable and include bilateral hilar adenopathy alone (radiographic stage I), hilar adenopathy and parenchymal involvement (radiographic stage II), parenchymal involvement alone (radiographic stage III), or advanced fibrotic changes principally in the upper lobes (radiographic stage IV). Parenchymal involvement is usually manifested radiographically by diffuse reticular infiltrates, but focal infiltrates, acinar shadows, nodules, and, rarely, cavitation may be seen. Echocardiogram may show signs of cardiomyopathy with HF or pulmonary hypertension.

D. Special Examinations

The diagnosis of sarcoidosis generally requires histologic demonstration of noncaseating granulomas in biopsies from a patient with other typical associated manifestations. Other granulomatous diseases (eg, berylliosis, tuberculosis), fungal infections, HIV, and lymphoma must be excluded. Biopsy of easily accessible sites (eg, palpable lymph nodes, skin lesions, or salivary glands) may be an initial step. Transbronchial lung biopsy has a high yield (75–90%) as well, especially in patients with radiographic evidence of parenchymal involvement. Some clinicians believe that tissue biopsy is not necessary when stage I radiographic findings are detected in a clinical situation that strongly favors the diagnosis of sarcoidosis. Biopsy is essential whenever clinical and radiographic findings suggest the possibility of an alternative diagnosis, such as lymphoma.

Patients require a yearly ophthalmologic evaluation, liver and renal function testing, PFTs, and an ECG. Cardiac MRI is favored over PET scan for patients with suspected cardiac involvement. Screening for pulmonary hypertension with echocardiogram is recommended in advanced disease.

Treatment

Oral corticosteroids are indicated for patients with disabling constitutional symptoms, hypercalcemia, iritis, uveitis, arthritis, CNS involvement, cardiac involvement, granulomatous hepatitis, cutaneous lesions other than erythema nodosum, and progressive pulmonary lesions. Oral prednisone, 0.5–1.0 mg/kg/day, is usually recommended. A study showed similar relapse rate and treatment failure with initial doses of prednisolone 20 mg and 40 mg daily. Long-term therapy is usually required over months to years. Immunosuppressive medications, most commonly methotrexate, azathioprine, or infliximab, are used in patients who are intolerant of corticosteroids or who have corticosteroid-refractory disease. A favorable response is defined by a decrease in symptoms, reduction of radiographic abnormalities, and improvement in PFTs.

Prognosis

The outlook is best for patients with hilar adenopathy alone or with erythema nodosum; radiographic involvement of the lung parenchyma is associated with a worse prognosis. About 20% of patients with lung involvement suffer irreversible lung impairment, characterized by progressive fibrosis, bronchiectasis, and cavitation. Pneumothorax, hemoptysis, mycetoma formation in lung cavities, pulmonary hypertension, and respiratory failure may often complicate this advanced stage. Myocardial sarcoidosis occurs in 5% of patients, sometimes leading to restrictive cardiomyopathy, cardiac dysrhythmias, and conduction disturbances. Death from respiratory insufficiency occurs in 5% of patients. Patients require long-term follow-up.

PULMONARY ALVEOLAR PROTEINOSIS

Pulmonary alveolar proteinosis is a rare disease characterized by accumulation of lipoproteinaceous material within alveolar spaces. The condition may be primary (idiopathic) or secondary (occurring in immunodeficiency; hematologic malignancies; inhalation of mineral dusts; or following lung infections, including tuberculosis and viral infections). Progressive dyspnea is the usual presenting symptom. CXR shows bilateral alveolar infiltrates, and chest CT features a characteristic “crazy-paving” that refers to ground-glass opacities with superimposed interlobular and intralobular septal thickening. The diagnosis is based on demonstration of characteristic findings on BAL (milky appearance and periodic acid-Schiff [PAS]-positive lipoproteinaceous material) in association with clinical and radiographic features. In secondary disease, an elevated anti-GM-CSF (anti-granulocyte-macrophage colony-stimulating factor) titer in serum or BAL fluid is highly sensitive and specific.

The course of the disease varies. Some patients experience spontaneous remission; others develop progressive respiratory insufficiency. For patients with minimal symptoms, supportive care with oxygen is recommended. Therapy for advanced disease consists of periodic whole-lung lavage, inhalational or subcutaneous GM-CSF, or both. Pulmonary superinfection with *Nocardia* or fungi may occur.

EOSINOPHILIC PULMONARY SYNDROMES

Eosinophilic pulmonary syndromes are a diverse group of disorders typically characterized by peripheral blood eosinophilia (typically > 500 cells/mcL [0.5 × 10^9/L]), eosinophilic pulmonary infiltrates, dyspnea, and cough. Many patients have constitutional symptoms, including fever. Common causes include medications (nitrofurantoin, daptomycin, phenytoin, NSAIDs, acetaminophen, mesalamine, sulfasalazine) or infection with helminths (eg, *Ascaris*, hookworms, *Strongyloides*) or filariae (eg, *Wuchereria bancrofti*, *Brugia malayi*, tropical pulmonary eosinophilia). **Löffler syndrome** refers to acute eosinophilic pulmonary infiltrates in response to transpulmonary passage of helminth larvae. Pulmonary eosinophilia can also be a feature of other illnesses, including ABPA, eosinophilic granulomatosis with polyangiitis, systemic hypereosinophilic syndromes, eosinophilic granuloma of the lung (properly referred to as pulmonary Langerhans cell histiocytosis), neoplasms, and numerous interstitial lung diseases.

One-third of cases are idiopathic, and there are two common syndromes. **Acute eosinophilic pneumonia** is an acute, febrile illness characterized by cough and dyspnea, sometimes rapidly progressing to respiratory failure. The CXR is abnormal but nonspecific. BAL fluid frequently shows eosinophilia, but peripheral blood eosinophilia is rare at the onset of symptoms. **Chronic eosinophilic pneumonia** has a subacute-chronic presentation, characterized by fever, night sweats, weight loss, and dyspnea. Asthma or atopy is present in half of cases. Radiologic imaging often shows peripheral infiltrates, the "photographic negative" of pulmonary edema. BAL typically has a marked eosinophilia, and peripheral blood eosinophilia is present in > 80%.

Both acute and chronic eosinophilic pneumonia are treated with steroids, which usually results in dramatic improvement. Therapies targeting IL-5 are increasingly utilized. If an extrinsic cause is identified, therapy consists of removal of the offending medication or treatment of the underlying parasitic infection.

DISORDERS OF THE PULMONARY CIRCULATION

PULMONARY VENOUS THROMBOEMBOLISM

ESSENTIALS OF DIAGNOSIS

- Third most common cardiovascular cause of death in the United States.
- Dyspnea, pleuritic chest pain, hemoptysis, syncope, tachypnea, tachycardia, hypoxia may be present.
- Risk stratification with clinical scores, cardiac biomarkers, and right ventricular imaging is key for management.

General Considerations

PE is a common, serious, and potentially fatal result of thrombus formation within the deep venous circulation that then migrates to the pulmonary circulation. Management demands a vigilant systematic approach to diagnosis and an understanding of risk factors so that appropriate therapy can be initiated.

Many substances can embolize to the pulmonary circulation. Although thrombus is most common, others include air (during neurosurgery, from central venous catheters), amniotic fluid (during active labor), fat (long bone fractures), foreign bodies (talc in injection drug users), parasite eggs (schistosomiasis), septic emboli (acute infective endocarditis), and tumor cells (renal cell carcinoma). PE will develop in 50–60% of patients with proximal DVT; half of these embolic events will be asymptomatic. Approximately 50–70% of patients who have symptomatic PE will have lower extremity DVT when evaluated.

Risk factors include venous stasis, injury to the vessel wall, and hypercoagulability (Virchow triad). Venous stasis increases with immobility (obesity, stroke, bed rest—especially postoperative), injury to vessels (caused by orthopedic surgery or trauma), hypercoagulability (caused by medications [oral contraceptives, hormonal replacement therapy]), diseases (malignancy, surgery), inherited gene defects (factor V Leiden, prothrombin mutation), or acquired thrombophilias (protein C and protein S deficiency, antithrombin deficiency, antiphospholipid antibodies).

Pulmonary thrombus occlusion of > 20–25% of the pulmonary vascular bed causes right ventricular dilation or dysfunction and increased pulmonary vascular resistance. Vascular obstruction increases physiologic dead space (wasted ventilation) and leads to hypoxemia through right-to-left shunting. This may cause decreased cardiac output with subsequent hypotension and cardiovascular collapse.

Clinical Findings

A. Symptoms and Signs

The clinical diagnosis of PE is notoriously challenging because the symptoms may be nonspecific. Dyspnea and chest pain on inspiration are common. Diagnosis primarily relies on clinical prediction scores to calculate the pretest probability of PE. Wells score is most commonly used and quantifies clinical risk assessment, allowing separation of patients into low, intermediate, or high probability groups, or PE-likely versus PE-unlikely groups (Table 9–17). The Pulmonary Embolism Rule-out Criteria (PERC) may be used to identify patients for whom no further testing is indicated (Table 9–18).

Table 9–17. Clinical prediction rule for PE.

Variable	Points
Clinical symptoms and signs of DVT (leg swelling and pain with palpation of deep veins)	3.0
Alternative diagnosis less likely than PE	3.0
Heart rate > 100 beats/min	1.5
Immobilization for > 3 days or surgery in previous 4 weeks	1.5
Previous PE or DVT	1.5
Hemoptysis	1.0
Cancer (with treatment within past 6 months or palliative care)	1.0
Add **Points** *to determine* **Score**, *then refer to* **probability assessments** *below*:	
Three-tiered clinical probability assessment (Wells criteria)	**Score**
High	> 6.0
Moderate	2.0 to 6.0
Low	< 2.0
Dichotomous clinical probability assessment (Modified Wells criteria)	**Score**
PE likely	> 4.0
PE unlikely	< or = 4.0

Data from Wells PS et al. Derivation of a simple clinical model to categorize patients' probability of pulmonary embolism: increasing the models' utility with the SimpliRED D-dimer. Thromb Haemost. 2000;83:416.

Table 9–18. Pulmonary Embolism Rule-out Criteria (PERC) for low-risk patients.

For patients with a Modified Wells Score ≤ 4[1] who meet ALL of the following criteria, PE is excluded, monitor off anticoagulation, and search for alternative diagnoses.

- Age < 50 years
- Heart rate < 100 bpm
- Oxyhemoglobin saturation on room air ≥ 95%
- No prior history of VTE
- No recent (within 4 weeks) trauma or surgery requiring hospitalization
- No presenting hemoptysis
- No estrogen therapy
- No unilateral leg swelling

[1] See Table 9–17.

Data from Kline JA et al. Impact of a rapid rule-out protocol for pulmonary embolism on the rate of screening, missed cases, and pulmonary vascular imaging in an urban US emergency room. Ann Emerg Med. 2004;44:490.

B. Laboratory Findings

The **ECG** is abnormal in 70% of patients with PE. However, the most common abnormalities are sinus tachycardia and nonspecific ST and T wave changes, nonspecific findings that are each seen in approximately 40% of patients. Less than 5% of patients in the PIOPED I study had P pulmonale, RVH, right axis deviation, and right bundle branch block.

ABGs usually reveal acute respiratory alkalosis due to hyperventilation and may show hypoxemia.

Plasma levels of **D-dimer**, a degradation product of cross-linked fibrin, are elevated in the presence of thrombus. A normal D-dimer may be used to exclude the diagnosis of PE in those patients who have low pretest probability of PE or are PE-unlikely on Wells score. Additionally, an age-adjusted D-dimer value has increased specificity than the usually specified cutoff. Due to much higher false-positive rates, D-dimer is not useful for hospital inpatients.

Serum troponin I, troponin T, and plasma BNP levels are elevated in approximately 25% of patients with PE and are useful in the risk stratification of PE because they correlate with adverse outcomes, including mechanical ventilation, prolonged hospitalization, shock, and death.

C. Imaging and Special Examinations

1. CXR—A CXR in PE is usually normal but is nonetheless necessary to exclude other common lung diseases. Profound hypoxia with a normal CXR is highly suspicious for PE.

2. Pulmonary CT-angiography—Helical CT-PA with intravenous radiocontrast dye timed for the pulmonary artery is the gold standard diagnostic study for suspected PE due to its high sensitivity and specificity as well as wide availability. CT-PA usually is recommended for patients with low or intermediate pretest probability (or PE-unlikely) who have a positive D-dimer, and those with high pretest probability (or PE-likely).

3. Ventilation-perfusion ($\dot{V}/\dot{Q}$) lung scanning—$\dot{V}/\dot{Q}$ scanning may be used as an alternative to CT-PA in patients in whom contrast is contraindicated, such as severe contrast-induced anaphylaxis or kidney dysfunction. A normal $\dot{V}/\dot{Q}$ scan excludes the diagnosis of clinically significant PE (negative predictive value of 91% in the PIOPED I study).

4. Venous thrombosis studies—Venous ultrasonography is the test of choice to detect DVT. Inability to compress the common femoral or popliteal veins in symptomatic patients is diagnostic (positive predictive value of 97%); full compressibility of both sites excludes proximal DVT (negative predictive value of 98%). A normal venous ultrasound does not rule out PE.

5. Pulmonary angiography—Although pulmonary angiography is the historical reference standard for the diagnosis of PE, it is now only used in the treatment of acute PE for catheter-directed thrombolysis or suction thrombectomy) or in chronic thromboembolic PE with pulmonary hypertension for balloon angioplasty.

Risk Stratification of Pulmonary Embolism

After a PE diagnosis is made, the next step is risk stratification since this will guide management. There are three categories based on mortality risk: high-risk PE, intermediate-risk PE, and low-risk PE. Patients with high-risk PE, also known as massive PE, have hemodynamic compromise, defined as systolic blood pressure < 90 mm Hg or a systolic blood pressure drop by 40 mm Hg or more for longer than 15 minutes, requiring a vasopressor, or causing a cardiac arrest. Patients with an intermediate-risk PE, also known as submassive PE, are hemodynamically stable but have signs of right ventricular strain or dysfunction, either by imaging (CT-PA or echocardiogram) or elevated troponin. Patients with low-risk PE have normotension without signs of right ventricular dysfunction.

PE severity scores, such as PE Severity Score Index (PESI) or the simplified PESI, compile useful patient characteristics that predict patient outcome. Such scores may also be used to decide which patients may be appropriate for outpatient PE treatment.

Prevention

Discussion of strategies for the prevention of VTE can be found in Chapter 16.

Treatment

A. Anticoagulation

Anticoagulation is the mainstay therapy for VTE. It impedes additional thrombus formation, allowing endogenous fibrinolytic mechanisms to lyse existing clot, thereby decreasing mortality and recurrence of PE. Initiation of anticoagulation should be considered even before a confirmed diagnosis when there is high clinical suspicion and low risk of bleeding.

DOACs are recommended over vitamin K antagonist (VKA or warfarin) as first-line anticoagulation for most patients. DOACs offer predictable pharmacokinetics and pharmacodynamics with fixed dosing, fewer drug interactions, and relatively short half-life. Unfractionated heparin binds to and accelerates the ability of antithrombin to inactivate thrombin, factor Xa, and factor IXa. Compared to unfractionated heparin, low-molecular-weight heparins (LMWHs) are as effective but have faster therapeutic activity in the treatment of VTE.

The optimal duration of anticoagulation therapy for VTE depends on the risk factors for VTE recurrence. Extended anticoagulation should be considered for patients with no identifiable risk factor for the index PE event, those with recurrent VTE, those with major persistent risk factors (malignancy), or those with a minor risk factor (such as immobility due to prolonged car or air travel, obesity, pregnancy, or increased age). However, those with major transient/reversible risk factors (such as fracture of lower limb; hip or knee surgery; or hospitalization for HF, atrial fibrillation, or MI) may be considered for discontinuation of anticoagulation after 3 months. Additionally, duration of therapy needs to take into consideration the patient's age, likelihood and potential consequences of hemorrhage, and preferences for continued therapy. In patients who continue taking extended anticoagulation, an annual risk-benefit assessment of continuing anticoagulation therapy should be done.

The major complication of anticoagulation is hemorrhage. Risk factors for hemorrhage include the intensity of the anticoagulation; duration of therapy; concomitant administration of medications, such as aspirin or NSAIDs, that interfere with platelet function; and patient characteristics, particularly increased age, previous GI hemorrhage, and coexistent kidney or liver disease.

B. Thrombolytic Therapy

Streptokinase, urokinase, and recombinant tissue plasminogen activator (rt-PA; alteplase) increase plasmin levels and thereby directly lyse intravascular thrombi accelerating resolution of emboli. Guidelines support systemic thrombolysis for high-risk or massive PE (hemodynamically unstable) with low risk of bleeding. Intermediate-risk or submassive PE patients (hemodynamically stable with evidence of right heart strain) do not have a mortality benefit with thrombolytic therapy but do have a significant decrease in incidence of hemodynamic collapse; however, they also have an increase in major hemorrhagic complications, including intracranial hemorrhage. Absolute contraindications to thrombolytic therapy include active bleeding and stroke within the past 3 months. Relative contraindications include surgery or trauma within the past 4 weeks, thrombocytopenia, and renal or liver dysfunction, or both.

Catheter-directed thrombolysis delivers a low-dose of the thrombolytic agent directly into the pulmonary artery, and reverses right ventricular dilation faster than anticoagulation alone. This procedure may be considered for patients with high-risk PE (though has higher risks of bleeding) and for those with intermediate-risk PE at increased risk of hemodynamic collapse.

C. Additional Therapies

Mechanical/suction pulmonary embolectomy or surgical embolectomy may be considered for selected patients with contraindications to thrombolysis or failure of thrombolysis, primarily those with intermediate-risk (submassive) with signs of clinical decompensation (such as severe hypoxemia, severe right ventricular dysfunction, persistent tachycardia) or high-risk PE with contraindications to thrombolysis.

Inferior vena cava filters should be inserted in patients with contraindications to anticoagulation (active bleeding) and PE with lower extremity DVT. Consideration should be given for those with acute PE and presence of free-floating proximal DVT, since it carries an increased risk of embolization. Once placed, it must be assessed for removal at the earliest opportunity.

When to Admit

The decision to admit patients with acute PE requires assessment of factors placing them at high risk, including their severity of illness (eg, severe hypoxemia), comorbidities (eg, DVT, cardiac dysfunction), educational needs (eg, lack of knowledge about PE and anticoagulation), and social situations (eg, prior nonadherence with therapy or follow-up care). Carefully selected patients with low-risk PE can be safely and effectively managed as outpatients with the aid of integrated clinical decision support systems.

PULMONARY HYPERTENSION

ESSENTIALS OF DIAGNOSIS

- Dyspnea, fatigue, chest pain, and syncope on exertion.
- Narrow splitting of second heart sound with loud pulmonary component; findings of RVH and HF in advanced disease.
- Echocardiographic evidence of right ventricular dilation, dysfunction, or hypertrophy; right atrial enlargement; or elevated right ventricular systolic pressure.
- Right heart catheterization required for confirmation of diagnosis

General Considerations

Pulmonary hypertension is a complex problem characterized by pathologic elevation in pulmonary arterial pressure. Normal pulmonary artery systolic pressure at rest is 15–30 mm Hg, with a mean pressure < 20 mm Hg. The pulmonary circulation is a low-pressure, low-resistance system due to its large cross-sectional area, and it can accommodate significant increase in blood flow during exercise. The primary pathologic mechanism in pulmonary hypertension is an increase in pulmonary vascular resistance that leads to an increase in the pulmonary systolic pressure. Pulmonary hypertension is defined by a mean pulmonary arterial pressure > 20 mm Hg on a resting cardiac catheterization.

The World Symposium on Pulmonary Hypertension (WSPH) updated clinical classification includes five groups that are based on etiology and mechanism.

Group 1 (pulmonary arterial hypertension [PAH]): This group comprises diseases to the pulmonary arteries that lead to structural changes, smooth muscle hypertrophy, and endothelial dysfunction. It includes idiopathic (formerly primary) PAH; heritable PAH; drug- and toxin-induced PAH; PAH associated with HIV infection, portal hypertension, connective tissue disorders (most commonly scleroderma), congenital heart disease, and schistosomiasis; and PAH with features of veno-occlusive disease and pulmonary capillary hemangiomatosis. PAH is defined on a resting cardiac catheterization by a mean pulmonary arterial pressure > 20 mm Hg with a pulmonary capillary wedge pressure of ≤ 15 mm Hg, and a pulmonary vascular resistance of ≥ 2 Wood units.

Group 2 (pulmonary venous hypertension due to left heart disease): This group includes LV systolic or diastolic dysfunction and valvular heart disease.

Group 3 (pulmonary hypertension due to lung disease or hypoxemia): This group is caused by advanced lung disease, including COPD, interstitial lung disease, pulmonary fibrosis, and high-altitude exposure.

Group 4 (pulmonary hypertension due to pulmonary obstruction): This group primarily includes chronic thromboembolic pulmonary hypertension but also other causes of pulmonary obstructions, such as sarcoma, metastatic malignancies, and congenital pulmonary artery stenosis.

Group 5 (pulmonary hypertension secondary to unclear or multifactorial mechanisms): These patients have pulmonary hypertension secondary to hematologic disorders (eg, chronic hemolytic anemia, sickle cell anemia, myeloproliferative disorders, splenectomy), systemic disorders (eg, sarcoidosis, vasculitis, pulmonary Langerhans cell histiocytosis, neurofibromatosis type 1), metabolic disorders (eg, glycogen storage disease, Gaucher disease, thyroid disease), and miscellaneous causes (eg, ESKD with or without hemodialysis, fibrosing mediastinitis).

The clinical severity of pulmonary hypertension is classified according to the NYHA/WHO classification system based primarily on symptoms and functional status. **Class I:** No limitation of physical activity; no dyspnea, fatigue, chest pain, or near syncope is present with exertion. **Class II:** Slight limitation of physical activity; no symptoms at rest, but ordinary physical activity causes dyspnea, fatigue, chest pain, or near syncope. **Class III:** Marked limitation of physical activity; no symptoms at rest, but less than ordinary activity causes dyspnea, fatigue, chest pain, or near syncope. **Class IV:** Inability to perform any physical activity without symptoms; dyspnea and fatigue are present at rest and symptoms worsen with any activity.

Clinical Findings

A. Symptoms and Signs

There are no specific symptoms or signs of pulmonary hypertension, which may delay its diagnosis and significantly affect its mortality. Typical symptoms include dyspnea with exertion. With advanced disease, there may be dyspnea at rest or syncope. Patients may have chest pain, nonproductive cough, and fatigue.

Findings on physical examination can include jugular venous distention, accentuated pulmonary valve component of the second heart sound, right-sided third heart sound, tricuspid regurgitation murmur, hepatomegaly, and lower extremity edema.

B. Laboratory Findings

BNP or pro-BNP is usually elevated. All patients should be evaluated for HIV, liver dysfunction, and connective tissue disorders.

The ECG is typically normal except in advanced disease, where RVH (right axis deviation, incomplete right bundle branch block) and right atrial enlargement (peaked P wave in the inferior and right-sided leads) can be noted.

C. Imaging and Special Examinations

Echocardiography is the best screening study. Right ventricular assessment is made by measuring right ventricular size, function, and systolic pressure. Additionally, the echocardiogram is useful for assessing underlying cardiac disease (eg, pulmonary hypertension due to left heart disease).

Radiographs and CT scans of the chest are useful in diagnosis. Enlargement of the right and left main pulmonary arteries is common; right ventricular and right atrial enlargement are seen in advanced disease. Chest CT scanning and PFTs are also useful in determining the cause of pulmonary hypertension for patients in Group 3 (pulmonary hypertension due to lung disease). In all patients, especially those with a history of PE or risk factors for thromboembolic disease, chronic thromboembolic pulmonary hypertension (Group 4) should be excluded before diagnosing idiopathic pulmonary hypertension with $\dot{V}/\dot{Q}$ lung scanning. If abnormal, CT-PA or pulmonary angiography is the next step in confirming the diagnosis and establishing the distribution and extent of disease.

Right-sided cardiac catheterization remains the gold standard for diagnosis and assessment of disease severity; it should be performed before initiation of vasodilator therapies. A vasodilator challenge can be performed during right heart catheterization; a significant acute vasodilator response consists of a drop in mean pulmonary pressure of > 10 mm Hg (or 20%) to < 40 mm Hg.

Treatment

Advanced therapies, such as pulmonary vasodilators, are available to treat pulmonary hypertension. Such therapies are chosen based on the patient's risk assessment which is based on a combination of clinical signs of right HF, functional status according to the NYHA/WHO classification, 6-minute walk distance, imaging, and hemodynamics. Their mechanisms of action follow four main pathways: (1) the nitric oxide pathway: phosphodiesterase inhibitors (PDE5I) (sildenafil, tadalafil) and soluble guanylate cyclase stimulators (sGCS) (riociguat); (2) the endothelin pathway: endothelin receptor antagonists (ERA) (bosentan, ambrisentan, macitentan); (3) the prostacyclin pathway: prostacyclin analogs (intravenous epoprostenol; intravenous, subcutaneous, inhaled, or oral treprostinil; inhaled iloprost) and prostacyclin receptor agonist (selexipag); and (4) the activin pathway (sotatercept).

Patients with Group 1 PAH and low/intermediate risk based on initial risk assessment, should be initiated on dual combination therapy with an ERA plus PDE5I. Following reassessment at 3–4 months, if the patient is not at low risk, additional therapy should be added, such as a prostacyclin or activin-signaling inhibitor or switching from PDE5I to sGCS. High-risk patients with Group 1 PAH should be started on combination therapy of continuous prostacyclin infusion (IV/SC) with ERA and PDE5I. Following a short-term interval reassessment if the risk is not improved, add an activin-signaling inhibitor and consider lung transplant referral. Oral calcium channel blockers may be used in patients with a significant vasodilator response during cardiac catheterization. Anticoagulation was commonly used in the past but has fallen out of favor due to lack of efficacy.

Treatment of patients with Group 2 pulmonary hypertension (due to left HF) is discussed in Chapter 10. The main goal is to decrease pulmonary venous pressure by providing goal-directed therapy of HF and volume overload, primarily with the use of diuretics, ACEI, ARBs, and spironolactone.

Patients with Group 3 pulmonary hypertension (due to lung disease) should be assessed for hypoxemia at rest or with physical activity and, if present, should receive supplemental oxygen. Patients with COPD, interstitial lung disease, or obstructive sleep apnea should receive treatment for underlying disease. Inhaled treprostinil is the only pulmonary vasodilator approved for patients with pulmonary hypertension due to interstitial lung disease since it improved exercise capacity based on 6-minute walk assessment.

For patients with Group 4 pulmonary hypertension (due to chronic thromboembolic disease), long-term anticoagulation is recommended. Additionally, patients with surgically accessible lesions and acceptable perioperative risk should undergo pulmonary thromboendarterectomy. For patients unable to undergo surgery or those with residual pulmonary hypertension postoperatively, medical therapy with riociguat, pulmonary artery balloon angioplasty, or both should be considered.

Lung transplantation is a treatment option for selected patients with pulmonary hypertension when medical therapy is no longer effective. Double-lung transplant is the preferred method; in some cases, transplantation of the heart and both lungs is needed.

When to Refer

Patients in whom pulmonary hypertension is suspected or has been diagnosed should be referred early to a specialized pulmonary hypertension center for expert management.

When to Admit

- Patients with pulmonary hypertension, severe symptoms, and evidence of decompensated right HF with volume overload should be admitted to the hospital for aggressive diuresis.
- Patients with Group 1 pulmonary hypertension and functional class IV symptoms should be admitted to a specialized center for initiation of advanced therapies, such as intravenous prostacyclins.

PULMONARY VASCULITIS

The pulmonary vasculature may be involved in several vasculitis syndromes. These include **antineutrophil cytoplasmic autoantibody (ANCA)–associated vasculitides, granulomatosis with polyangiitis, eosinophilic granulomatosis with polyangiitis, and anti-glomerular basement membrane (anti-GBM) antibody disease.** These are reviewed in Chapter 23.

ALVEOLAR HEMORRHAGE SYNDROMES

Diffuse alveolar hemorrhage may occur in a variety of immune and nonimmune disorders. Acute dyspnea, anemia, hemoptysis and, occasionally, fever are characteristic. CXR or CT chest with rapid clearing of diffuse lung infiltrates may be indicative of the diagnosis of diffuse alveolar hemorrhage. Sequential BAL on bronchoscopy is the preferred method for diagnosis with lavage aliquots becoming progressively more hemorrhagic.

Causes of diffuse **immune alveolar hemorrhage** include anti-basement membrane antibody disease (Goodpasture syndrome), granulomatosis with polyangiitis, systemic necrotizing vasculitis, pulmonary capillaritis associated with idiopathic rapidly progressive glomerulonephritis, SLE, and other vasculitic and collagen-vascular diseases (Chapter 23). **Nonimmune causes** of diffuse hemorrhage include coagulopathy, mitral stenosis, necrotizing pulmonary infection, drugs (penicillamine), toxins (trimellitic anhydride), and idiopathic pulmonary hemosiderosis.

Idiopathic pulmonary hemosiderosis is a disease of children or young adults characterized by recurrent pulmonary hemorrhage; iron deficiency is typical. It is frequently associated with celiac disease. Treatment of acute episodes of hemorrhage with corticosteroids may be useful. Recurrent episodes of pulmonary hemorrhage may result in interstitial fibrosis and respiratory failure.

ENVIRONMENTAL & OCCUPATIONAL LUNG DISORDERS

SMOKE INHALATION

The inhalation of products of combustion may cause serious respiratory complications. As many as one-third of patients admitted to burn-treatment units have pulmonary injury from smoke inhalation. Morbidity and mortality due to smoke inhalation may exceed those attributed to the burns themselves. Pulmonary complications following burns and inhalation injury account for up to 77% of deaths.

All patients in whom significant smoke inhalation is suspected must be assessed for three consequences of smoke inhalation: impaired tissue oxygenation, thermal injury to the upper airway, and injury to the lower airways and lung parenchyma. Impaired tissue oxygenation may result from inhalation of a hypoxic gas mixture, carbon monoxide or cyanide, or from alterations in $\dot{V}/\dot{Q}$ matching, and is an immediate threat to life. Immediate treatment with 100% oxygen is essential. The management of patients with carbon monoxide and cyanide poisoning is discussed in Chapter 43.

Thermal injury to the mucosal surfaces of the upper airway occurs from inhalation of super-heated gases. Complications, including mucosal edema, upper airway obstruction, and impaired ability to clear oral secretions, usually become evident by 18–24 hours and produce inspiratory stridor. Respiratory failure occurs in severe cases. Early management (Chapter 42) includes the use of a high-humidity face mask with supplemental oxygen, gentle suctioning to evacuate oral secretions, elevation of the head 30 degrees to promote clearing of secretions, and topical epinephrine to reduce edema of the oropharyngeal mucous membrane. Helium-oxygen gas mixtures (Heliox) may reduce labored breathing due to critical upper airway narrowing. Close monitoring with ABGs and later with oximetry is important. Examination of the upper airway with a fiberoptic laryngoscope or bronchoscope is superior to routine physical examination. Endotracheal intubation is often necessary to maintain airway patency and is likely to be necessary in patients with deep facial burns or oropharyngeal or laryngeal edema. Tracheotomy should be avoided, if possible, because of an increased risk of pneumonia and death from sepsis.

Injury to the lower airways and lung parenchyma results from inhalation of toxic gases and products of combustion, including aldehydes and organic acids. The site of lung injury depends on the solubility of the gases inhaled, the duration of exposure, and the size of inhaled particles that transport noxious gases to distal lung units. Bronchorrhea and bronchospasm occur early after exposure along with dyspnea, tachypnea, and tachycardia. Labored breathing and cyanosis may follow. Physical examination at this stage reveals diffuse wheezing and rhonchi. Bronchiolar and alveolar edema (eg, ARDS) may develop within 1–2 days after exposure. Sloughing of the bronchiolar mucosa may occur within 2–3 days, leading to airway obstruction, atelectasis, and worsening hypoxemia. Bacterial colonization and pneumonia are common by 5–7 days after the exposure.

Treatment of smoke inhalation consists of supplemental oxygen, bronchodilators, suctioning of mucosal debris and mucopurulent secretions via an indwelling endotracheal tube, chest physical therapy to aid clearance of secretions, and adequate humidification of inspired gases. Positive end-expiratory pressure (PEEP) has been advocated to treat bronchiolar edema. Judicious fluid management and close monitoring for secondary bacterial infection round out the management protocol.

The routine use of corticosteroids for lung injury from smoke inhalation has been shown to be ineffective and may even be harmful. Routine or prophylactic use of antibiotics is not recommended.

Patients who survive should be watched for the late development of bronchiolitis obliterans.

E-CIGARETTE OR VAPING PRODUCT–ASSOCIATED LUNG INJURY

General Considerations

E-cigarette- or vaping product–associated lung injury (EVALI) began in the United States in 2019. Approximately 66% of patients have been male and 80% are under age 35. Over 95% of reported cases required hospitalization: 47% were admitted to intensive care, 22% were intubated, and many died. Based on the characteristics of these patients, the diagnosis of EVALI requires reported use of e-cigarette or vaping products within 3 months of symptom onset, compatible chest imaging findings, and an evaluation that excludes infectious etiologies.

No single causative agent has been identified. Most cases involved vaping products containing tetrahydrocannabinol (THC) or nicotine or both. Postulated factors contributing to the development of EVALI include e-cigarette flavorings, exposure to diacetyl (a popcorn flavoring that has been associated with lung injury), THC, adulteration of THC, adulteration of delivery devices, and vitamin E acetate (used as a thickening agent).

Clinical Findings

A. Symptoms and Signs

Patients with EVALI have respiratory symptoms (95%), including cough, shortness of breath, chest pain, and hemoptysis; GI symptoms (77%), including nausea, vomiting, and diarrhea; and constitutional symptoms (85%), including fever and chills. The illness is usually acute to subacute with patients having symptoms for days to weeks before seeking health care.

Tachycardia and tachypnea are present in 55% and 45% of patients, respectively, and 57% have a room air oxygen saturation of < 95%. Given the nonspecific nature of the presentation especially during influenza season and the COVID-19 pandemic, providers must have a high degree of clinical suspicion and ask patients specifically about vaping.

B. Laboratory Findings

There are no laboratory findings specific for the diagnosis of EVALI. There may be leukocytosis, elevated CRP, and elevated ESR. It is important to exclude other possible etiologies such as infectious or eosinophilic pneumonia.

C. Imaging

Imaging findings in EVALI show various patterns of lung injury. CXRs typically show bilateral diffuse pulmonary opacities. Chest CT scan findings are nonspecific and may show bilateral distribution with ground-glass densities with subpleural sparing.

Differential Diagnosis

The EVALI case definition requires a negative workup for infectious causes. Other diagnoses to consider include acute eosinophilic pneumonia, ARDS, hypersensitivity pneumonitis, lipoid pneumonia, and organizing pneumonia. Influenza testing should be done in season, and SARS-CoV-2 testing, as indicated.

Treatment

In published reports of hospitalized patients with EVALI who have received corticosteroids, rapid improvement has been described. Symptoms of fatigue, dyspnea, decreased exercise capacity, and cough may persist for months.

Rebuli ME et al. The e-cigarette or vaping product use-associated lung injury epidemic: pathogenesis, management, and future directions: an official American Thoracic Society workshop report. Ann Am Thorac Soc. 2023;20:1. [PMID: 36584985]

PULMONARY ASPIRATION SYNDROMES

1. Acute Aspiration of Gastric Contents

Acute aspiration of gastric contents may be catastrophic. The pulmonary response depends on the characteristics and amount of gastric contents aspirated. The more acidic the material, the greater the degree of chemical pneumonitis. Aspiration of pure gastric acid causes extensive desquamation of the bronchial epithelium, bronchiolitis, hemorrhage, and pulmonary edema and may lead to ARDS. The clinical picture is one of abrupt onset of respiratory distress, with cough, wheezing, fever, and tachypnea. Crackles may be audible at the bases of the lungs. Hypoxemia may be noted immediately after aspiration occurs. Radiographic abnormalities, consisting of patchy alveolar opacities in dependent lung zones, appear within a few hours. If particulate food matter has been aspirated along with gastric acid, radiographic features of bronchial obstruction may be observed. Fever and leukocytosis are common even in the absence of infection.

Recently, GLP-1 receptor agonists have been associated with reports of pulmonary aspiration due to delayed gastric emptying.

Treatment of acute aspiration of gastric contents consists of supplemental oxygen, measures to maintain the airway, and the usual measures for treatment of acute respiratory failure. There is no evidence to support the routine use of prophylactic antibiotics or corticosteroids. Secondary pulmonary infection, which occurs in about one-fourth of patients, typically appears 2–3 days after aspiration. Hypotension or shock secondary to alveolar-capillary membrane injury and intravascular volume depletion may occur and is managed with typical supportive care.

2. Chronic Aspiration of Gastric Contents

Chronic aspiration of gastric contents may result from primary disorders of the larynx or the esophagus, such as achalasia, esophageal stricture, systemic sclerosis (scleroderma), esophageal carcinoma, esophagitis, and GERD. In GERD, relaxation of the tone of the lower esophageal sphincter allows reflux of gastric contents into the esophagus and predisposes to chronic pulmonary aspiration, especially when supine. Cigarette smoking, consumption of alcohol or caffeine, and certain medications (ie, anticholinergics, benzodiazepines, nitroglycerin) are all known to relax the lower esophageal sphincter. Pulmonary disorders linked to GERD and chronic aspiration include asthma, chronic cough, bronchiectasis, and pulmonary fibrosis. Even in the absence of aspiration, acid in the esophagus may trigger bronchospasm or bronchial hyperreactivity through reflex mechanisms.

The diagnosis and management of GERD and chronic aspiration are challenging. A discussion of strategies for the evaluation, prevention, and management of extraesophageal reflux manifestations can be found in Chapter 17.

3. Retention of an Aspirated Foreign Body

Retention of an aspirated foreign body in the tracheobronchial tree may produce both acute and chronic conditions, including atelectasis, postobstructive hyperinflation, acute or recurrent pneumonia, bronchiectasis, and lung abscess. Occasionally, a misdiagnosis of asthma, COPD, or lung cancer is made in adult patients who have aspirated a foreign body. The plain CXR usually suggests the site of the foreign body. In some cases, an expiratory film, demonstrating regional hyperinflation due to a check-valve effect, is helpful. Bronchoscopy is usually necessary to establish the diagnosis and attempt removal of the foreign body.

Simpson AJ et al. BTS clinical statement on aspiration pneumonia. Thorax. 2023;78:s3. [PMID: 36863772]

4. Aspiration of Toxic Material

Aspiration of toxic material into the lung usually results in clinically evident pneumonia. **Hydrocarbon pneumonitis** is caused by aspiration of ingested petroleum distillates, eg, gasoline, kerosene, furniture polish, and other household petroleum products. Lung injury results mainly from vomiting of ingested products and secondary aspiration. Therapy is supportive. The lung should be protected from repeated aspiration with a cuffed endotracheal tube if necessary. **Lipoid pneumonia** is a chronic syndrome related to the repeated aspiration of oily materials, eg, mineral oil, cod liver oil, and oily nose drops; it usually occurs in older patients with impaired swallowing. Patchy opacities in dependent lung zones and lipid-laden macrophages in expectorated sputum are characteristic findings.

OCCUPATIONAL PULMONARY DISEASES

Many acute and chronic pulmonary diseases are related to inhalation of noxious substances encountered in the workplace. Disorders linked to occupational exposures may be classified as: (1) pneumoconioses, (2) hypersensitivity pneumonitis, (3) obstructive airway disorders, (4) toxic lung injury, (5) lung cancer, (6) pleural diseases, and (7) other.

1. Pneumoconioses

Pneumoconioses are chronic fibrotic lung diseases caused by the inhalation of inert inorganic dusts. Pneumoconioses range from asymptomatic disorders with diffuse nodular opacities on CXR to severe, symptomatic, life-shortening disorders. Clinically important pneumoconioses include coal worker's pneumoconiosis, silicosis, and asbestosis (Table 9–19). Treatment for each is supportive; pulmonary rehabilitation may be considered.

Table 9–19. Selected pneumoconioses.

Disease	Agent	Occupations
Asbestosis	Asbestos	Mining, insulation, construction, shipbuilding
Baritosis	Barium salts	Glass and insecticide manufacturing
Coal worker's pneumoconiosis	Coal dust	Coal mining
Kaolin pneumoconiosis	Sand, mica, aluminum silicate	Mining of china clay; pottery and cement work
Shaver disease	Aluminum powder	Manufacture of corundum
Siderosis	Metallic iron or iron oxide	Mining, welding, foundry work
Silicosis	Free silica (silicon dioxide)	Rock mining, quarrying, stone cutting, tunneling, sandblasting, pottery, diatomaceous earth
Stannosis	Tin, tin oxide	Mining, tin-working, smelting
Talcosis	Magnesium silicate	Mining, insulation, construction, shipbuilding

A. Coal Worker's Pneumoconiosis

In coal worker's pneumoconiosis, ingestion of inhaled coal dust by alveolar macrophages leads to the formation of coal macules, usually 2–5 mm in diameter, that appear on CXR as diffuse small opacities that are especially prominent in the upper lung. Simple coal worker's pneumoconiosis is usually asymptomatic with minimal impact on PFTs. In complicated coal worker's pneumoconiosis **("progressive massive fibrosis")**, conglomeration and contraction in the upper lung zones occur, with radiographic features resembling complicated silicosis.

B. Silicosis

In silicosis, extensive or prolonged inhalation of free silica (silicon dioxide) particles (sandblasters, foundry, granite and stone cutting, molding, ceramics) in the respirable range (0.3–5 mcm) causes the formation of small, rounded opacities (silicotic nodules) throughout the lung. Calcification of the periphery of hilar lymph nodes ("eggshell" calcification) is an unusual radiographic finding that strongly suggests silicosis. Simple silicosis is usually asymptomatic and without change on routine PFTs; in complicated silicosis, large conglomerate densities appear in the upper lung and are accompanied by dyspnea and obstructive and restrictive pulmonary dysfunction. The incidence of pulmonary tuberculosis is increased in patients with silicosis. All patients with silicosis should have a tuberculin skin test and a CXR to rule out tuberculosis.

C. Asbestosis

Asbestosis is a nodular interstitial fibrosis occurring in workers exposed to asbestos fibers (shipyard and construction workers, pipe fitters, insulators) over many years (typically 10–20 years). Patients with asbestosis usually first seek medical attention at least 15 years after exposure with the following symptoms and signs: progressive dyspnea, inspiratory crackles, and in some cases, clubbing and cyanosis. The radiographic features of asbestosis include linear streaking at the lung bases, opacities of various shapes and sizes, and honeycomb changes in advanced cases. The presence of pleural plaques may be a clue to diagnosis. HRCT scanning is the best imaging method for asbestosis because of its ability to detect parenchymal fibrosis and define the presence of coexisting pleural plaques. Cigarette smoking in asbestos workers increases the prevalence of radiographic pleural and parenchymal changes and markedly increases the incidence of lung carcinoma. It may also interfere with the clearance of short asbestos fibers from the lung. PFTs show restrictive dysfunction and reduced diffusing capacity. There is no specific treatment.

2. Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis (also called extrinsic allergic alveolitis) is a nonatopic, nonasthmatic inflammatory pulmonary disease precipitated by exposure to an inhaled organic antigen such as microbial, avian, and animal antigens, and less commonly to an inorganic agent (Table 9–20). The immunologic hypersensitivity reaction leads to an acute illness. Prompt diagnosis is essential since symptoms are usually reversible if the offending antigen is removed from the patient's environment early in the course of illness. Continued exposure may lead to progressive fibrotic or nonfibrotic disease The histopathology of acute hypersensitivity pneumonitis is characterized by interstitial infiltrates of lymphocytes and plasma cells, with noncaseating granulomas in the interstitium and air spaces.

Table 9–20. Selected causes of hypersensitivity pneumonitis.

Disease	Antigen	Source
Farmer's lung	*Saccharopolyspora rectivirgula* (formerly, *Micropolyspora faeni), Thermoactinomyces vulgaris*	Moldy hay
"Humidifier" lung	Thermophilic actinomycetes	Contaminated humidifiers, heating systems, or air conditioners
Bird fancier's lung	Avian proteins	Bird serum and excreta
Bagassosis	*Thermoactinomyces sacchari* and *T vulgaris*	Moldy sugar cane fiber (bagasse)
Sequoiosis	*Graphium, Aureobasidium*, and other fungi	Moldy redwood sawdust
Maple bark stripper's disease	*Cryptostroma (Coniosporium) corticale*	Rotting maple tree logs or bark
Mushroom picker's disease	Same as farmer's lung	Moldy compost
Suberosis	*Penicillium frequentans*	Moldy cork dust
Detergent worker's lung	*Bacillus subtilis* enzyme	Enzyme additives

Clinical Findings

A. Acute Illness

Cough and dyspnea develop within days to weeks of exposure; constitutional symptoms such as low-grade fever, chills, and malaise are less common. Inspiratory squeaks on chest auscultation are characteristic when present. Small nodular densities sparing the apices and bases of the lungs are noted on CXR. Laboratory studies reveal an increase in the WBC count with a shift to the left, hypoxemia, and the presence in serum of precipitating antibodies to the offending agent. Hypersensitivity pneumonitis antibody panels against common offending antigens are available; positive results, while supportive, do not establish a definitive diagnosis. PFTs reveal restrictive dysfunction and reduced diffusing capacity.

B. Subacute and Chronic Illness

A subacute hypersensitivity pneumonitis syndrome (15% of cases) is characterized by the insidious onset of chronic cough and, with continued exposure, slowly progressive dyspnea, anorexia, and weight loss. Characteristic HRCT findings of nonfibrotic disease include upper- or mid-lung ground-glass or nodular opacities and signs of air trapping. Fibrotic disease is characterized by reticulation either in a random or mid-lung zone distribution. Surgical lung biopsy may be necessary for the diagnosis of subacute and chronic hypersensitivity pneumonitis, although the histopathologic patterns are nonspecific and overlap with several idiopathic interstitial pneumonias.

Treatment

Treatment of acute hypersensitivity pneumonitis consists of identification of the offending agent and avoidance of further exposure. In severe acute or protracted cases, oral corticosteroids (prednisone, 0.5 mg/kg daily as a single morning dose for 2 weeks, tapered to nil over 4–6 weeks) may be given. Change in occupation is often required.

Koster MA et al. Diagnosis of hypersensitivity pneumonitis in adults, 2020 clinical practice guideline: summary for clinicians. Ann Am Thorac Soc. 2021;18:559. [PMID: 33141595]

3. Obstructive Airway Disorders

Occupational pulmonary diseases manifested as obstructive airway disorders include occupational asthma and byssinosis.

A. Occupational Asthma

Asthma is one of the most common presentations of occupational lung disease. Approximately 25% of all cases of asthma are related to occupation. Offending agents in the workplace are numerous and classified into low- and high-molecular weight chemicals. High-molecular weight chemicals include animal proteins, flours, enzymes such as pancreatic extracts, and plant-based proteins such as wheat, grain dust, coffee beans, tobacco dust, and tobacco. Low-molecular weight inhaled agents include isocyanates, anhydrides, metals, pharmaceutical drugs, wood dust, dyes and bleaches, resins and glue, and various other agents. Treatment consists of avoidance of further exposure to the offending agent and bronchodilators, but symptoms may persist for years after workplace exposure has been terminated.

Morimoto Y et al. Lung disorders induced by respirable organic chemicals. J Occup Health. 2021;63:e12240. [PMID: 34128301]

B. Byssinosis

Byssinosis is an asthma-like disorder in textile workers caused by inhalation of cotton dust. Repeated exposure leads to chronic bronchitis.

4. Lung Cancer

Many industrial pulmonary carcinogens have been identified, including asbestos, radon gas, arsenic, iron, chromium, nickel, coal tar fumes, petroleum oil mists, isopropyl oil, mustard gas, and printing ink. Cigarette smoking acts as a cocarcinogen with asbestos and radon gas to cause bronchogenic carcinoma. Asbestos alone causes malignant mesothelioma.

5. Other Occupational Pulmonary Diseases

Occupational diseases of the pleura may result from exposure to asbestos or talc. Inhalation of talc causes pleural plaques that are like those caused by asbestos. In some asbestos workers, benign asbestos pleural effusions (BAPE) occur, which are typically small, unilateral, and precede the onset of interstitial lung disease. Pleural adhesions at the site of BAPE may cause a “rounded atelectasis” appearance on CXR. Occupational agents are also responsible for other pulmonary disorders, with a range of pathologies including occupational COPD, and interstitial lung diseases. For this reason, it is important to obtain a thorough occupational history in any patient presenting with pulmonary symptoms.

MEDICATION-INDUCED LUNG DISEASE

Typical patterns of pulmonary response to medications implicated in medication-induced respiratory disease are summarized in Table 9–21. Pulmonary injury due to medications occurs because of allergic reactions, idiosyncratic reactions, overdose, or undesirable side effects. In most patients, the mechanism of pulmonary injury is unknown.

Precise diagnosis of medication-induced pulmonary disease is often difficult because results of routine laboratory studies are not helpful and radiographic findings are not specific. A high index of suspicion and a thorough history of medication usage are critical to establishing the diagnosis of medication-induced lung disease. The clinical response to cessation of the suspected offending agent is also helpful. Acute episodes of medication-induced pulmonary disease may disappear 24–48 hours after the medication has been discontinued, but chronic syndromes may take longer to resolve. Challenge tests to confirm the diagnosis are risky and rarely performed.

Treatment of medication-induced lung disease consists of discontinuing the offending agent immediately, managing the pulmonary symptoms appropriately, and treating with corticosteroids if pulmonary toxicity is rapidly progressive. Observational data support the use of corticosteroids in severe cases; however, controlled data are lacking. Immune checkpoint inhibitors, commonly used treatments for a variety of malignant and nonmalignant conditions, are associated with a 5% risk of pneumonitis with up to 20% mortality when severe. Observational data support concurrent corticosteroid treatment in these cases.

Table 9–21. Pulmonary manifestations of selected medication toxicities.

- **Asthma**
  - β-Blockers
  - Aspirin
  - NSAIDs
  - Histamine
  - Methacholine
  - Acetylcysteine
  - Aerosolized pentamidine
  - Any nebulized medication
- **Chronic cough**
  - ACE inhibitors
- **Pulmonary infiltration**
  - Without eosinophilia
    - Amitriptyline
    - Azathioprine
    - Amiodarone
  - With eosinophilia
    - Sulfonamides
    - L-Tryptophan
    - Nitrofurantoin
    - Penicillin
    - Methotrexate
    - Crack cocaine
- **Drug-induced SLE**
  - Hydralazine
  - Procainamide
  - Isoniazid
  - Chlorpromazine
  - Phenytoin
- **Interstitial pneumonitis/fibrosis**
  - Nitrofurantoin
  - Bleomycin
  - Busulfan
  - Cyclophosphamide
  - Immune checkpoint inhibitors
  - Methysergide
  - Phenytoin
- **Pulmonary edema**
  - Noncardiogenic
    - Aspirin
    - Chlordiazepoxide
    - Cocaine
    - Ethchlorvynol
    - Heroin/opiates
  - Cardiogenic
    - β-Blockers
- **Pleural effusion**
  - Bromocriptine
  - Nitrofurantoin
  - Any drug inducing SLE
  - Methysergide
  - Chemotherapeutic agents
    - (eg, carmustine, cyclophosphamide, dasatinib, docetaxel, GM-CSF, methotrexate)
  - Tyrosine kinase inhibitors
- **Mediastinal widening**
  - Phenytoin
  - Corticosteroids
  - Methotrexate
- **Respiratory failure**
  - Neuromuscular blockade
    - Aminoglycosides
    - Paralytic agents
  - CNS depression
    - Sedatives
    - Hypnotics
    - Opioids
    - Alcohol
    - Tricyclic antidepressants

GM-CSF, granulocyte-macrophage colony-stimulating factor.

Inhalation of crack cocaine may cause a spectrum of acute pulmonary syndromes, including pulmonary infiltration with eosinophilia, pneumothorax and pneumomediastinum, bronchiolitis obliterans, and acute respiratory failure associated with diffuse alveolar damage and alveolar hemorrhage. Corticosteroids have been used with variable success to treat alveolar hemorrhage.

RADIATION LUNG INJURY

The lung is an exquisitely radiosensitive organ that can be damaged by external beam radiation therapy. The degree of pulmonary injury is determined by the volume of lung irradiated, the dose and rate of exposure, and potentiating factors (eg, concurrent chemotherapy, previous radiation therapy in the same area, and simultaneous withdrawal of corticosteroid therapy). Symptomatic radiation lung injury occurs in about 10% of patients treated for carcinoma of the breast, 5–15% of patients treated for carcinoma of the lung, and 5–35% of patients treated for lymphoma. Two phases of the pulmonary response are apparent: an acute phase (radiation pneumonitis) and a chronic phase (radiation fibrosis).

1. Radiation Pneumonitis

Acute radiation pneumonitis usually occurs 4–12 weeks (range 1–6 months) after completion of radiotherapy and is characterized by insidious onset of dyspnea, intractable dry cough, chest fullness or pain, weakness, and fever. Late radiation pneumonitis may develop 6–12 months after completion of radiation. Occasionally, patients who are months to years removed from radiation therapy will experience "radiation recall" with an inflammatory reaction in the radiated region after treatment with a new round of chemotherapy; this phenomenon has also been reported with immune checkpoint inhibitors. Inspiratory crackles may be heard in the involved area. In severe disease, respiratory distress and cyanosis occur that are characteristic of ARDS. An increased WBC count and elevated ESR are common. PFTs reveal reduced lung volumes, reduced lung compliance, hypoxemia, reduced diffusing capacity, and reduced maximum voluntary ventilation. CXR, which correlates poorly with the presence of symptoms, usually demonstrates alveolar or nodular opacities limited to the irradiated area. Air bronchograms are often observed. Sharp borders of an opacity may help distinguish radiation pneumonitis from other conditions, such as infectious pneumonia, lymphangitic spread of carcinoma, and recurrent tumor; however, the opacity may extend beyond the radiation field.

No specific therapy is proven effective in radiation pneumonitis. Spontaneous resolution may occur in mild disease, but prednisone (1 mg/kg/day orally) is commonly given immediately to patients with a more severe presentation or pulmonary function decline; higher doses may be given in patients who are critically ill. After 1 week, the dose is reduced and maintained at 20–40 mg/day for several weeks, then slowly tapered. Radiation pneumonitis may improve in 2–3 weeks following onset of symptoms as the exudative phase resolves. Acute respiratory failure, if present, is treated supportively. Death from ARDS is unusual in radiation pneumonitis.

Wang Y et al. Cytological changes in radiation-induced lung injury. Life Sci. 2024;358:123188. [PMID: 39481833]

2. Pulmonary Radiation Fibrosis

Radiation fibrosis may occur with or without antecedent radiation pneumonitis. Radiographic findings include obliteration of normal lung markings, dense interstitial and pleural fibrosis, reduced lung volumes, tenting of the diaphragm, and sharp delineation of the irradiated area. No specific therapy is proven effective, and corticosteroids have no value. Pulmonary fibrosis may develop after an intervening period (6–12 months) of well-being in patients who experience radiation pneumonitis. Pulmonary radiation fibrosis occurs in most patients who receive a full course of radiation therapy for cancer of the lung or breast. Most patients are asymptomatic, although slowly progressive dyspnea may occur.

Salem PP et al. Proton radiation therapy: a systematic review of treatment-related side effects and toxicities. Int J Mol Sci. 2024;25:10969. [PMID: 39456752]

PLEURAL DISEASES

PLEURITIS

Pleuritic pain or "pleurisy" is due to inflammation of the parietal pleura. It is typically well localized, sharp, fleeting, and made worse by coughing, sneezing, deep breathing, or movement. The pain, which is felt over the chest wall, is due to the cutaneous distribution of the intercostal nerves innervating the rib cage and lateral portion of each hemidiaphragm. Inflammation of the parietal pleura or central diaphragm, which are innervated by phrenic nerve fibers, may cause pain that is referred to the ipsilateral shoulder or neck. There are numerous causes of pleuritis. In young, otherwise healthy individuals, pleuritis is usually caused by viral respiratory infections or pneumonia (including tuberculosis in endemic regions). Other causes include PE, inflammatory disorders (serositis), malignancy, and drug reactions. The presence of pleural effusion, pleural thickening, or air in the pleural space requires further diagnostic and therapeutic measures, including pleural fluid sampling and analysis.

Treatment of pleuritis consists of treating the underlying condition. Anti-inflammatory analgesic medications are often helpful for pain relief.

Guo H et al. Pleural diseases in connective tissue diseases. Semin Respir Crit Care Med. 2024;45:305. [PMID: 38547917]

PLEURAL EFFUSION

ESSENTIALS OF DIAGNOSIS

- May be asymptomatic; chest pain frequently seen in the setting of pleuritis, trauma, or infection; dyspnea is common with large effusions.
- Dullness to percussion and decreased breath sounds over the effusion.
- Radiographic evidence of pleural effusion.
- Diagnostic findings on thoracentesis.

General Considerations

A pleural effusion is an abnormal accumulation of fluid in the pleural space. Pleural effusions may be classified by differential diagnosis (Table 9–22) or by underlying pathophysiology. Five pathophysiologic processes account for most effusions: increased production of fluid in the setting of normal capillaries due to increased hydrostatic or decreased oncotic pressures **(transudates);** increased production of fluid due to abnormal capillary permeability **(exudates);** decreased lymphatic clearance of fluid from the pleural space **(exudates);** infection in the pleural space **(empyema);** and bleeding into the pleural space **(hemothorax).**

Diagnostic thoracentesis should be performed whenever there is a new pleural effusion and no clinically apparent cause. Observation is appropriate in some situations (eg, symmetric bilateral pleural effusions in the setting of HF), but an atypical presentation or failure of an effusion to resolve as expected warrants thoracentesis to identify the underlying process.

Clinical Findings

A. Symptoms and Signs

Patients with pleural effusions most often report dyspnea, cough, or respirophasic chest pain. Symptoms are more common in patients with existing cardiopulmonary disease. Small pleural effusions are less likely to be symptomatic than larger effusions. Physical findings are usually absent in small effusions. Larger effusions may present with dullness to percussion and diminished or absent breath sounds over the effusion. Compressive atelectasis may cause bronchial breath sounds and egophony just above the effusion. A massive effusion with increased intrapleural pressure may cause contralateral shift of the trachea and bulging of the intercostal spaces. A pleural friction rub indicates pulmonary infarction or pleuritis.

Table 9–22. Causes of pleural fluid transudates and exudates.

Transudates	Exudates
HF Cirrhosis with ascites Nephrotic syndrome Peritoneal dialysis Myxedema Atelectasis (acute) Constrictive pericarditis Superior vena cava obstruction PE Hypoalbuminemia Pulmonary arterial hypertension Post dialysis	Pneumonia (parapneumonic effusion, including empyema) Cancer PE Bacterial infection (including empyema) Tuberculosis Connective tissue disease Viral infection Fungal infection Rickettsial infection Parasitic infection Asbestos Meigs syndrome Pancreatic disease Uremia Chronic atelectasis Trapped lung Chylothorax Sarcoidosis Drug reaction (eg, dasatinib) Post–myocardial injury syndrome Esophageal perforation Chest radiation therapy

B. Laboratory Findings

The gross appearance of pleural fluid helps identify several types of pleural effusion. Grossly purulent fluid signifies empyema. Milky white pleural fluid should be centrifuged. A clear supernatant above a pellet of white cells indicates empyema, whereas a persistently turbid supernatant suggests a **chylous effusion;** analysis of this supernatant reveals chylomicrons and a high triglyceride level (> 100 mg/dL [1 mmol/L]), often from disruption of the thoracic duct. **Hemorrhagic pleural effusion** is a mixture of blood and pleural fluid. Ten thousand red cells per microliter create blood-tinged pleural fluid; 100,000 red cells/mcL (100×10^9/L) create grossly bloody pleural fluid. **Hemothorax** is the presence of gross blood in the pleural space, usually following chest trauma or instrumentation. It is defined as a ratio of pleural fluid hematocrit to peripheral blood hematocrit > 0.5.

Pleural fluid samples should be sent for measurement of protein, glucose, and LD in addition to total and differential WBC counts. Chemistry determinations are used to classify effusions as transudates or exudates. This classification is important because the differential diagnosis and subsequent evaluation for each entity varies (see Table 9–22). A **pleural exudate** is an effusion that has one or more of the following laboratory features: (1) ratio of pleural fluid protein to serum protein > 0.5; (2) ratio of pleural fluid LD to serum LD > 0.6; or (3) pleural fluid LD > two-thirds the upper limit of normal serum LD. Alternative diagnostic criteria that do not require the simultaneous sampling of serum but that perform similarly include the “two-test” (pleural fluid cholesterol > 40–55 mg/dL, pleural fluid LD > 0.67 times upper limit of normal serum LD) and the “three-test” (which adds pleural fluid protein > 3.0 g/dL). **Pleural transudates** occur in the setting of normal capillary integrity and have none of the laboratory features of exudates. A transudate suggests the absence of local pleural disease; characteristic laboratory findings include a glucose near to serum glucose, pH between 7.40 and 7.55, and fewer than 1000 WBCs/mcL (1.0×10^9/L) with a predominance of mononuclear cells. Discrimination of exudate from transudate is less reliable near the cutoff values for any of the criteria. In conditions such as HF, effective diuresis may increase the protein or LD concentration in the transudative pleural fluid as water is reabsorbed, thus creating a borderline “pseudoexudative” chemistry.

HF accounts for most transudates. Bacterial pneumonia, cancer, and tuberculosis (in endemic regions) are the most common causes of exudative effusion. Other causes of exudates with characteristic laboratory findings are summarized in Table 9–23.

Table 9–23. Characteristics of important exudative pleural effusions.

Etiology or Type of Effusion	Gross Appearance	WBC Count (cells/mcL)	RBC Count (cells/mcL)	Glucose	Comments
Malignancy	Turbid to bloody; occasionally serous	1000–100,000 (1.0–100 × 10^9/L) M	100 (0.1 × 10^9/L) to several hundred thousand	Equal to serum levels; < 60 mg/dL in 15% of cases	Eosinophilia uncommon; positive results on cytologic examination
Uncomplicated parapneumonic	Clear to turbid	5000–25,000 (5.0–25 × 10^9/L) P	< 5000 (5.0 × 10^9/L)	Equal to serum levels	Tube thoracostomy unnecessary
Empyema	Turbid to purulent	25,000–100,000 (25–100 × 10^9/L) P	< 5000 (5.0 × 10^9/L)	Less than serum levels; often very low	Drainage necessary; putrid odor suggests anaerobic infection
Tuberculosis	Serous to serosanguineous	5000–10,000 (5.0–10 × 10^9/L) M	< 10,000 (10 × 10^9/L)	Equal to serum levels; occasionally < 60 mg/dL	Protein > 4.0 g/dL (may exceed 5 g/dL); frequently lymphocyte predominant (> 50%); eosinophils (> 10%) or mesothelial cells (> 5%) make diagnosis unlikely; see text for additional diagnostic tests
Rheumatoid	Turbid; greenish yellow	1000–20,000 (1.0–20 × 10^9/L) M or P	< 1000 (1.0 × 10^9/L)	< 40 mg/dL	Secondary empyema common; high LD, low complement, high rheumatoid factor, cholesterol crystals are characteristic
Pulmonary infarction	Serous to grossly bloody	1000–50,000 (1.0–50 × 10^9/L) M or P	100 (0.1 × 10^9/L) to > 100,000 (100 × 10^9/L)	Equal to serum levels	Variable findings; no pathognomonic features
Esophageal rupture	Turbid to purulent; red-brown	< 5000 (5.0 × 10^9/L) to > 50,000 (50 × 10^9/L) P	1000–10,000 (1.0–10 × 10^9/L)	Usually low	High amylase level (salivary origin); pneumothorax in 25% of cases; effusion usually on left side; pH < 6.0 strongly suggests diagnosis
Pancreatitis	Turbid to serosanguineous	1000–50,000 (1.0–50 × 10^9/L) P	1000–10,000 (1.0–10 × 10^9/L)	Equal to serum levels	Usually left-sided; high amylase level

M, mononuclear cell predominance; P, polymorphonuclear leukocyte predominance.

Pleural fluid pH (normal = 7.60) is useful in the assessment of parapneumonic effusions, if it can be reliably measured, and is more useful than glucose measurement in determining need for drainage. A pH < 7.20 suggests a complex parapneumonic pleural effusion that may require drainage; however, other causes include rheumatoid arthritis, lupus, malignancy, esophageal rupture, hemothorax, and pancreatic-pleural fistula. An elevated pleural fluid amylase suggests acute pancreatitis, pancreatic pseudocyst, adenocarcinoma of the lung or pancreas, or esophageal rupture.

Suspected tuberculous pleural effusion should be evaluated by thoracentesis with culture, although pleural fluid culture positivity for *M tuberculosis* is low. Tests for pleural fluid adenosine deaminase (approximately 90% sensitivity and specificity for pleural tuberculosis at levels > 60 U/L, tuberculosis rare if level is < 40 U/L) and interferon-γ (89% sensitivity, 97% specificity) can be helpful diagnostic aids, particularly in making decisions to pursue invasive testing in complex patients. Closed pleural biopsy is more sensitive than pleural fluid culture for diagnosis, revealing granulomatous inflammation in approximately 60% of patients; culture of three pleural biopsy specimens combined with histologic examination of a pleural biopsy for granulomas yields a diagnosis in up to 90% of patients.

Between 40% and 80% of exudative pleural effusions are malignant, while over 90% of malignant pleural effusions are exudative. Almost any form of cancer may cause effusions, but the most common are lung (one-third) and breast cancer. In 5–10% of malignant pleural effusions, no primary tumor is identified.

Pleural fluid specimens should be sent for cytologic examination in all cases of exudative effusions in patients suspected of harboring an underlying malignancy. The diagnostic yield depends on the nature and extent of the underlying malignancy. Sensitivity is 50–65% but may increase with serial sampling. In a patient with a high prior probability of malignancy, a negative cytologic examination should be followed by one repeat thoracentesis. If that examination is negative, thoracoscopy (sensitivity 92–96%) is preferred to closed pleural biopsy.

C. Imaging

The lung is less dense than water and floats on pleural fluid that accumulates in dependent regions. On a standard upright CXR (Figure 9–6), approximately 75–100 mL of pleural fluid must accumulate in the posterior costophrenic sulcus to be visible on the lateral view and 175–200 mL in the lateral costophrenic sulcus to be visible on the frontal view. Ultrasonography increases the safety of thoracentesis and should be incorporated routinely by trained users. Chest CT scans may identify as little as 10 mL of fluid and allows assessment of the entire thorax.

Pleural fluid may become trapped (loculated) by pleural adhesions, thereby forming unusual collections along the lateral chest wall or within lung fissures. Round or oval fluid collections in fissures that resemble intraparenchymal masses are called pseudotumors.

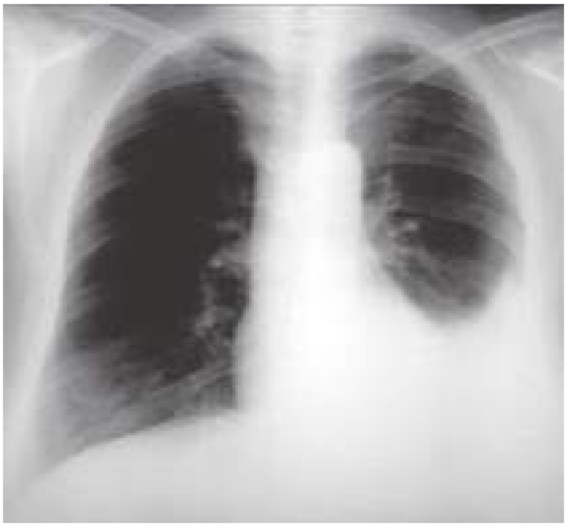
▶ Treatment

A. Transudative Pleural Effusion

Transudative pleural effusions characteristically occur in the absence of pleural disease. Therefore, treatment is directed at the underlying condition. Therapeutic thoracentesis for severe dyspnea typically offers only transient benefit. Pleurodesis or indwelling pleural catheters are rarely indicated but are appropriate for management of symptoms in selected patients whose symptoms respond to drainage and whose effusions are refractory to maximal medical therapy.

B. Malignant Pleural Effusion

Chemotherapy, radiation therapy, or both offer temporary control in some malignant effusions but are generally ineffective in lung cancer in the pleural space except for small-cell lung cancer. Asymptomatic malignant effusions usually do not require specific treatment. Symptomatic patients should be offered pleural drainage, either via initial therapeutic thoracentesis to determine symptomatic response to drainage, following which an indwelling pleural catheter can be placed, or via immediate placement of an indwelling pleural catheter.



▲ **Figure 9–6.** Left pleural effusion. Frontal CXR showing a meniscus-shaped density at the left costophrenic angle sulcus indicative of a moderate-sized pleural effusion. (Reproduced, with permission, from Lechner AJ, Matuschak GM, Brink DS. *Respiratory: An Integrated Approach to Disease*. McGraw-Hill, 2012.)

C. Parapneumonic Pleural Effusion

Parapneumonic pleural effusions are divided into three categories, the classification of which can only be determined by sampling the fluid: uncomplicated (simple), complicated, and empyema. **Uncomplicated (simple) parapneumonic effusions** are free-flowing sterile exudates of modest size that resolve quickly with antibiotic treatment of pneumonia. They do not need drainage.

Complicated parapneumonic effusions present the most difficult management decisions. They tend to be larger than simple parapneumonic effusions and to show more evidence of inflammatory stimuli, such as low glucose level, low pH, or evidence of loculation. Inflammation probably reflects ongoing bacterial invasion of the pleural space despite negative bacterial cultures. Tube thoracostomy usually is indicated when pleural fluid glucose is < 60 mg/dL (< 3.3 mmol/L) or the pH is < 7.2. The clinician may also consider drainage of a complicated effusion if the pleural fluid pH is between 7.2 and 7.3 or the LD is > 1000 U/L (> 20 mckat/L). Pleural fluid cell count and protein have little diagnostic value in this setting.

Empyema is gross infection of the pleural space indicated by positive Gram stain or culture. Empyema should be drained and the patient referred to a thoracic specialist to determine whether tube thoracostomy versus decortication is needed to facilitate clearance of infection and to reduce the probability of permanent fibrous encasement of the lung.

Tube thoracostomy drainage of empyema or complicated parapneumonic effusions is frequently complicated by loculation that prevents adequate drainage. Intrapleural instillation of fibrinolytic agents alone has not been shown in controlled trials to improve drainage. The combination of intrapleural tissue plasminogen activator and deoxyribonuclease (DNase), an enzyme that catalyzes extracellular DNA and degrades biofilm formation within the pleural cavity, has been found to improve clinical outcome (increased drainage, decreased length of stay, and decreased surgical referral) compared with placebo or either agent alone, and should be considered when fever, leukocytosis, or anorexia persist despite antibiotics and tube thoracostomy, or when the lung fails to re-expand.

D. Hemothorax

A small-volume hemothorax that is stable or improving on CXRs may be managed by close observation. In all other cases, hemothorax is treated by immediate insertion of a thoracostomy tube to (1) drain existing blood and clot and prevent lung entrapment, (2) quantify the amount of bleeding, (3) reduce the risk of fibrothorax, and (4) permit apposition of the pleural surfaces to reduce hemorrhage. Thoracic surgery consultation is indicated. Thoracotomy may be required to control hemorrhage, remove clot, and treat complications.

PNEUMOTHORAX

ESSENTIALS OF DIAGNOSIS

- Acute onset of unilateral chest pain and dyspnea.
- Minimal physical findings in mild cases; unilateral chest expansion, decreased tactile fremitus, hyperresonance, diminished breath sounds, mediastinal shift, cyanosis, and hypotension in tension pneumothorax.
- Presence of pleural air on CXR.

General Considerations

Pneumothorax, or accumulation of air in the pleural space, is classified as spontaneous (primary or secondary), traumatic, or iatrogenic. **Primary spontaneous pneumothorax** occurs in the absence of an underlying lung disease, whereas **secondary spontaneous pneumothorax** is a complication of preexisting pulmonary disease. **Traumatic pneumothorax** results from penetrating or blunt trauma and includes **iatrogenic pneumothorax** following procedures, such as thoracentesis, pleural biopsy, subclavian or internal jugular vein catheter placement, percutaneous lung biopsy, bronchoscopy with transbronchial biopsy, and positive-pressure mechanical ventilation. **Tension pneumothorax** usually occurs in the setting of penetrating trauma, lung infection, CPR, or positive-pressure mechanical ventilation. In tension pneumothorax, the pressure of air in the pleural space exceeds alveolar and venous pressures throughout the respiratory cycle, resulting in compression of lung and reduction of venous return to the hemithorax; a check-valve mechanism may allow air to enter the pleural space on inspiration and to prevent egress of air on expiration.

Primary spontaneous pneumothorax is more likely among tall, thin, young (age < 45 years) individuals, more commonly men. It is thought to occur from rupture of subpleural apical blebs in response to high negative intrapleural pressures. Cigarette smoking is correlated with occurrence of primary spontaneous pneumothorax, as are connective tissue disorders such as Marfan and Ehlers-Danlos syndromes.

Secondary pneumothorax occurs as a complication of COPD, interstitial lung disease, asthma, cystic fibrosis, tuberculosis, *Pneumocystis* pneumonia, necrotizing bacterial pneumonia, menstruation (catamenial pneumothorax), and a wide variety of cystic lung diseases, including lymphangioleiomyomatosis, tuberous sclerosis, Langerhans cell histiocytosis, and Birt-Hogg-Dube syndrome (a hereditary condition with multiple benign skin tumors, lung cysts, and increased risk of both benign and malignant kidney tumors). Secondary pneumothorax, particularly in patients with underlying symptomatic lung disease, is more poorly tolerated due to the decreased respiratory reserve in this group.

Clinical Findings

A. Symptoms and Signs

Chest pain ranging from minimal to severe on the affected side and dyspnea occur in nearly all patients, and cough is commonly reported. Pneumothorax may present with life-threatening respiratory failure if underlying lung disease is present or if tension pneumothorax physiology ensues.

If pneumothorax is small (< 15% of a hemithorax), physical findings, other than mild tachycardia, are normal. If pneumothorax is large, diminished breath sounds, decreased tactile fremitus, decreased movement of the chest, and hyperresonant percussion note are often found. Tension pneumothorax should be suspected in the presence of marked tachycardia, hypotension, and mediastinal or tracheal shift.

B. Laboratory Findings

ABG analysis is often unnecessary but reveals hypoxemia and acute respiratory alkalosis in most patients. Left-sided primary pneumothorax may produce QRS axis and precordial T-wave changes on the ECG that may be misinterpreted as acute MI.

C. Imaging

Demonstration on CXR of lucency without lung markings between the chest wall and lung, and visualization of the visceral pleura (a "pleural line") is diagnostic. A few patients have secondary pleural effusion that demonstrates a characteristic air-fluid level on CXR. In supine patients, pneumothorax on a conventional CXR may appear as an abnormally radiolucent costophrenic sulcus (the "deep sulcus" sign). In patients with tension pneumothorax, CXRs show a large amount of air in the affected hemithorax and contralateral shift of the mediastinum.

Chest ultrasonography, performed at the bedside by experienced clinicians or technicians, demonstrates characteristic findings in the region of the pneumothorax. Ultrasound may be more sensitive than supine CXR (supine positioning necessitated by clinical circumstance) for detecting pneumothorax in trauma patients and is frequently used in critical care, though comparisons of ultrasound to CXR or to CT scan report variable test characteristics.

A chest CT scan is more accurate than a chest X-ray (CXR) for evaluating the size of a pneumothorax and identifying secondary pneumothorax etiologies such as cystic lung disease. However, its use as a first-line examination is limited due to higher costs, longer imaging times, and increased radiation exposure.

Differential Diagnosis

If the patient is young with typical clinical characteristics, the diagnosis of primary spontaneous pneumothorax is usually obvious and can be confirmed by CXR. Occasionally, pneumothorax may mimic MI, PE, or pneumonia.

Complications

Tension pneumothorax may be life-threatening. Pneumomediastinum and subcutaneous emphysema may occur as complications of spontaneous pneumothorax. If pneumomediastinum is detected, rupture of the esophagus or a bronchus should be considered in the differential diagnosis.

Treatment

Treatment depends on the severity of the pneumothorax, based on size and symptoms, and the nature of the underlying disease. In a reliable patient with a stable, spontaneous primary pneumothorax, observation alone may be appropriate; many cases resolve spontaneously as air is absorbed from the pleural space. A 2020 US study demonstrated that even moderate to large pneumothoraces in a stable patient (no oxygen requirement, no limitation to ambulation, and no increase in size of pneumothorax over 4 hours of monitoring) can be managed without intervention provided the patient is reliable. Simple needle aspiration drainage of pleural air with a small-bore catheter (eg, 16-gauge angiocatheter or larger drainage catheter) can be performed for spontaneous primary pneumothoraxes that are large or progressive. Length of hospital stay appears to be shorter for conservative management (observation or needle aspiration) of primary spontaneous pneumothorax. Placement of a small-bore chest tube (7F to 14F) attached to a one-way Heimlich valve provides protection against development of tension pneumothorax and may permit observation from home. The patient should be treated symptomatically for cough and chest pain and monitored with serial CXRs every 24 hours. A 2021 observational report of pneumothorax following percutaneous lung biopsy found monitoring and noninvasive management to be sufficient in most patients.

Patients with secondary pneumothorax, tension pneumothorax, or severe symptoms or those who have a pneumothorax on mechanical ventilation should undergo chest tube placement (tube thoracostomy). The chest tube is placed under water-seal drainage, and suction is applied until the lung expands. The chest tube can be removed after the air leak subsides.

All patients who smoke should be advised to discontinue smoking and warned that the risk of recurrence is higher if cigarette smoking is continued.

Indications for surgical management (video-assisted thoracoscopic surgery) include recurrences of spontaneous pneumothorax, any occurrence of bilateral pneumothorax, and failure of tube thoracostomy for the first episode (failure of lung to re-expand or persistent air leak). Surgical intervention is also generally recommended for any patient with a secondary pneumothorax (presence of underlying lung disease) because the risk of recurrence is high, and the consequences of recurrences are greater. Surgery permits resection or repair of blebs or bullae responsible for the pneumothorax as well as mechanical or chemical pleurodesis. Patients who are not acceptable surgical candidates can be treated with chemical pleurodesis via a chest tube.

Prognosis

About 30% of patients with spontaneous pneumothorax experience recurrence after either observation or tube thoracostomy for the first episode. Recurrence after surgical therapy is less frequent. Following successful therapy, there are no long-term complications. Secondary pneumothorax has up to a 50% likelihood of recurrence following the first event if surgical intervention is not undertaken.

Roberts ME et al. British Thoracic Society Guideline for pleural disease. Thorax. 2023;78(Suppl 3):s1. [PMID: 37433578]

DISORDERS OF CONTROL OF VENTILATION

The principal influences on ventilatory control are arterial Pco_2, pH, Po_2, and brainstem tissue pH. These variables are monitored by peripheral and central chemoreceptors. Under normal conditions, the ventilatory control system maintains arterial pH and Pco_2 within narrow limits; arterial Po_2 is more loosely controlled.

Abnormal control of ventilation can be seen with a variety of conditions ranging from rare disorders, such as primary alveolar hypoventilation, COVID-19, neuromuscular disorders, myxedema, starvation, and carotid body resection, to more common disorders, such as asthma, COPD, obesity, HF, and sleep-related breathing disorders. A few of these disorders will be discussed in this section.

HYPERVENTILATION SYNDROMES

Hyperventilation is an increase in alveolar minute ventilation that leads to hypocapnia. It may be caused by a variety of conditions, such as pregnancy, hypoxemia, obstructive and infiltrative lung diseases, sepsis, liver dysfunction, fever, and pain. Functional hyperventilation may be acute or chronic. **Acute hyperventilation** presents with hyperpnea, anxiety, paresthesia, carpopedal spasm, and tetany. Once organic causes of hyperventilation have been excluded, treatment of acute hyperventilation consists of breathing through pursed lips or through the nose with one nostril pinched or rebreathing expired gas from a paper bag held over the face to decrease respiratory alkalemia and its associated symptoms. Anxiolytic drugs may also be useful. **Chronic hyperventilation** may present with various nonspecific symptoms, including fatigue, dyspnea, anxiety, palpitations, and dizziness. The diagnosis of chronic hyperventilation syndrome is established if symptoms are reproduced during voluntary hyperventilation. When the symptoms are associated with paresthesia and dizziness, the diagnosis is often overlooked. Patients often report poor quality of life and most recently condition is described in post COVID syndrome and long COVID syndrome.

Genecand L et al. Dysfunctional breathing symptoms, functional impact and quality of life in patients with long COVD-19: a prospective case series. BMJ Open Respir Res. BMJ Open Respir Res. 2023;1: e001770 [PMID: 37433720]

Tavel ME. Hyperventilation syndrome: why is it regularly overlooked? Am J Med. 2021;134:13. [PMID: 32791056]

OBESITY-HYPOVENTILATION SYNDROME (Pickwickian Syndrome)

In obesity-hypoventilation syndrome, awake alveolar hypoventilation appears to result from a combination of blunted ventilatory drive and increased mechanical load imposed upon the chest by obesity. Diagnostic criteria include a BMI > 30, an arterial partial pressure of carbon dioxide > 45 mm Hg, sleep disordered breathing, and exclusion of other causes of alveolar hypoventilation. Most patients with obesity-hypoventilation syndrome also suffer from obstructive sleep apnea (90% of patients with obesity-hypoventilation syndrome), which must be treated aggressively if identified as a comorbid disorder. Therapy of obesity-hypoventilation syndrome consists mainly of continuous positive airway pressure to treat the underlying obstructive sleep apnea or noninvasive ventilation when hypoventilation and hypercapnia predominates over obstructive sleep apnea. Lifestyle modification, including weight loss and rehabilitation strategies, in turn improves hypercapnia and hypoxemia as well as the ventilatory responses to hypoxia and hypercapnia; physiological responses described mostly in first year of bariatric surgery. Finally, targeting management of comorbidities, particularly during an exacerbation of respiratory failure, such as treatment of acute coronary syndrome, PE, pneumonia or decompensated HF should be managed aggressively. Avoidance of sedative-hypnotics, opioids, and alcohol is also recommended and the use of respiratory stimulants such as medroxyprogesterone and acetazolamide has been studied and improves $Paco_2$ and Pao_2; however, they incur side effects and should only be used cautiously. Patients with obesity-hypoventilation syndrome have a higher risk of complications in the perioperative period, including respiratory failure, intubation, and HF. Recognition of these patients in the perioperative period is an important safety measure.

Orozco González BN et al. Obesity hypoventilation syndrome, literature review. Sleep Adv. 2024;5:zpae033 [PMID: 38966619]

SLEEP-RELATED BREATHING DISORDERS

Abnormal ventilation during sleep is manifested by apnea (breath cessation for at least 10 seconds) or hypopnea (decrement in airflow with drop in oxygen saturation of at least 4%). Episodes of apnea are **central** if ventilatory effort is absent for the duration of the apneic episode, **obstructive** if ventilatory effort persists throughout the apneic episode but no airflow occurs because of transient obstruction of the upper airway, or **mixed**. Obstructive and mixed sleep apneas are more common and may be associated with daytime somnolence that impacts quality of life and, in severe form, is associated with severe hypoxemia during sleep that may cause life-threatening cardiac arrhythmias, pulmonary hypertension, right-sided HF, systemic hypertension, and secondary erythrocytosis. Central sleep apnea is less prevalent in the general population. It may be an isolated finding or may occur in patients with HF, stroke with brainstem lesions, and opioid medication use.

Javaheri S et al. Central sleep apnea: pathophysiologic classification. Sleep. 2023;46:zsac113. [PMID: 35551411]

OBSTRUCTIVE SLEEP APNEA

ESSENTIALS OF DIAGNOSIS

- Daytime somnolence or fatigue.
- A history of loud snoring with witnessed apneic events.
- Overnight polysomnography demonstrating apneic episodes with hypoxemia.

General Considerations

Upper airway obstruction during sleep occurs when loss of normal pharyngeal muscle tone allows the pharynx to collapse passively during inspiration. Patients with anatomically narrowed upper airways (eg, micrognathia, macroglossia, obesity, tonsillar hypertrophy) are predisposed to the development of obstructive sleep apnea. Ingestion of alcohol or sedatives before sleeping or nasal obstruction of any type, including the common cold, may precipitate or worsen the condition. Hypothyroidism and cigarette smoking are additional risk factors for obstructive sleep apnea. Before making the diagnosis of obstructive sleep apnea, a drug history should be obtained; a seizure disorder, narcolepsy, and depression should be excluded.

Clinical Findings

A. Symptoms and Signs

Most patients with obstructive or mixed sleep apnea are middle-aged men with obesity. Arterial hypertension is common. Patients may report excessive daytime somnolence, morning sluggishness and headaches, daytime fatigue, cognitive impairment, recent weight gain, and impotence. Bed partners usually report loud cyclical snoring, breath cessation, witnessed apneas, restlessness, choking or gasping for air, and thrashing movements of the extremities during sleep. Personality changes, poor judgment, work-related problems, depression, and intellectual deterioration (memory impairment, inability to concentrate) may also be observed. The USPSTF does not recommend screening asymptomatic adults for sleep apnea.

Physical examination may be normal and includes a comprehensive assessment of BMI, neck circumference, and anatomy of craniofacial and upper airway structures. The patient may appear sleepy or even fall asleep during the evaluation. The oropharynx is frequently found to be narrowed by excessive soft tissue folds, large tonsils, elongated uvula, Mallampati class IV, or macroglossia. Nasal obstruction by a deviated nasal septum, poor nasal airflow, and a nasal twang to the speech may be observed. A "bull neck" appearance is common.

B. Laboratory Findings

Erythrocytosis is common. Thyroid function tests (serum TSH, FT_4) should be obtained to exclude hypothyroidism.

C. Other Studies

Observation of the sleeping patient may reveal loud snoring interrupted by episodes of increasingly strong respiratory effort that fail to produce airflow. A loud snort often accompanies the first breath following an apneic episode. Definitive diagnostic evaluation for suspected sleep apnea includes otorhinolaryngologic examination and overnight polysomnography (the monitoring of multiple physiologic factors during sleep). A complete **polysomnography** examination includes electroencephalography, electro-oculography, electromyography, ECG, pulse oximetry, and measurement of respiratory effort and airflow. Home sleep studies are best performed in patients without cardiorespiratory disease and a moderate to high pretest probability of obstructive sleep apnea. While some home studies cannot quantify the stages of sleep, they can provide a reliable index of respiratory and desaturation events. Obstructive sleep apnea is determined by the calculated apnea hypopnea index. Treatment is considered if the calculated apnea hypopnea index is above five events per hour with sleep symptoms or above 15 events per hour without symptoms.

Treatment

Weight loss with obesity management is an important strategy, recognized as part of the comprehensive management of obstructive sleep apnea. Incretins, hormones that regulate blood glucose levels, such as tirzepatide, a dual GLP-1 and glucose-dependent insulinotropic polypeptide (GIP) receptor agonist, resulted in approximately 16–17% weight loss compared with placebo and were accompanied by a reduction in apnea hypopnea index. **Continuous positive airway pressure (CPAP)** at night is curative in many patients. Auto-titrating airway pressure machines (APAP) allow a range of pressures (5–20 cm H_2O) that auto-adjust based on airflow obstruction. Unfortunately, CPAP adherence is suboptimal, and only 75% of patients continue to use nasal CPAP after 1 year. Supplemental oxygen may lessen the severity of nocturnal desaturation but may also lengthen apneas; it should not be routinely prescribed for treatment of obstructive sleep apnea. An **oral mandibular device** (mandibular repositioning device) at bedtime to hold the jaw forward and prevent pharyngeal occlusion is as effective as CPAP for treatment of mild to moderate obstructive sleep apnea.

Hypoglossal nerve stimulation can be an option for selected patients with moderate to severe obstructive sleep apnea (apnea hypopnea index between 15–100 events/hour) who do not tolerate or respond to CPAP. Patients are eligible who have absence of complete concentric collapse of the airway during drug-induced sleep endoscopy, BMI ≤ 35 (FDA recently approved for BMI < 40), and 25% respiratory events are due to central apneas.

Uvulopalatopharyngoplasty (UPPP), a procedure consisting of resection of pharyngeal soft tissue and amputation of approximately 15 mm of the free edge of the soft palate and uvula, is helpful in approximately 50% of selected patients. It is more effective in eliminating snoring than apneic episodes. **Nasal septoplasty** is performed if gross anatomic nasal septal deformity is present and may improve with adherence to CPAP therapy as opposed to improving apnea hypopnea index. **Tracheostomy** relieves upper airway obstruction and its physiologic consequences and represents the definitive treatment for obstructive sleep apnea. However, it has numerous adverse effects, including granuloma formation, difficulty with speech, and stoma and airway infection.

ACUTE RESPIRATORY FAILURE

Respiratory failure is defined as respiratory dysfunction resulting in abnormalities of oxygenation or ventilation (Co_2 elimination) severe enough to threaten the function of vital organs. ABG criteria for respiratory failure are not absolute but may be arbitrarily established as a Po_2 < 60 mm Hg (7.8 kPa) or a Pco_2 > 50 mm Hg (6.5 kPa). Acute respiratory failure may occur in a variety of pulmonary and nonpulmonary disorders (Table 9–24). Only a few selected general principles of management will be reviewed here.

Clinical Findings

Symptoms and signs of acute respiratory failure are those of the underlying disease combined with those of hypoxemia or hypercapnia. The chief symptom of hypoxemia is dyspnea, though profound hypoxemia may exist in the absence

Table 9–24. Selected causes of acute respiratory failure in adults.

- **Airway disorders**
  - Asthma
  - Acute exacerbation of chronic bronchitis or emphysema
  - Obstruction of pharynx, larynx, trachea, mainstem bronchus, or lobar bronchus by edema, mucus, mass, or foreign body
- **Pulmonary edema**
  - Increased hydrostatic pressure
    - LV dysfunction (eg, myocardial ischemia, HF)
    - Mitral regurgitation
    - Left atrial outflow obstruction (eg, mitral stenosis)
    - Volume overload states
  - Increased pulmonary capillary permeability
    - Acute respiratory distress syndrome
    - Acute lung injury
  - Unclear etiology
    - Neurogenic
    - Negative pressure (inspiratory airway obstruction)
    - Re-expansion
    - Tocolytic-associated
- **Parenchymal lung disorders**
  - Pneumonia
  - Interstitial lung diseases
  - Diffuse alveolar hemorrhage syndromes
  - Aspiration
  - Lung contusion
- **Pulmonary vascular disorders**
  - Thromboembolism
  - Air embolism
  - Amniotic fluid embolism
- **Chest wall, diaphragm, and pleural disorders**
  - Rib fracture
  - Flail chest
  - Pneumothorax
  - Pleural effusion
  - Massive ascites
  - Abdominal distention and abdominal compartment syndrome
- **Neuromuscular and related disorders**
  - Primary neuromuscular diseases
    - Guillain-Barré syndrome
    - Myasthenia gravis
    - Poliomyelitis
    - Polymyositis
  - Drug- or toxin-induced
    - Botulism
    - Organophosphates
    - Neuromuscular blocking agents
    - Aminoglycosides
  - Spinal cord injury
  - Phrenic nerve injury or dysfunction
  - Electrolyte disturbances
    - Hypokalemia
    - Hypophosphatemia
  - Myxedema
- **CNS disorders**
  - Drugs: sedatives, hypnotics, opioids, anesthetics
  - Brainstem respiratory center disorders: trauma, tumor, vascular disorders, hypothyroidism
  - Intracranial hypertension
  - CNS infections
- **Increased CO_2 production**
  - Fever
  - Infection
  - Hyperalimentation with excess caloric and carbohydrate intake
  - Hyperthyroidism
  - Seizures
  - Rigors
  - Drugs

of symptoms. Signs of hypoxemia include cyanosis, restlessness, confusion, anxiety, delirium, tachypnea, bradycardia or tachycardia, hypotension or hypertension, cardiac dysrhythmias, and tremor. Dyspnea and headache are the cardinal symptoms of hypercapnia. Signs of hypercapnia include peripheral and conjunctival hyperemia, hypertension, tachycardia, tachypnea, impaired consciousness, papilledema, myoclonus, and asterixis. The symptoms and signs of acute respiratory failure are both insensitive and nonspecific; therefore, the clinician must maintain a high index of suspicion and obtain ABG analysis if respiratory failure is suspected.

Treatment

Treatment of the patient with acute respiratory failure consists of (1) specific therapy directed toward the underlying disease, (2) respiratory supportive care directed toward the maintenance of adequate gas exchange, and (3) general supportive care. Only the last two aspects are discussed below.

A. Respiratory Support

Respiratory support has both nonventilatory and ventilatory aspects.

1. Nonventilatory aspects—The main therapeutic goal in acute hypoxemic respiratory failure is to ensure adequate oxygenation of vital organs. Inspired oxygen concentration should be the lowest value that results in an arterial hemoglobin saturation of 88% (Po_2 55 mm Hg or 7.3 kPa) or more. Higher arterial oxygen tensions are of no proven benefit and may be deleterious. Restoration of normoxemia may rarely cause hypoventilation in patients with chronic hypercapnia; however, oxygen therapy should not be withheld for that concern. Hypoxemia in patients with obstructive airway disease is usually easily corrected by administering low-flow oxygen by nasal cannula (1–3 L/min) or Venturi mask (24–40%). Higher concentrations of oxygen are necessary to correct hypoxemia in patients with ARDS, pneumonia, and other parenchymal lung diseases. Humidified, high-flow nasal cannulae provide adjustable oxygen delivery and flow-dependent clearance of carbon dioxide from the upper airway, resulting in reduced work of breathing and better matching of respiratory demand during respiratory distress. In hypoxemia due to acute respiratory failure, oxygenation with use of humidified, high-flow nasal cannulae has been shown to be similar and, in some cases, superior to conventional low-flow oxygen supplementation and noninvasive positive-pressure ventilation (NIPPV); however, the use of high-flow nasal cannulae has no impact on mortality, and the impact on intubation rates, length of stay, dyspnea, and comfort are uncertain.

2. Ventilatory aspects—Ventilatory support consists of maintaining patency of the airway and ensuring adequate alveolar ventilation. Mechanical ventilation may be provided via mask (noninvasive) or through tracheal intubation.

A. NONINVASIVE POSITIVE-PRESSURE VENTILATION—NIPPV delivered via a full-face mask or nasal mask is first-line therapy in COPD patients with hypercapnic respiratory failure who can protect and maintain the patency of their airway, handle their own secretions, and tolerate the mask apparatus. Several studies have demonstrated the effectiveness of this therapy in reducing intubation rates and ICU stays in patients with ventilatory failure. A bilevel positive-pressure ventilation mode is preferred for most patients. Patients with acute lung injury or ARDS or those who suffer from severely impaired oxygenation are less likely to benefit and should be intubated if they require mechanical ventilation.

B. Tracheal intubation—Indications for tracheal intubation include (1) hypoxemia despite supplemental oxygen; (2) upper airway obstruction; (3) impaired airway protection; (4) inability to clear secretions; (5) respiratory acidosis; (6) progressive general fatigue, tachypnea, use of accessory respiratory muscles, or mental status deterioration; and (7) apnea. Patients in respiratory failure who undergo a trial of NIPPV and do not improve within 30–90 minutes should be intubated. In general, orotracheal intubation is preferred to nasotracheal intubation in urgent or emergency situations because it is easier, faster, and less traumatic. The tip of the endotracheal tube should be positioned 2–4 cm above the carina and be verified by CXR immediately following intubation. Only tracheal tubes with high-volume, low-pressure air-filled cuffs should be used. Cuff inflation pressure should be kept < 20 mm Hg, if possible, to minimize tracheal mucosal injury.

C. Mechanical ventilation—Indications for mechanical ventilation include (1) apnea, (2) acute hypercapnia that is not quickly reversed by appropriate specific therapy, (3) severe hypoxemia, and (4) progressive patient fatigue despite appropriate treatment.

Several modes of positive-pressure ventilation are available. Controlled mechanical ventilation (CMV; also known as assist-control [A-C]) and synchronized intermittent mandatory ventilation (SIMV) are ventilatory modes in which the ventilator delivers a minimum number of breaths of a specified pattern (either a set volume or a set pressure) each minute. In both CMV and SIMV, the patient may trigger the ventilator to deliver additional breaths. Numerous alternative modes of mechanical ventilation now exist, the most popular being pressure support ventilation (PSV), proportional-assist ventilation, and CPAP.

Positive end-expiratory pressure (PEEP) is useful in improving oxygenation in patients with diffuse parenchymal lung disease, such as ARDS. It should be used cautiously in patients with localized parenchymal disease, emphysema, hyperinflation, or very high airway pressure requirements during mechanical ventilation.

D. Complications of mechanical ventilation—Potential complications of mechanical ventilation are numerous. Migration of the tip of the endotracheal tube into a main bronchus can cause atelectasis of the contralateral lung and overdistention of the intubated lung. Barotrauma refers to rupture and loss of integrity of the alveolar space secondary to high transmural pressures applied during positive-pressure ventilation. Barotrauma is manifested by subcutaneous emphysema, pneumomediastinum, subpleural air cysts, pneumothorax, or systemic gas embolism. Volutrauma is sometimes used to refer to subtle parenchymal injury due to overdistention of alveoli from excessive tidal volumes without alveolar rupture, mediated through inflammatory rather than physical mechanisms. The principal strategy to avoid volutrauma is the use of low tidal volume ventilation (a tidal volume of 6 mL/kg of ideal body weight is supported by the ARDS literature).

Acute respiratory alkalosis caused by overventilation is common. Hypotension induced by elevated intrathoracic pressure that results in decreased return of systemic venous blood to the heart may occur in patients treated with PEEP, particularly those with intravascular volume depletion, and in patients with severe airflow obstruction at high respiratory rates that promote dynamic hyperinflation (“breath stacking”). Ventilator-associated pneumonia is another serious complication of mechanical ventilation.

B. General Supportive Care

Hypokalemia and hypophosphatemia may worsen hypoventilation due to respiratory muscle weakness. Sedative-hypnotics and opioid analgesics should be titrated carefully to avoid oversedation and delirium, leading to prolongation of intubation. Temporary paralysis with a nondepolarizing neuromuscular blocking agent is used to facilitate mechanical ventilation and to lower oxygen consumption. Prolonged muscle weakness due to an acute myopathy is a potential complication of these agents.

Psychological and emotional support of the patient and family, skin care to avoid pressure injuries, and meticulous avoidance of health care–associated infection and complications of endotracheal tubes are vital aspects of comprehensive care for patients with acute respiratory failure.

Attention must also be paid to preventing complications associated with serious illness. The risk of DVT and PE may be reduced by subcutaneous administration of heparin or low-molecular-weight heparin (LMWH) (see Table 16–14), or placement of sequential compression devices on the lower extremities.

▶ Course & Prognosis

The course and prognosis of acute respiratory failure vary and depend on the underlying disease. The prognosis of acute respiratory failure caused by uncomplicated sedative or opioid overdose is excellent. Acute respiratory failure in patients with COPD who do not require intubation, and mechanical ventilation has a good immediate prognosis. On the other hand, ARDS and respiratory failure associated with sepsis have a poor prognosis.

Munshi L et al. Noninvasive respiratory support for adults with acute respiratory failure. N Engl J Med. 2022;387:1688. [PMID: 36322846]

ACUTE RESPIRATORY DISTRESS SYNDROME

ESSENTIALS OF DIAGNOSIS

- Onset of respiratory distress, often progressing to respiratory failure, within 7 days of a clinical insult.
- New, bilateral radiographic pulmonary opacities not explained by pleural effusion, atelectasis, or nodules.
- Respiratory failure not fully explained by HF or volume overload.
- Impaired oxygenation, with ratio of partial pressure of oxygen in arterial blood (Pao_2) to fractional concentration of inspired oxygen (Fio_2) < 300 mm Hg, with PEEP ≥ 5 cm H_2O.

General Considerations

Acute respiratory distress syndrome (ARDS) as a clinical syndrome is based on three inclusion criteria plus one exclusion criterion, as detailed above. The severity of ARDS is based on the level of oxygenation impairment: **mild**, Pao_2/Fio_2 ratio of 200–300 mm Hg; **moderate**, Pao_2/Fio_2 ratio of 100–200 mm Hg; and **severe**, Pao_2/Fio_2 ratio < 100 mm Hg.

ARDS may follow a wide variety of clinical events (Table 9–25). Common risk factors for ARDS include sepsis, aspiration of gastric contents, shock, infection, lung contusion, nonthoracic trauma, toxic inhalation, near-drowning, and multiple blood transfusions. About one-third of patients with ARDS initially have sepsis syndrome. Damage to capillary endothelial cells and alveolar epithelial cells is common to ARDS regardless of cause or mechanism of lung injury and results in increased vascular permeability and decreased production and activity of surfactant. These abnormalities in turn lead to interstitial and alveolar pulmonary edema, alveolar collapse, and hypoxemia.

Table 9–25. Selected disorders associated with ARDS.

Systemic Insults	Pulmonary Insults
Trauma Sepsis Pancreatitis Shock Multiple transfusions Disseminated intravascular coagulation Burns Drugs and drug overdose Opioids Aspirin Phenothiazines Tricyclic antidepressants Amiodarone Chemotherapeutic agents Nitrofurantoin Protamine Thrombotic thrombocytopenic purpura Cardiopulmonary bypass Head injury Paraquat	Aspiration of gastric contents Embolism of thrombus, fat, air, or amniotic fluid Miliary tuberculosis Diffuse pneumonia (eg, SARS, COVID-19) Acute eosinophilic pneumonia Cryptogenic organizing pneumonitis Upper airway obstruction Free-base cocaine smoking Near-drowning Toxic gas inhalation Nitrogen dioxide Chlorine Sulfur dioxide Ammonia Smoke Oxygen toxicity Lung contusion Radiation exposure High-altitude exposure Lung re-expansion or reperfusion

ARDS, acute respiratory distress syndrome; SARS, severe acute respiratory syndrome.

Clinical Findings

ARDS is marked by the rapid onset of profound dyspnea that usually occurs 12–48 hours after the initiating event. Labored breathing, tachypnea, intercostal retractions, and crackles are noted on physical examination. CXR shows diffuse or patchy bilateral infiltrates that rapidly become confluent; these characteristically spare the costophrenic angles. Air bronchograms occur in about 80% of cases. Heart size is usually normal, and pleural effusions are small or nonexistent. Marked hypoxemia occurs that is refractory to treatment with supplemental oxygen. Many patients with ARDS demonstrate multiple organ failure, particularly involving the kidneys, liver, gut, CNS, and cardiovascular system.

Differential Diagnosis

Since ARDS is a physiologic and radiographic syndrome rather than a specific disease, the concept of differential diagnosis does not strictly apply. Normal-permeability ("cardiogenic" or hydrostatic) pulmonary edema must be excluded because specific therapy is available for that disorder. Diffuse alveolar hemorrhage, inflammatory or autoimmune causes, and bilateral pneumonia should be excluded. Emergent echocardiogram or measurement of pulmonary capillary wedge pressure by means of a flow-directed pulmonary artery catheter may be required in selected patients with suspected cardiac dysfunction; however, routine use in ARDS is discouraged.

Prevention

No measures that effectively prevent ARDS have been identified. Specifically, neither PEEP, prophylactic aspirin, nor intravenous methylprednisolone prevents ARDS when given early to patients with sepsis syndrome or septic shock.

Treatment

The first principle in management is to identify and treat the primary condition that has led to ARDS. Meticulous supportive care must then be provided to compensate for the severe dysfunction of the respiratory system associated with ARDS and to prevent complications.

Treatment of the hypoxemia seen in ARDS usually requires tracheal intubation and positive-pressure mechanical ventilation. The lowest levels of PEEP (used to recruit atelectatic alveoli) and supplemental oxygen required to maintain the Pao_2 > 55 mm Hg (7.13 kPa) or the $Sa_{O_2} > 88\%$ should be used. Efforts should be made to decrease F_{IO_2} as soon as possible to avoid oxygen toxicity. PEEP can be increased as needed if cardiac output and oxygen delivery do not decrease and airway pressures do not increase excessively (ie, plateau pressures remain below 30 cm H_2O). Prone positioning frequently improves oxygenation by helping recruit atelectatic alveoli and has been shown in some trials to provide a mortality benefit in severe ARDS. Routine use of neuromuscular blockade is controversial; one major trial showed improved mortality but a subsequent trial (intended to be confirmatory) did not.

A variety of mechanical ventilation strategies are available. Over the past 20 years, the recognition of the potential for excessive alveolar stretch to cause lung injury has led to widespread adoption of low tidal volume ventilation. A multicenter study of 800 patients demonstrated that a protocol using volume-control ventilation with low tidal volumes (6 mL/kg of ideal body weight) resulted in an 8.8% absolute mortality reduction over therapy with standard tidal volumes (defined as 12 mL/kg of ideal body weight). Varying ventilator modes have been used; conventional modes of ventilation are essentially equivalent, while high-frequency oscillatory ventilation should not be used an as initial mode.

Approaches to hemodynamic monitoring and fluid management in patients with acute lung injury have been carefully studied. Based on a prospective RCT comparing hemodynamic management guided either by a pulmonary artery catheter or a central venous catheter, a pulmonary artery catheter should not be routinely used for the management of acute lung injury. A subsequent randomized, prospective clinical study of restrictive fluid intake and diuresis as needed to maintain CVP < 4 mm Hg or pulmonary artery occlusion pressure < 8 mm Hg (conservative strategy group) versus a fluid management protocol to target a CVP of 10–14 mm Hg or a pulmonary artery occlusion pressure 14–18 mm Hg (liberal strategy group) showed that patients in the conservative strategy group experienced faster improvement in lung function and spent significantly fewer days on mechanical ventilation and in the ICU without an improvement in death by 60 days or worsening nonpulmonary organ failure at 28 days. Oxygen delivery can be increased in anemic patients by ensuring that the hemoglobin concentration is at least 7 g/dL (70 g/L); patients are not likely to benefit from higher levels.

Numerous innovative therapeutic interventions to improve outcomes in ARDS patients have been or are being investigated. Unfortunately, to date, none has consistently shown benefit in clinical trials. The 2024 American Thoracic Society (ATS) guidelines on ARDS recommend the use of corticosteroids for ARDS patients as a conditional recommendation with moderate certainty of evidence, highlighting their potential to reduce mortality and possibly reduce hospital stay and duration of mechanical ventilation while acknowledging the need for patient-specific considerations where corticosteroids are most effective in < 14 days of ARDS, in severe community-acquired pneumonia, or in COVID-19 patients.

Another therapeutic intervention is extracorporeal membrane oxygenation (ECMO). A 2018 trial comparing the early use of ECMO in very severe ARDS with conventional strategies built on low-tidal-volume ventilation failed to show a difference in 60-day mortality; however, 28% of the control group crossed over to receive ECMO. ECMO seems unlikely to become a standard first-line therapy but is likely to remain a salvage option for patients with very severe ARDS.

Course & Prognosis

ARDS mortality with low tidal volume ventilation is around 30%. The major causes of death are the primary illness and secondary complications, such as multiple organ system failure or sepsis. Many patients who die of ARDS and its complications die after withdrawal of mechanical ventilation (see Chapter 5). Mortality of ARDS in community hospitals continues to be higher than at academic hospitals, possibly because community hospitals still have not adopted low tidal volume ventilation.

Different clinical syndromes that lead to ARDS carry different prognoses. For example, patients with trauma-associated ARDS have better prognosis, with a mortality rate close to 20%, whereas those with end-stage liver disease have an 80% mortality rate. A hyperinflammatory phenotype associated with high levels of IL-6 and soluble TNF receptor in ARDS patients precipitated by sepsis is associated with more multiorgan dysfunction and higher mortality.

Failure to improve in the first week of treatment is a poor prognostic sign, although this may not be true of ARDS from certain etiologies, including COVID-19. Persons who have been impacted by ARDS tend to be young and pulmonary function generally recovers over 6–12 months, although residual abnormalities often remain, including restrictive or obstructive defects, low diffusion capacity, and impaired gas exchange with exercise. These persons also have diminished health-related and pulmonary disease–specific quality of life as well as systemic effects, such as muscle wasting, weakness, and fatigue.

LUNG TRANSPLANTATION

Introduction

Lung transplantation is a therapeutic option for patients with end-stage lung disease who have not responded to other therapies. The full topic is beyond the scope of this text; therefore, only issues related to candidate selection and post-transplant care will be discussed.

Candidate Selection

Patients should be considered for lung transplantation if they have advanced, progressive lung disease despite appropriate medical therapy. The most common indications are interstitial lung disease, COPD, cystic fibrosis, and pulmonary arterial hypertension. The International Society of Heart and Lung Transplantation has produced guidelines for candidate selection; broadly speaking, the ideal candidate has a high (> 50%) risk of dying within 2 years without lung transplantation, has minimal other comorbidities, is very likely to survive transplantation, and has good social support. Contraindications are numerous and include obesity, active smoking or substance abuse, uncontrolled infection, active malignancy, significant organ dysfunction (eg, cirrhosis, CKD, HF, non-revascularizable coronary disease), and medical noncompliance. Each transplant center has a slightly different selection process; however, common practice includes a detailed multidisciplinary evaluation. Patients should ideally be referred to transplant centers before the need for transplantation is emergent.

Care After Transplantation

As with other solid organ transplantation, care of the post–lung transplant patient is particularly concerned with immunosuppression and prophylaxis against infection, as well as with management of the side effects of immunosuppression. Most patients are immunosuppressed with a combination of a calcineurin inhibitor (eg, tacrolimus), a cell-cycle inhibitor (eg, mycophenolate mofetil), and glucocorticoids. Most centers screen for rejection with regular PFTs as well as bronchoscopies and biopsies, particularly in the first 1–2 years after transplantation.

Common complications include acute cellular rejection (treated with intensified immunosuppression), infection, chronic rejection (for which few effective treatments exist), and sequelae of immunosuppression. These include hypertension, dyslipidemia, diabetes mellitus, CKD, osteopenia/osteoporosis, and increased risk of malignancy, especially skin cancers. Post-transplant care thus necessitates close cooperation between the patient's transplant team and his or her other physicians.

Outcomes After Transplantation

While lung transplantation can be transformative for those living with advanced lung disease, long-term survival remains limited to those receiving kidney or liver transplants. As of the 2021 International Society of Heart and Lung Transplantation Report, median survival after lung transplantation was approximately 7 years. Survival is affected by many variables; two consistent findings have been that survival is improved in double (versus single) lung transplant patients, and in those transplanted for cystic fibrosis (versus other indications).

Coronary Artery Disease, Valvular Disease, & Other Key Topics in Cardiology

10

Todd Kiefer, MD

ADULT CONGENITAL HEART DISEASE

In the United States, there are many more adults with congenital heart disease than children, with an estimated 2 million adults in the United States surviving with congenital heart disease. In 2018, the American College of Cardiology (ACC) and American Heart Association (AHA) released updated guidelines for the assessment and treatment of patients with adult congenital heart disease. The European Society of Cardiology (ESC) completed their update on the same topic in 2020. As the number of patients with adult congenital heart disease has grown, there has been an increased appreciation of the need for more training and guidelines. A specific subspecialty board and training program has been established.

Baumgartner H et al. 2020 ESC Guidelines for the management of adult congenital heart disease. Eur Heart J. 2021;42:563. [PMID: 32860028]

PULMONARY VALVE STENOSIS

ESSENTIALS OF DIAGNOSIS

- Severe cases may present with right-sided HF.
- P_2 delayed and soft or absent.
- Pulmonary ejection click often present and decreases with inspiration—the only right heart sound that *decreases* with inspiration; all other right heart sounds increase.
- Echocardiography/Doppler is diagnostic.
- Patients with peak pulmonic valve gradient > 64 mm Hg or a mean of 35 mm Hg by echocardiography/Doppler should undergo intervention regardless of symptoms. Otherwise, operate for symptoms or evidence for RV dysfunction.

General Considerations

Stenosis of the pulmonary valve or RV infundibulum increases the resistance to RV outflow, raises the RV pressure, and limits pulmonary blood flow. Pulmonic stenosis is often congenital and associated with other cardiac lesions. Pulmonary blood flow preferentially goes to the left lung in valvular pulmonic stenosis. In the absence of associated shunts, arterial saturation is normal. Peripheral pulmonic stenosis can accompany valvular pulmonic stenosis and may be part of a variety of clinical syndromes, including the congenital rubella syndrome. Patients who have had the **Ross procedure** for aortic valve disease (transfer of the pulmonary valve to the aortic position with a homograft pulmonary valve placed in the pulmonary position) may experience noncongenital postoperative pulmonic valvular or main pulmonary artery (PA) stenosis due to an immune response in the homograft. RV outflow obstructions can also occur when there is a conduit from the RV to the PA that becomes stenotic from degenerative changes over time or when there is degeneration of a bioprosthetic replacement pulmonary valve.

Clinical Findings

A. Symptoms and Signs

Mild cases of pulmonic stenosis are asymptomatic; moderate to severe pulmonic stenosis may cause symptoms of dyspnea on exertion, syncope, chest pain, and eventually RV failure.

On examination, there is often a palpable parasternal lift due to RVH and the pulmonary outflow tract may be palpable if the PA is enlarged. A loud, harsh systolic murmur and occasionally a prominent thrill are present in the left second and third interspaces parasternally. The murmur radiates toward the left shoulder due to the flow pattern within the main PA and increases with inspiration. In mild to moderate pulmonic stenosis, a loud ejection click can be heard to precede the murmur; this sound decreases with inspiration as the increased RV filling from inspiration prematurely opens the valve during atrial systole when inspiratory increased blood flow to the right heart occurs. The valve excursion during systole is thus less with inspiration than with expiration, and the click is therefore less audible with inspiration. *This is the only right-sided auscultatory event that decreases with inspiration.* All of the other auscultatory events increase with the increased right heart output that occurs with inspiration. In severe pulmonic stenosis, the second sound is obscured by the murmur and the pulmonary component of S_2 may be diminished, delayed, or absent. A right-sided S_4 and a prominent *a* wave in the venous pulse are present when there is RV diastolic dysfunction or a *c-v* wave may be observed in the jugular venous pressure if tricuspid regurgitation is present. Pulmonary valve regurgitation is relatively uncommon in primary pulmonic stenosis and may be very difficult to hear, as the gradient between the reduced PA diastolic pressure and the elevated RV diastolic pressure may be quite small (low-pressure pulmonary valve regurgitation).

B. ECG and Chest Radiography

Right axis deviation or RVH is noted; peaked P waves provide evidence of right atrial (RA) overload. Heart size may be normal on radiographs, or there may be a prominent RV and RA or gross cardiac enlargement, depending on the severity. There is often poststenotic dilation of the main and left pulmonary arteries. Pulmonary vascularity is usually normal, although there tends to be preferential flow to the left lung.

C. Diagnostic Studies

Echocardiography/Doppler is the diagnostic tool of choice, can provide evidence for a doming valve versus a dysplastic valve, can determine the gradient across the valve, and can provide information regarding subvalvular obstruction and the presence or absence of tricuspid or pulmonic valvular regurgitation. Grading the severity of pulmonic stenosis is based on the peak or mean gradient by echocardiography/Doppler (see Table 10–1). A lower gradient may be significant if there is RV dysfunction. Catheterization is usually unnecessary for the diagnosis; it should be used only if the data are unclear or in preparation for either percutaneous intervention or surgery.

Prognosis & Treatment

Patients with mild pulmonic stenosis have a normal life span with no intervention. Moderate stenosis may be asymptomatic in childhood and adolescence, but symptoms often appear as patients grow older. The degree of stenosis does worsen with time in a few patients, so serial follow-up is important. Severe stenosis is rarely associated with sudden death but can cause right HF in patients as early as in their 20s and 30s. Pregnancy and exercise tend to be well tolerated except in severe stenosis.

Table 10–1. Severity of pulmonary valve stenosis.

Mild	Moderate	Severe
Peak velocity < 3 m/sec Peak gradient < 36 mm Hg	Peak velocity 3–4 m/sec Peak gradient 36–64 mm Hg	Peak velocity > 4 m/sec Peak gradient > 64 mm Hg

Adapted from J Am Coll Cardiol. 2019;73:e81.

The AHA/ACC guidelines and the ESC guidelines generally agree, though the ESC suggests severe pulmonic stenosis should be considered if the RV systolic pressure is > 80 mm Hg. Class I (definitive) indications for intervention include all symptomatic patients and all those with a resting peak-to-peak gradient > 64 mm Hg or a mean > 35 mm Hg, regardless of symptoms. Symptoms can include cyanosis due to right-to-left shunting via a patent foramen ovale (PFO) or atrial septal defect (ASD). **Percutaneous balloon valvuloplasty** is highly successful in domed valve patients and is the treatment of choice. **Surgical commissurotomy** can also be done, or pulmonary **valve replacement** (with either a bioprosthetic valve or homograft) when pulmonary valve regurgitation is too severe or the valve is dysplastic. Pulmonary outflow tract obstruction due to RV to PA conduit obstruction or to homograft pulmonary valve stenosis can often be relieved with a percutaneously implanted pulmonary valve (both the Medtronic Melody valve and the Edwards SAPIEN XT valve are FDA-approved). Frequently the seating of these valves is facilitated by placing a stent within the PA first, then the transcatheter device within this stent. Because the new catheter valve may result in compression of the coronary artery, *it is a class I requirement to assess the effect of the device on the coronary by use of a temporary balloon inflation prior to delivery of the device.* Percutaneous pulmonary valve replacement is also FDA-approved for those with conduit stenosis or following the Ross procedure. Percutaneous valve replacements have also been performed off-label for patients with native pulmonary valve disease, including those who have had tetralogy of Fallot repair (assuming the PA root size is small enough to seat a percutaneous valve).

Endocarditis prophylaxis is *unnecessary* for native valves even after valvuloplasty unless there has been prior pulmonary valve endocarditis (an unusual occurrence). It should be used if surgical or percutaneous valve replacement has occurred. Research has shown infective endocarditis following transcatheter pulmonary valve replacement occurs in 9.5% of cases at 5 years and 16.9% of cases at 8 years. However, multivariate analysis did not show an association between infective endocarditis and specific transcatheter valve type.

When to Refer

All symptomatic patients (regardless of gradient) and all asymptomatic patients whose peak pulmonary valve gradient is > 64 mm Hg or whose mean gradient is > 35 mm Hg should be referred to a cardiologist with expertise in adult congenital heart disease. Patients also require intervention if cyanosis occurs due to a PFO or ASD or if there is exercise intolerance.

McElhinney DB et al. Multicenter study of endocarditis after transcatheter pulmonary valve replacement. J Am Coll Cardiol. 2021;78:575. [PMID: 34353535]

COARCTATION OF THE AORTA

ESSENTIALS OF DIAGNOSIS

- Usual presentation is systemic hypertension.
- Echocardiography/Doppler is diagnostic; a peak gradient of > 20 mm Hg may be significant due to collaterals around the coarctation reducing gradient despite severe obstruction.
- Associated bicuspid aortic valve in 50–80% of patients.
- Delayed pulse in femoral artery compared to brachial artery.
- Systolic pressure is higher in upper extremities than in lower extremities; diastolic pressures are similar.

General Considerations

Coarctation of the aorta consists of localized narrowing of the aortic arch just distal to the origin of the left subclavian artery. If the stenosis is severe, collateral circulation develops around the coarctation site through the intercostal arteries and the branches of the subclavian arteries and can result in a lower trans-coarctation gradient by enabling blood flow to bypass the obstruction. *Coarctation is a cause of secondary hypertension and should be considered in young patients with elevated blood pressure (BP).* The renin-angiotensin system is often abnormal, however, and contributes to the hypertension occasionally seen even after coarctation repair. A bicuspid valve is seen in approximately 50–80% of the cases, and there is an increased incidence of cerebral berry aneurysms. Significant native or recurrent aortic coarctation has been defined as follows: upper extremity/lower extremity resting peak-to-peak gradient > 20 mm Hg or mean Doppler systolic gradient > 20 mm Hg; upper extremity/lower extremity gradient > 10 mm Hg or mean Doppler gradient > 10 mm Hg when there is either decreased LV systolic function or aortic regurgitation; or upper extremity/lower extremity gradient > 10 mm Hg or mean Doppler gradient > 10 mm Hg when there is evidence for collateral flow around the coarctation. This should be coupled with anatomic evidence for coarctation of the aorta, typically defined by advanced imaging (cardiac magnetic resonance, CT angiography). The ESC guidelines have expanded the severity criteria and suggest stenting is appropriate if the patient is normotensive but has a peak gradient of > 20 mm Hg (class IIa) or if the stenosis by angiography is > 50% (class IIb).

Clinical Findings

A. Symptoms and Signs

If cardiac failure does not occur in infancy, there are usually no symptoms until the hypertension produces LV failure. Cerebral hemorrhage, though rare, may occur. Approximately 10% of patients with coarctation of the aorta have intracranial aneurysms identified on magnetic resonance angiography or CT angiography. Increasing age has been identified as a risk factor. Strong arterial pulsations are seen in the neck and suprasternal notch. Hypertension is present in the arms, but the pressure is normal or low in the legs. This difference is exaggerated by exercise. Femoral pulsations are weak and are delayed in comparison with the brachial or radial pulse. A continuous murmur heard superiorly and midline in the back or over the left anterior chest may be present when large collaterals are present and is a clue that the coarctation is severe. The coarctation itself may result in systolic ejection murmurs heard in the left upper lung field anteriorly and near the spine on the left side posteriorly. There may be an aortic regurgitation or stenosis murmur due to an associated bicuspid aortic valve. Coarctation is associated with **Turner syndrome** (a sex chromosomal abnormality [XO]); a webbed neck may be present in these patients.

B. ECG and Chest Radiography

The ECG usually shows LVH. Radiography may show scalloping of the inferior portion of the ribs (**rib notching**) due to enlarged collateral intercostal arteries. Dilation of the left subclavian artery and poststenotic aortic dilation along with LV enlargement may be present. The coarctation region and the poststenotic dilation of the descending aorta may result in a **"3" sign** along the aortic shadow on the PA CXR (the notch in the "3" representing the area of coarctation).

C. Diagnostic Studies

Echocardiography/Doppler is usually diagnostic and may provide additional evidence for a bicuspid aortic valve. Both MRI and CT can provide excellent images of the coarctation anatomy, and one or the other should always be done to define the coarctation anatomic structure. MRI and echocardiography/Doppler can also provide estimates of the gradient across the lesion. Cardiac catheterization provides definitive gradient information and is obviously necessary if percutaneous stenting is to be considered.

Prognosis & Treatment

Cardiac failure is common in infancy and in older untreated patients when the coarctation is severe. Patients with a demonstrated peak gradient of > 20 mm Hg should be considered for intervention, especially if there is evidence of collateral blood vessels. As noted above, the ESC guidelines incorporate the stenosis severity (> 50%) as defining severe coarctation as well. Many untreated patients with severe coarctation die of hypertension, rupture of the aorta, infective endarteritis, or cerebral hemorrhage before the age of 50. Aortic dissection also occurs with increased frequency. Coarctation of any significance may be poorly tolerated in pregnancy because of the inability to support the placental flow.

Resection of the coarctation site has a surgical mortality rate of 1–4% and includes risk of spinal cord injury. The percutaneous interventional procedure of choice is

endovascular stenting; when anatomically feasible, self-expanding and balloon-expandable covered stents have been shown to be advantageous over bare metal stents. These covered stents are FDA-approved. Most coarctation repair in adults is percutaneous. Otherwise, surgical resection (usually with end-to-end anastomosis) should be performed. About 25–50% of surgically corrected patients continue to be hypertensive years after surgery because of permanent changes in the renin-angiotensin system, endothelial dysfunction, aortic stiffness, altered arch morphology, and increased ventricular stiffness. Whether the repair was by balloon dilatation, stenting, or surgical resection may make a difference in the development of hypertension. Recurrence of the coarctation stenosis following intervention requires long-term follow-up.

When to Refer

All patients with aortic coarctation and any detectable gradient should be referred to a cardiologist with expertise in adult congenital heart disease.

ATRIAL SEPTAL DEFECT & PATENT FORAMEN OVALE

ESSENTIALS OF DIAGNOSIS

- Often asymptomatic and discovered on routine physical examination.
- With an ASD and left-to-right shunt: RV lift; S2 widely split and fixed.
- Echocardiography/Doppler is diagnostic.
- ASDs should be closed if there is evidence of an RV volume overload regardless of symptoms.
- A PFO, present in 25% of the population, rarely can lead to paradoxical emboli.

General Considerations

The most common form of ASD (80% of cases) is persistence of the ostium secundum in the mid-septum. A less common abnormality is persistence of the ostium primum (low in the septum). In most patients with an ostium primum defect, there are mitral or tricuspid valve “clefts” as well as a ventricular septal defect (VSD) as part of the atrioventricular (AV) septal defect. A sinus venosus defect is a hole, usually at the upper (or rarely the lower) part of the atrial septum, due to failure of the embryonic superior vena cava or the inferior vena cava to merge with the atria properly. The superior vena cava sinus venosus defect is usually associated with an anomalous connection of the right upper pulmonary vein into the superior vena cava. The coronary sinus ASD is rare and is basically an unroofed coronary sinus that results in shunting from the left atrium (LA) to the coronary sinus and then to the RA.

In all cases, *normally oxygenated blood from the higher-pressure LA shunts into the RA, increasing RV output and pulmonary blood flow.* In children, the degree of shunting across these defects may be quite large (pulmonary to systemic blood flow ratios of 3:1 or so). As the RV compliance worsens from the chronic volume overload, the RA pressure may rise and the degree of left-to-right shunting may decrease over time. Eventually, if the RA pressure exceeds the LA, the shunt may reverse and be primarily right-to-left. When this happens, systemic cyanosis appears. The major factor in the direction of shunt flow is thus the compliance of the respective atrial chambers.

The pulmonary pressures are modestly elevated in most patients with an ASD due to the high pulmonary blood flow, but severe pulmonary hypertension with cyanosis (**Eisenmenger physiology**) is actually unusual, occurring in only about 15% of the patients with an ASD alone. Increased pulmonary vascular resistance (PVR) and pulmonary hypertension secondary to pulmonary vascular disease rarely occur in childhood or young adult life in secundum defects and are more common in primum defects, especially if there is an associated VSD. Eventual RV failure may occur with any atrial shunt of significant size, and most shunts should be corrected unless they are quite small (< 1.5:1 left-to-right shunt). In adults, a large left-to-right shunt may have begun to reverse, so the absolute left-to-right shunt measurement (Qp/Qs, where Qp = pulmonary flow and Qs = systemic flow) at the time the patient is studied may underestimate the original shunt size. In addition, in most people the LV and LA compliance normally declines more over time than the RV and RA compliance; for this reason, the natural history of small atrial septal shunts is to increase the left-to-right shunting as the patient ages. There is generally only trivial shunting with a PFO compared to a true ASD. ASDs predispose to atrial fibrillation due to RA enlargement, and paradoxical right-to-left emboli do occur. If pulmonary hypertension does occur, the 2018 guidelines recommend that the shunt should still be closed as long as the left-to-right shunt is still > 1.5:1 and the systolic PA pressure is less than one-half the systemic arterial pressure and the PVR calculation is less than one-third systemic vascular resistance.

Interestingly, paradoxical emboli may be more common in patients with a PFO than a true ASD, especially when there is an atrial septal aneurysm. An aneurysm of the atrial septum is not a true aneurysm but rather simply a redundancy of the atrial septum that causes it to swing back and forth (> 10 mm). When present with a PFO, the back-and-forth swinging tends to pull open the PFO, encouraging shunting. This may help explain why more right-to-left shunting occurs in patients with an atrial septal aneurysm and PFO than in those with a PFO alone. This creates the anatomic substrate for the occurrence of paradoxical emboli. Other factors may distort the atrial septum (such as an enlarged aorta) and result in an increased shunting in patients with a PFO. Right-to-left PFO shunting may be more prominent upright than supine, creating orthostatic hypoxemia **(platypnea orthodeoxia).** There may also be increased shunting in patients with a PFO and sleep apnea as the RA compliance may worsen during apneic spells when pulmonary pressures increase.

Clinical Findings

A. Symptoms and Signs

Patients with a small or moderate ASD or with a PFO are asymptomatic unless a complication occurs. There is only trivial shunting in a PFO unless the RA pressure increases for some other reason or the atrial septum is distorted. With larger ASD shunts, exertional dyspnea or HF may develop, most commonly in the fourth decade of life or later. Prominent RV and PA pulsations are then readily visible and palpable. A moderately loud systolic ejection murmur can be heard in the second and third interspaces parasternally as a result of increased flow through the pulmonary valve. S_2 is widely split and does not vary with respiration. The left-to-right shunt across the defect decreases with inspiration (as the RA pressure increases) and then increases with expiration (as the RA pressure decreases), thus keeping the RV stroke volume relatively constant in inspiration and expiration. A **"fixed" splitting** of the second sound results. In very large left-to-right shunts, a tricuspid rumble may be heard due to the high flow across the tricuspid valve in diastole.

B. ECG and Chest Radiography

Right axis deviation or RVH may be present depending on the size of the RV volume overload. Incomplete or complete right bundle branch block is present in nearly all cases of ASD, and superior axis deviation (left anterior fascicular block) is noted in the complete AV septal defect, where complete heart block is often seen as well. With sinus venosus defects, the P axis is leftward of +15° due to abnormal atrial activation with loss of the upper RA tissue from around the sinus node. This creates the negative P waves in the inferior leads. The CXR shows large pulmonary arteries, increased pulmonary vascularity, and an enlarged RA and RV as with all pre-tricuspid valve cardiac left-to-right shunts. The LA is not traditionally enlarged due to an ASD shunt because the chamber is being decompressed.

C. Diagnostic Studies

Echocardiography demonstrates evidence of RA and RV volume overload. The atrial defect is usually observed by echocardiography, although sinus venosus defects may be elusive since they are high in the atrial septum. Many patients with a PFO also have an atrial septal aneurysm (defined as > 10-mm excursion of the septum from the static position). Echocardiography with saline injection **(bubble contrast)** can demonstrate the right-to-left component of the shunt, and both pulsed and color flow Doppler flow studies can demonstrate shunting in either direction. In platypnea orthodeoxia, the shunt may primarily result from inferior vena cava blood, and a femoral vein saline injection may be required to demonstrate the shunt. Transesophageal echocardiography (TEE) is helpful when transthoracic echocardiography quality is not optimal because it improves the sensitivity for detection of small shunts and provides a better assessment of PFO or ASD anatomy. Both CT and MRI can elucidate the atrial septal anatomy, better detect multiple fenestrations, and demonstrate associated lesions such as anomalous pulmonary venous connections. Atrial septal anatomy can be complex, and either MRI, TEE, or CT can reveal whether there is an adequate rim around the defect to allow for safe positioning of an atrial septal occluder device. These studies can also help identify any anomalous pulmonary venous connections. Cardiac catheterization can define the size and location of the shunt and determine the pulmonary pressure and PVR.

Prognosis & Treatment

Patients with small atrial shunts live a normal life span with no intervention. Large shunts usually cause disability by age 40 years. Because left-to-right shunts and RV overload tend to increase with normal age-related reduction in LV (and subsequently LA) compliance, both AHA/ACC and the ESC guidelines suggest that *closure of all left-to-right shunts > 1.5:1 should be accomplished either by a percutaneous device or by surgery if any right heart structures are enlarged at all.* If the pulmonary systolic pressure is more than two-thirds the systemic systolic pressure, then pulmonary hypertension may preclude ASD closure. The ESC guidelines add the pulmonary vascular resistance to the criteria and consider it a class IIa indication if the PVR is between 3 and 5 Wood units, and the guidelines preclude the use of closure if the PVR is ≥ 5 Wood units. Testing with transient balloon occlusion of the shunt, with pulmonary vasodilators, or with both may be required in the presence of pulmonary hypertension. Preservation of the cardiac output after transient balloon occlusion and evidence for preserved pulmonary vasoreactivity with pulmonary vasodilator testing all favor closure when pulmonary hypertension and at least a 1.5:1 left-to-right shunt are present. ESC guidelines favor bringing the patient back to the catheterization laboratory for retesting on pulmonary vasodilators, rather than using acute testing, to see if the PVR can be reduced below 5 Wood units. The ESC guidelines also suggest considering fenestrated closure in the face of pulmonary hypertension. The use of bosentan or sildenafil is recommended if the PVR is over 5 Wood units and there is a right-to-left shunt. After age 40 years, cardiac arrhythmias (especially atrial fibrillation) and HF occur with increased frequency due to the chronic right heart volume overload. Paradoxical systemic arterial embolization also becomes more of a concern as RV compliance is lost and the left-to-right shunt begins to reverse.

PFOs are usually *not* associated with significant shunting, and therefore, the patients are hemodynamically asymptomatic and the heart size is normal. However, PFOs can be responsible for paradoxical emboli and are a possible cause of **cryptogenic strokes** in patients under age 55 years. Some shunting may occur with exercise if the right heart is enlarged or stiff. *Interestingly, the risk of recurrent paradoxical emboli is low regardless of whether the PFO is closed or not, and that observation has reduced the value of closing these defects in cryptogenic stroke.* Further confounding the advantage of PFO closure for cryptogenic stroke or transient ischemic attack (TIA) has been the discovery of frequent bouts of paroxysmal atrial fibrillation using **30-day monitoring** in these patients, suggesting atrial fibrillation is actually the real stroke/TIA risk factor in some patients.

Occasionally, a PFO that has not been pathologic may become responsible for cyanosis, especially if the RA pressure is elevated from pulmonary or RV hypertension or from severe tricuspid regurgitation.

Surgery involves stitching or patching of the foramen. For ostium secundum ASDs, percutaneous closure by use of a variety of devices is preferred over surgery when the anatomy is appropriate (usually this means there must be an adequate atrial septal rim around the defect to secure the occluder device).

Patients who have hypoxemia (especially upon standing or with exercise) should have the PFO closed if no other cause for hypoxemia is evident and there is right-to-left shunting demonstrated through the PFO. *For patients with cryptogenic stroke or TIA, it remains uncertain whether closure of the PFO, either by open surgical or percutaneous techniques, has any advantage over anticoagulation with either warfarin, a DOAC, or aspirin.*

From a practical standpoint, *patients younger than 55 years with cryptogenic stroke/TIA and no other identifiable cause except for the presence of a PFO should still be considered for PFO closure.* A 2020 update from the guideline subcommittee of the American Academy of Neurology reaffirms no change in this overall policy. The presence of an atrial septal aneurysm (with the septum appearing "floppy" on echocardiogram) has been associated with a higher risk of recurrent stroke/TIA in patients with cryptogenic stroke/TIA. A workup for any causes for hypercoagulability and a 30-day monitor should be part of the clinical assessment to exclude other potential causes for cryptogenic stroke/TIA. In meta-analysis of data in patients with cryptogenic stroke/TIA and PFO who have their PFO closed, ischemic stroke recurrence is less frequent compared with patients receiving medical treatment. Atrial fibrillation is more frequent but mostly transient in patients who have device closure. *There is no difference in TIA, all-cause mortality, or MI between those treated with medicine versus a closure device.* In a large, multicenter trial in France among patients who had had a recent cryptogenic stroke attributed to PFO with an associated atrial septal aneurysm or large interatrial shunt, the rate of stroke recurrence was lower among those assigned to PFO closure combined with antiplatelet therapy than among those assigned to antiplatelet therapy alone. PFO closure was associated with an increased risk of atrial fibrillation. Residual shunting after device closure is also present in up to 25% of patients. A report from Massachusetts General Hospital found a medium to large residual shunt increased the risk of a recurrent stroke or TIA threefold.

When to Refer

- All patients with an ASD should be evaluated by a cardiologist with expertise in adult congenital disease to ensure no other structural disease is present and to investigate whether the RV is enlarged.
- If the RA and RV sizes remain normal, serial echocardiography should be performed every 3–5 years.
- If the RA and RV volumes are increased, then referral to a cardiologist who performs percutaneous closure is warranted.
- Patients younger than 55 years with cryptogenic stroke when no other source is identified except for a PFO with right-to-left shunting should be considered for PFO closure or medical therapy. An associated atrial septal aneurysm or evidence for hypercoagulability increases risk. Aspirin alone appears *not* to be effective. DOACs with or without device closure of the PFO may have a role in preventing recurrent stroke.
- Patients with cyanosis and a PFO with evidence of a right-to-left shunt by agitated saline bubble contrast on echocardiography, especially if the cyanosis is worsened upon assuming the upright posture.

VENTRICULAR SEPTAL DEFECT

ESSENTIALS OF DIAGNOSIS

- A restrictive VSD is small and makes a louder murmur than an unrestricted one, often with an accompanying thrill. The higher the gradient across the septum, the smaller the left-to-right shunt.
- Small defects may be asymptomatic.
- Larger defects result in pulmonary hypertension (Eisenmenger physiology) if not repaired or if the pulmonary circuit is not protected by RV outflow tract obstruction.
- Echocardiography/Doppler is diagnostic.

General Considerations

Congenital VSDs occur in various parts of the ventricular septum. Membranous and muscular septal defects may spontaneously close in childhood as the septum grows and hypertrophies. A left-to-right shunt is present, with the degree depending on associated systolic RV pressure. The smaller the defect, the greater is the gradient from the LV to the RV and the louder the murmur. The presentation in adults depends on the size of the shunt and whether there is associated pulmonic or subpulmonic stenosis that has protected the lung from the systemic pressure and volume. Unprotected lungs with large shunts invariably lead to pulmonary vascular disease and severe pulmonary hypertension (Eisenmenger physiology). VSD sizes are defined by comparison to the aortic root size; a small or restrictive VSD diameter is < 25% of the aortic root diameter, a moderately restrictive VSD diameter is 25–75% of the aorta, and an unrestricted VSD size is > 75% of the aortic diameter. The size can also be quantitated based on the Qp/Qs (left-to-right shunt), with a restrictive lesion being < 1.5:1, moderately restrictive VSD being 1.5–2.2:1, and an unrestricted lesion being > 2.2:1. In rare cases of a VSD high in the ventricular septum, an aortic cusp (right coronary cusp) may prolapse into the VSD and reduce the VSD shunt but result in acute aortic regurgitation and acute HF.

Clinical Findings

A. Symptoms and Signs

The clinical features depend on the size of the defect and the presence or absence of RV outflow obstruction or increased PVR. Small shunts are associated with loud, harsh holosystolic murmurs in the left third and fourth interspaces along the sternum. A systolic thrill is common. Larger shunts may create both LV and RV volume and pressure overload. If pulmonary hypertension occurs, high-pressure pulmonary valve regurgitation may result. Right HF may gradually become evident late in the course, and the shunt will begin to balance or reverse as RV and LV systolic pressures equalize with the advent of pulmonary hypertension. Cyanosis from a developing right-to-left shunt may then occur. Cyanosis with pulmonary hypertension and an intracardiac shunt define the **Eisenmenger syndrome.**

B. ECG and Chest Radiography

The ECG may be normal or may show right, left, or biventricular hypertrophy, depending on the size of the defect and the PVR. With large shunts, the LV, the LA, and the pulmonary arteries are enlarged and pulmonary vascularity is increased on CXRs. The RV is often normal until late in the process. If an increased PVR (pulmonary hypertension) evolves, an enlarged PA with pruning of the distal pulmonary vascular bed is seen.

C. Diagnostic Studies

Echocardiography can demonstrate the size of the overloaded chambers and can usually define the defect anatomy. Doppler can qualitatively assess the magnitude of shunting by noting the gradient from LV to RV and, if some tricuspid regurgitation is present, the RV systolic pressure can be estimated. The septal leaflet of the tricuspid valve may be part of the VSD anatomy and the complex appears as a ventricular septal "aneurysm." These membranous septal aneurysms resemble a "windsock" and may fenestrate and result in a VSD shunt being present or they may remain intact. Color flow Doppler helps delineate the shunt severity and the presence of valvular regurgitation. MRI and cardiac CT can often visualize the defect and describe any other anatomic abnormalities. MRI can provide quantitative shunt data as well.

Cardiac catheterization is usually reserved for those with at least moderate shunting, to quantitate the PVR and the degree of pulmonary hypertension. The 2018 adult congenital heart disease guidelines suggest that if there is still at least a 1.5:1 left-to-right shunt and if the PVR is less than one-third that of the systemic vascular resistance, and the PA systolic pressure is more than one-half of the aortic systolic pressure, then the risk of VSD closure despite some pulmonary hypertension is acceptable and it should be done. If the PVR/systemic vascular resistance ratio or the systolic PA pressure/systolic aortic pressure ratio is greater than two-thirds or there is a net right-to-left shunt, then closure is contraindicated.

The vasoreactivity of the pulmonary circuit may be tested at catheterization using agents such as inhaled nitric oxide. The AHA/ACC guidelines suggest that if the pulmonary pressures can be lowered enough and the above ratios fall below the two-thirds value, then repair is reasonable as long as the left-to-right VSD shunt is > 1.5:1. The 2020 ESC guidelines focus not on the pulmonary to systemic systolic BP ratio, but on the pulmonary pressure and the PVR. A PVR of ≥ 5 Wood units is considered inoperable unless pulmonary vasodilators can reduce the PVR to below that value. Bosentan, an endothelial receptor blocker that reduces pulmonary pressure in Eisenmenger syndrome, has been given a class I indication in these patients in both guidelines.

Prognosis & Treatment

Patients with a small VSD have a normal life expectancy except for the small risk of infective endocarditis. *Antibiotic prophylaxis after dental work is recommended only when the VSD is residual from a prior patch closure or when there is associated pulmonary hypertension and cyanosis.* With large VSD shunts, HF may develop early in life, and survival beyond age 40 years is unusual without intervention.

Small shunts (pulmonary to systemic flow ratio < 1.5) in asymptomatic patients do not require surgery or other intervention. The presence of RV infundibular stenosis or pulmonary valve stenosis may protect the pulmonary circuit such that some patients, even with a large VSD, may still be surgical candidates as adults if there is no pulmonary hypertension.

Surgical repair of a VSD is generally a low-risk procedure unless there is significant Eisenmenger physiology. Devices for nonsurgical closure of muscular VSDs are approved and those for membranous VSDs are being implanted with promising results; however, conduction disturbance is a major complication. The percutaneous devices are also approved for closure of a VSD related to acute MI, although the results in this patient population with very high risk have not been encouraging. In the acute MI setting, the devices have also been put across the ventricular septum at surgery to help provide a firm base on which to sew a pericardial patch, given the VSD in acute MI is often associated with widespread necrosis and multiple, serpiginous pathways. A percutaneous method, wherein the two sides of the device are sewn together using a subxiphoid approach, has been described. The medications used to treat pulmonary hypertension secondary to a VSD are similar to those used to treat idiopathic ("primary") pulmonary hypertension and at times can be quite effective in relieving symptoms and reducing the degree of cyanosis. *All patients who have a right-to-left shunt present should have filters placed on any intravenous lines to avoid any contamination or air bubbles from becoming systemic.*

When to Refer

All patients with a VSD should be referred to a cardiologist with expertise in adult congenital disease to decide if long-term follow-up or further studies are warranted.

TETRALOGY OF FALLOT

ESSENTIALS OF DIAGNOSIS

- Five features are characteristic:
  - VSD.
  - Concentric RVH.
  - RV outflow obstruction due to infundibular stenosis.
  - Septal overriding of the aorta in half the patients.
  - A right-sided aortic arch in 25%.
- Most adult patients with tetralogy of Fallot have been operated on, usually with an RV outflow patch and VSD closure. If patch overrides the pulmonary valve annulus, pulmonary regurgitation is common.
- Physical examination may be deceptive after classic tetralogy repair, with severe pulmonary valve regurgitation difficult to detect.
- Echocardiography/Doppler may underestimate significant pulmonary valve regurgitation. Be wary if the RV is enlarged or enlarging.
- Arrhythmias are common; periodic ambulatory monitoring is recommended.
- Serious arrhythmias and sudden death may occur if the QRS is wide or the RV becomes quite large, or both.

General Considerations

Patients with tetralogy of Fallot have a VSD, RV infundibular stenosis, RVH, and a dilated aorta (in about half of patients it overrides the septum). If there is an associated ASD, the complex is referred to as **pentalogy of Fallot**. The basic lesion is a large VSD with migration of the septum above the VSD and under the pulmonary valve. There may be pulmonary valve stenosis as well, usually due to either a bicuspid pulmonary valve or RV outflow hypoplasia. The aorta can be quite enlarged and aortic regurgitation may occur. If > 50% of the aorta overrides the ventricular septum, it is called **double outlet RV**. Two vascular abnormalities are common: a right-sided aortic arch (in 25%) and an anomalous left anterior descending coronary artery from the right cusp (7–9%). The latter is important in that surgical correction must avoid injuring the coronary artery when repairing the RV outflow obstruction. Pulmonary branch stenosis may also be present.

Most adult patients have undergone prior surgery. If significant RV outflow obstruction is present in the neonatal period, a systemic arterial to PA shunt may be the initial surgical procedure to improve pulmonary blood flow, though many infants undergo repair without this first step. Most adults will have had this initial palliative repair, however. The palliative procedure enables blood to reach the underperfused lung either by directly attaching one of the subclavian arteries to a main PA branch (**classic Blalock shunt**) or, more likely, by creating a conduit between the two (**modified Blalock shunt**). Total repair of the tetralogy of Fallot generally includes a VSD patch and usually an enlarging RV outflow tract patch, as well as a take-down of any prior arterial-PA shunt. If the RV outflow tract patch extends through the pulmonary valve into the PA (transannular patch), varying degrees of pulmonary valve regurgitation develop. Most surgeons approach the inside of the RV via the right atrium and through the tricuspid valve and try to avoid a transannular patch if possible. Over the years, the volume overload from residual severe pulmonary valve regurgitation becomes the major hemodynamic problem to deal with in adults. A large RV outflow patch contributes to a relative RV volume load. Ventricular arrhythmias can originate from the edge of either the VSD or outflow tract patch and tend to increase in frequency as the size of the RV increases.

Clinical Findings

Most adult patients in whom tetralogy of Fallot has been repaired are relatively asymptomatic unless right HF occurs or arrhythmias become an issue. Patients can be active and generally require no specific therapy.

A. Symptoms and Signs

Physical examination should include checking both arms for any loss of pulse from a prior shunt procedure in infancy. The jugular venous pulsations (JVP) may reveal an increased *a* wave from poor RV compliance or rarely a *c-v* wave due to tricuspid regurgitation. The right-sided arch has no consequence. The precordium may be active, often with a persistent pulmonary outflow murmur. P_2 may or may not be audible. A right-sided gallop may be heard. A residual VSD or an aortic regurgitation murmur may be present.

B. ECG and Chest Radiography

The ECG reveals RVH and right axis deviation; in repaired tetralogy, there is often a right bundle branch block pattern. The CXR shows a classic boot-shaped heart with prominence of the RV and a concavity in the RV outflow tract. This may be less impressive following repair. The aorta may be enlarged and right-sided. *Importantly, the width of the QRS on ECG should be examined yearly because a QRS width of > 180 msec is one of the risks for sudden death.* Most experts recommend ambulatory monitoring periodically (every 1–2 years) as well, especially if the patient experiences palpitations. Other identified risk factors for ventricular arrhythmias include having multiple prior cardiac surgeries, an elevated LVEDP, and older age at time of repair. In fact, it appears that the more the left side of the heart is involved, the higher the risk of sudden death.

C. Diagnostic Studies

Echocardiography/Doppler usually establishes the diagnosis by noting the unrestricted (large) VSD, the RV infundibular stenosis, and the enlarged aorta. In patients who have had tetralogy of Fallot repaired, echocardiography/Doppler also provides data regarding the amount of residual pulmonary valve regurgitation if a transannular patch is present, RV and LV function, and the presence of aortic regurgitation. Elevated N-terminal pro B-type natriuretic peptide (NT-proBNP) blood levels have also been correlated with increasing RV enlargement.

Cardiac MRI and CT can quantitate both the pulmonary regurgitation and the RV volumes. In addition, cardiac MRI and CT can identify whether there is either a native pulmonary arterial branch stenosis or a stenosis at the distal site of a prior arterial-to-PA shunt or other anomalies, such as an ASD. The ability of cardiac MRI to accurately quantitate the pulmonary regurgitation severity and provide more accurate RV volume measurements gives it an advantage over other imaging studies. Cardiac catheterization may be required to document the degree of pulmonary valve regurgitation because noninvasive studies depend on velocity gradients. Pulmonary angiography demonstrates the degree of pulmonary valve regurgitation, and RV angiography helps assess any postoperative outflow tract aneurysm.

The need for electrophysiologic studies with ventricular stimulation and potential ventricular tachycardia ablation has been suggested by some experts for patients who have had evidence for ventricular tachycardia, unexplained syncope, a wide QRS, are older, or who are about to undergo pulmonary valve replacement.

Prognosis & Treatment

A few patients with “just the right amount” of subpulmonic stenosis enter adulthood without having had surgical correction. However, most adult patients have had surgical repair, including VSD closure, resection of infundibular muscle, and insertion of an outflow tract patch to relieve the subpulmonic obstruction. Patients with pulmonary valve regurgitation should be monitored to ensure the RV volume does not progressively increase. In patients with tetralogy of Fallot, transthoracic echocardiogram monitoring of pulmonary valve regurgitation is recommended every 12–24 months based on the degree of regurgitation. Low-pressure pulmonary valve regurgitation is difficult to diagnose due to the fact that the RV diastolic pressures tend to be high and the pulmonary arterial diastolic pressure low. This means there is little gradient between the PA and the RV in diastole, so that there may be little murmur or evidence of turbulence on color flow Doppler. *If the RV begins to enlarge, it must be assumed that this is due to pulmonary valve regurgitation until proven otherwise.* Early surgical pulmonary valve replacement is increasingly being favored. The RV volumes from cardiac MRI are important in deciding when to intervene if the patient is not very symptomatic; an RV end-diastolic volume index of > 160 mm/m^2 or an RV end-systolic volume index of > 80 mm/m^2 is recommended as the cutoff. There are also a number of other triggers for intervention, details of which can be found in the AHA/ACC and ESC guidelines. A percutaneous approach to pulmonary valve regurgitation remains limited as the available percutaneous valve diameters are frequently too small for the size of the pulmonary annulus. The Melody valve is a bovine jugular vein prosthesis with the largest size being 22 mm in diameter. Percutaneous stented valves, particularly the Edwards SAPIEN XT, have been used successfully and can be used in patients with larger pulmonary root sizes. Often, a regular stent is placed within the PA first, with the stented valve then placed within this first stent. The expansion of the PA must not impede flow down any coronary artery; this is tested by a trial balloon expansion while imaging the coronary artery at the same time (class I requirement). There has been an increase in stented valve endocarditis noted after the placement of the Melody valve; this is being closely monitored.

If an anomalous coronary artery is present, then an extracardiac conduit around it from the RV to the PA may be necessary as part of the tetralogy repair. By 20-year follow-up, reoperation of the common tetralogy repair is needed in about 10–15%, not only for severe pulmonary valve regurgitation but also for residual infundibular stenosis. Usually the pulmonary valve is replaced with a pulmonary homograft, although a porcine bioprosthetic valve is also suitable. Percutaneous valve-in-valve stented bioprosthetic valves have successfully been used when there is surgical bioprosthetic valve dysfunction. Cryoablation of the tissue giving rise to arrhythmias is sometimes performed at the time of reoperation. Branch pulmonary stenosis may be percutaneously opened by stenting. If a conduit has been used already for repair of the RV outflow obstruction, a percutaneous approach with a stented pulmonary valve may be possible. All patients require endocarditis prophylaxis. Most adults with stable hemodynamics can be quite active, and most women can carry a pregnancy adequately if RV function is preserved.

Atrial fibrillation, reentrant atrial arrhythmias, and ventricular ectopy are common, especially after the age of 45. Left heart disease appears to cause arrhythmias more often than right heart disease. Biventricular dysfunction is not an uncommon consequence as the patient ages. The cause of associated LV dysfunction is often multifactorial and frequently unclear. Similarly, the aorta may enlarge with accompanying aortic regurgitation, and these lesions can become severe enough to warrant surgical intervention. Patients with RV or LV dysfunction or with dysfunction of both ventricles may require a prophylactic defibrillator.

When to Refer

All patients with tetralogy of Fallot should be referred to a cardiologist with expertise in adult congenital heart disease.

Ros D et al. Infectious endocarditis after percutaneous pulmonary valve implantation with a stent mounted bovine jugular vein valve. Clinical experience and the evaluation of the modified Duke criteria. Int J Cardiol. 2021;323;40. [PMID: 32860844]

VALVULAR HEART DISEASE

The typical findings of each native valve lesion are described in Table 10–2. Table 10–3 outlines bedside maneuvers to distinguish among the various systolic murmurs.

Table 10–2. Differential diagnosis of valvular heart disease.

	Mitral Stenosis	Mitral Regurgitation	Aortic Stenosis	Aortic Regurgitation	Tricuspid Stenosis	Tricuspid Regurgitation
Inspection	Malar flush, precordial bulge, and diffuse pulsation in young patients.	Usually prominent and hyperdynamic apical impulse to left of MCL.	Sustained PMI, prominent atrial filling wave.	Hyperdynamic PMI to left of MCL and downward. Visible carotid pulsations. Pulsating nailbeds (Quincke sign), head bob (de Musset sign).	Giant *a* wave in jugular pulse with sinus rhythm. Peripheral edema or ascites, or both.	Large *v* wave in jugular pulse; time with carotid pulsation. Peripheral edema or ascites, or both.
Palpation	"Tapping" sensation over area of expected PMI. RV pulsation in left third to fifth ICS parasternally when pulmonary hypertension is present. P_2 may be palpable.	Forceful, brisk PMI; systolic thrill over PMI. Pulse normal, small, or slightly collapsing.	Powerful, heaving PMI to left and slightly below MCL. Systolic thrill over aortic area, sternal notch, or carotid arteries in severe disease. Small and slowly rising carotid pulse. If bicuspid AS, check for delay at femoral artery to exclude coarctation.	Apical impulse forceful and displaced significantly to left and downward. Prominent carotid pulses. Rapidly rising and collapsing pulses (Corrigan pulse).	Pulsating, enlarged liver in ventricular systole.	RV pulsation. Systolic pulsation of liver.
Heart sounds, rhythm, and blood pressure	S_1 loud if valve mobile. Opening snap following S_2. The worse the disease, the closer the S_2-opening snap interval.	S_1 normal or buried in early part of murmur (exception in mitral prolapse where murmur may be late). Prominent third heart sound when severe MR. Atrial fibrillation common. Blood pressure normal. Midsystolic clicks may be present and may be multiple.	A_2 normal, soft, or absent. Prominent S_4. Blood pressure normal, or systolic pressure normal with high diastolic pressure.	S_1 normal or reduced, A_2 loud. Wide pulse pressure with diastolic pressure < 60 mm Hg. When severe, gentle compression of femoral artery with diaphragm of stethoscope may reveal diastolic flow (Duroziez) and pressure in leg on palpation > 40 mm Hg than in arm (Hill).	S_1 often loud.	Atrial fibrillation may be present.
Murmurs						
Location and transmission	Localized at or near apex. Diastolic rumble best heard in left lateral position; may be accentuated by having patient do sit-ups. Rarely, short diastolic murmur along lower left sternal border (Graham Steell) in severe pulmonary hypertension.	Loudest over PMI; posteriorly directed jets (ie, anterior mitral prolapse) transmitted to left axilla, left infrascapular area; anteriorly directed jets (ie, posterior mitral prolapse) heard over anterior precordium. Murmur unchanged after premature beat.	Right second ICS parasternally or at apex, heard in carotid arteries and occasionally in upper interscapular area. May sound like MR at apex (Gallavardin phenomenon), but murmur occurs after S_1 and stops before S_2.	Diastolic: louder along left sternal border in third to fourth interspace. Heard over aortic area and apex. May be associated with low-pitched mid-diastolic murmur at apex (Austin Flint) due to functional mitral stenosis. If due to an enlarged aorta, murmur may radiate to right sternal border.	Third to fifth ICS along left sternal border out to apex. Murmur increases with inspiration.	Third to fifth ICS along left sternal border. Murmur hard to hear but increases with inspiration. Sit-ups can increase cardiac output and accentuate murmur.

Timing	Relation of opening snap to A_2 important. The higher the LA pressure, the earlier the opening snap. Presystolic accentuation before S_1 if in sinus rhythm. Graham Steell begins with P_2 (early diastole) if associated pulmonary hypertension.	Pansystolic: begins with S_1 and ends at or after A_2. May be late systolic in mitral valve prolapse.	Begins after S_1, ends before A_2. The more severe the stenosis, the later the murmur peaks.	Begins immediately after aortic second sound and ends before first sound (blurring both); helps distinguish from MR.	Rumble often follows audible opening snap.	At times, hard to hear. Begins with S_1 and fills systole. Increases with inspiration.
Character	Low-pitched, rumbling; presystolic murmur merges with loud S_1.	Blowing, high-pitched; occasionally harsh or musical.	Harsh, rough.	Blowing, often faint.	As for mitral stenosis.	Blowing, coarse, or musical.
Optimum auscultatory conditions	After exercise, left lateral recumbency. Use stethoscope bell, lightly applied.	After exercise; use stethoscope diaphragm. In prolapse, findings may be more evident while standing.	Use stethoscope diaphragm. Patient resting, leaning forward, breath held in full expiration.	Use stethoscope diaphragm. Patient leaning forward, breath held in expiration.	Use stethoscope bell. Murmur usually louder and at peak during inspiration. Patient recumbent.	Use stethoscope diaphragm. Murmur usually becomes louder during inspiration.
Radiography	Straight left heart border from enlarged LA appendage. Elevation of left mainstem bronchus. Large RV and pulmonary artery if pulmonary hypertension is present. Calcification in mitral valve in rheumatic mitral stenosis or in annulus in calcific mitral stenosis.	Enlarged LV and LA.	Concentric LVH. Prominent ascending aorta. Calcified aortic valve common.	Moderate to severe LV enlargement. Aortic root often dilated.	Enlarged right atrium with prominent SVC and azygous shadow.	Enlarged right atrium and RV.
ECG	Broad P waves in standard leads; broad negative phase of diphasic P in V_1. If pulmonary hypertension is present, tall peaked P waves, right axis deviation, or RVH appears.	Left axis deviation or frank LVH. P waves broad, tall, or notched in standard leads. Broad negative phase of diphasic P in V_1.	LVH.	LVH.	Tall, peaked P waves. Possible RVH.	Right axis usual.

Table 10–2. Differential diagnosis of valvular heart disease. (continued)

	Mitral Stenosis	Mitral Regurgitation	Aortic Stenosis	Aortic Regurgitation	Tricuspid Stenosis	Tricuspid Regurgitation
Echocardiography						
Two-dimensional echocardiography	Thickened, immobile mitral valve with anterior and posterior leaflets moving together. "Hockey stick" shape to opened anterior leaflet in rheumatic mitral stenosis. Annular calcium with thin leaflets in calcific mitral stenosis. LA enlargement, normal to small LV. Orifice can be traced to approximate mitral valve orifice area.	Thickened mitral valve in rheumatic disease; mitral valve prolapse; flail leaflet or vegetations may be seen. Dilated LV in volume overload. Operate for LV end-systolic dimension < 4.5 cm.	Dense persistent echoes from the aortic valve with poor leaflet excursion. LVH late in the disease. Bicuspid valve in younger patients.	Abnormal aortic valve or dilated aortic root. Diastolic vibrations of the anterior leaflet of the mitral valve and septum. In acute aortic regurgitation, premature closure of the mitral valve before the QRS. When severe, dilated LV with normal or decreased contractility. Operate when LV end-systolic dimension > 5.0 cm.	In rheumatic disease, tricuspid valve thickening, decreased early diastolic filling slope of the tricuspid valve. In carcinoid, leaflets fixed, but no significant thickening.	Enlarged RV with paradoxical septal motion. Tricuspid valve often pulled open by displaced chordae.
Continuous and color flow Doppler and TEE	Prolonged pressure half-time across mitral valve allows estimation of gradient. MVA estimated from pressure half-time. Indirect evidence of pulmonary hypertension by noting elevated RV systolic pressure measured from the tricuspid regurgitation jet.	Regurgitant flow mapped into LA. Use of PISA helps assess MR severity. TEE important in prosthetic mitral valve regurgitation.	Increased transvalvular flow velocity; severe AS when peak jet > 4 m/sec (64 mm Hg). Valve area estimate using continuity equation is poorly reproducible.	Demonstrates regurgitation and qualitatively estimates severity based on percentage of LV outflow filled with jet and distance jet penetrates into LV. TEE important in aortic valve endocarditis to exclude abscess. Mitral inflow pattern describes diastolic dysfunction.	Prolonged pressure half-time across tricuspid valve can be used to estimate mean gradient. Severe tricuspid stenosis present when mean gradient > 5 mm Hg.	Regurgitant flow mapped into right atrium and venae cavae. RV systolic pressure estimated by tricuspid regurgitation jet velocity.

A_2, aortic second sound; AS, aortic stenosis; ICS, intercostal space; LA, left atrial; MCL, midclavicular line; MR, mitral regurgitation; MVA, measured valve area; P_2, pulmonary second sound; PISA, proximal isovelocity surface area; PMI, point of maximal impulse; S_1, first heart sound; S_2, second heart sound; S_4, fourth heart sound; SVC, superior vena cava; TEE, transesophageal echocardiography; V_1, chest ECG lead 1.

Table 10–3. Effect of various interventions on systolic murmurs. (Listed in alphabetical order)

Intervention	Hypertrophic Cardiomyopathy	Aortic Stenosis	Mitral Regurgitation	Mitral Prolapse
Exercise	↑	↑ or ×	↓	↑
Handgrip or squatting	↓	↓ or ×	↑	↓
Standing	↑	↑ or ×	↓ or ×	↑

The 2017 ACC/AHA valvular heart disease guidelines suggest all lesions may be best classified clinically into one of six categories based on anatomy and symptoms.

Stage A: Patients at risk for valvular heart disease.

Stage B: Patients with progressive valvular heart disease (mild to moderate severity) and asymptomatic.

Stage C: Asymptomatic patients who have reached criteria for severe valvular heart disease.

C1: Severe valve lesion. Asymptomatic. Normal LV function.

C2: Severe valve lesion. Asymptomatic. Abnormal LV function.

Stage D: Symptomatic patients as a result of valvular heart disease.

In 2020, the ACC/AHA guideline for the management of patients with valvular heart disease was published, and this chapter will highlight the changes and additions from the prior guidelines, first published in 2014 and then updated in 2017.

MITRAL STENOSIS

ESSENTIALS OF DIAGNOSIS

- Fatigue, exertional dyspnea, and orthopnea when the stenosis becomes severe.
- Symptoms often precipitated by onset of atrial fibrillation or pregnancy.
- Intervention indicated for symptoms, atrial fibrillation, or evidence of pulmonary hypertension. Most symptomatic patients have a mitral valve area of < 1.5 cm^2.

General Considerations

Most patients with native valve mitral stenosis are presumed to have had rheumatic heart disease, although a history of rheumatic fever is noted in only about one-third. (Also see section on Rheumatic Fever.) Rheumatic mitral stenosis results in thickening of the leaflets, fusion of the mitral commissures, retraction, thickening and fusion of the chordae, and calcium deposition in the valve. Mitral stenosis can also occur due to congenital disease with chordal fusion or papillary muscle malposition. The papillary muscles may be abnormally close together, sometimes so close that they merge into a single papillary muscle (the **"parachute mitral valve"**). In these patients, the chordae or valvular tissue (or both) may also be fused. In older patients and in those undergoing dialysis, mitral annular calcification may stiffen the mitral valve and reduce its motion to the point where a mitral gradient is present. Calcium in the mitral annulus virtually invades the mitral leaflet from the annulus inward as opposed to the calcium buildup in the leaflets and commissures as seen in rheumatic heart disease. Mitral valve obstruction may also develop in patients who have had mitral valve repair with a mitral annular ring that is too small, or in patients who have had a surgical valve replacement (prosthetic valve-patient mismatch or degeneration of the prosthetic valve over time).

Clinical Findings

A. Symptoms and Signs

Two clinical syndromes classically occur in patients with mitral stenosis. In mild to moderate mitral stenosis, LA pressure and cardiac output may be essentially normal, and the patient is either asymptomatic or symptomatic only with extreme exertion. The measured valve area is usually between 1.5 cm^2 and 1.0 cm^2. In severe mitral stenosis (valve area < 1.0 cm^2), severe pulmonary hypertension develops due to a "secondary stenosis" of the pulmonary vascular bed. In this condition, pulmonary edema is uncommon, but symptoms of low cardiac output and right HF predominate. Any measured valve area < 1.5 cm^2 should be considered significant.

A characteristic finding of rheumatic mitral stenosis is an **opening snap** following A$_2$ due to the stiff mitral valve. The interval between the opening snap and aortic closure sound is long when the LA pressure is low but shortens as the LA pressure rises and approaches the aortic diastolic pressure. As mitral stenosis worsens, there is a localized low-pitched diastolic murmur whose duration increases with the severity of the stenosis as the mitral gradient continues throughout more of diastole. The diastolic murmur is best heard at the apex with the patient in the left lateral position (Table 10–2). Mitral regurgitation may be present as well.

Paroxysmal or chronic atrial fibrillation eventually develops in 50–80% of patients. Any increase in the heart rate reduces diastolic filling time and increases the mitral gradient. A sudden increase in heart rate may precipitate pulmonary edema. Therefore, *heart rate control is important*, with slow heart rates allowing for more diastolic filling of the LV.

B. Diagnostic Studies

Echocardiography is the most valuable technique for assessing mitral stenosis (Table 10–2). LA size can also be determined by echocardiography; increased size denotes an increased likelihood of atrial fibrillation and thrombus formation. Because echocardiography and careful symptom evaluation provide most of the needed information, cardiac catheterization is used primarily to detect associated coronary or myocardial disease—usually after the decision to intervene has been made.

Treatment & Prognosis

In most cases, there is a long asymptomatic phase after the initial rheumatic infection, followed by subtle limitation of activity. Pregnancy and its associated increase in stroke volume and heart rate result in an increased transmitral pressure gradient and may precipitate symptoms. In particular, toward the end of pregnancy, the cardiac output continues to be maintained by an increase in heart rate, increasing the mitral gradient by shortening diastolic time. Patients with moderate to severe mitral stenosis should have the condition corrected prior to becoming pregnant if possible (when the measured valve area is about 2.0 cm^2). Pregnant patients who become symptomatic can undergo successful surgery, preferably in the third trimester, although balloon valvuloplasty is the treatment of choice if the echocardiography valve score is low enough.

The onset of atrial fibrillation often precipitates symptoms, which improve with control of the ventricular rate or restoration of sinus rhythm. Conversion to and subsequent maintenance of sinus rhythm are most commonly successful when the duration of atrial fibrillation is brief (< 6–12 months) and the LA is not severely dilated (diameter < 4.5 cm). *Once atrial fibrillation occurs, the patient should receive warfarin even if sinus rhythm is restored*, since atrial fibrillation often recurs even with antiarrhythmic therapy and 20–30% of these patients will have systemic embolization if untreated. Systemic embolization in the presence of only mild to moderate disease is not an indication for surgery but should be treated with warfarin. DOACs (dabigatran, apixaban, rivaroxaban, edoxaban) are *not* recommended by the most recent guidelines, since patients with atrial fibrillation were excluded from the approval trials. A randomized clinical trial published in 2022 supports this recommendation.

Indications for intervention focus on symptoms such as an episode of pulmonary edema, a decline in exercise capacity, or any evidence of pulmonary hypertension (peak systolic pulmonary pressure > 50 mm Hg). Some experts believe that the presence of atrial fibrillation should also be a consideration for an intervention. Most interventions are not pursued until the patient is symptomatic (stage D). In some patients, symptoms develop with calculated mitral valve areas between 1.5 cm^2 and 1.0 cm^2. Symptoms or evidence of pulmonary hypertension should drive the decision to intervene in these patients, not the estimated valve area. See Table 10–4.

Open mitral commissurotomy is now rarely performed and has been replaced by percutaneous balloon valvuloplasty. Ten-year follow-up data comparing surgery to balloon valvuloplasty suggest no real difference in outcome between the two modalities. Replacement of the valve is indicated when combined stenosis and regurgitation are present or when the mitral valve echo score is much > 8–10. To determine the valve score, numbers 1 to 4 are assigned to four valve characteristics: mobility, calcification, thickening, and submitral scar. Thus, a maximum score is 16. Percutaneous balloon valvuloplasty has a very low mortality rate (< 0.5%) and a low morbidity rate (3–5%). Operative mortality rates are also low: 1–3% in most institutions. Repeat balloon valvuloplasty can be done if the morphology of the valve remains suitable. At surgery, a **Maze procedure** may be done at the same time to reduce recurrent atrial arrhythmias. It involves a number of endocardial incisions across the right and left atria to disrupt the electrical activity that sustains atrial arrhythmias. In many institutions, the LA appendage is sewn closed to help remove a potential future source for thrombosis.

Mechanical mitral prosthetic valves are more prone to thrombosis than mechanical aortic prosthetic valves. *The recommended INR range is thus higher (INR 2.5–3.5 or average of 3.0). Low-dose aspirin should be used in conjunction with warfarin if the bleeding risk is low. DOACs are **not** recommended as an anticoagulant.* It is a class IIa recommendation that warfarin be used for up to 6 months after implantation of a bioprosthetic mitral valve. Bioprosthetic valves tend to degenerate after about 10–15 years. Percutaneous balloon valvuloplasty is not effective when bioprosthetic valve stenosis occurs, but transcatheter valve-in-valve procedures have been successful. Transcatheter valve-in-valve procedures are becoming more common in patients at high risk for repeat cardiac surgical valve replacement. Reported early outcomes have been positive in patients with bioprosthetic valves, ring annuloplasty, and even in some patients with calcific mitral stenosis. Younger patients and those with ESKD are generally believed to do the poorest with bioprosthetic heart valves, although data have questioned the role of CKD as a major risk factor. Endocarditis prophylaxis is indicated for patients with prosthetic heart valves but is not indicated in native valve disease. Mitral stenosis due to calcific encroachment of the leaflets from mitral annular calcium can progress to severe mitral stenosis at times (estimated to be about 1 in 6 over 10 years). It does not lend itself to percutaneous valvuloplasty, and there are only case reports of using a percutaneous mitral valve replacement option.

Table 10–4. Management of rheumatic mitral stenosis.

Type of MS	Definition	Treatment
Progressive	Mitral valve area > 1.5 cm^2 Mean pressure gradient ≤ 5 mm Hg Half-life < 150 msec	Periodic monitoring when • Asymptomatic (stage B or C) *or* • Symptomatic with no other cause • PCWP < 25 mm Hg; mean pressure gradient < 15 mm Hg with exercise *or* • Symptomatic with no other cause • PCWP > 25 mm Hg; mean pressure gradient > 15 mm Hg with exercise • Unfavorable valve morphology,[1] left atrial clot, mitral regurgitation that is > mild PBMC (level IIb recommendation) when • Symptomatic with no other cause • PCWP > 25 mm Hg; mean pressure gradient > 15 mm Hg with exercise • Favorable valve morphology, no left atrial clot, mitral regurgitation is mild or absent
Severe	Mitral valve area ≤ 1.5 cm^2 Mean pressure gradient > 5 mm Hg Half-life ≥ 150 msec	Periodic monitoring when • Asymptomatic (stage B or C) *or* • New-onset AF and unfavorable valve morphology, left atrial clot, mitral regurgitation that is > mild PBMC (level IIb recommendation) when • New-onset atrial fibrillation and favorable valve morphology, no left atrial clot, mitral regurgitation that is mild or absent *or* • Symptomatic (stage D) • Unfavorable valve morphology, left atrial clot, mitral regurgitation that is > mild • NYHA class III/IV symptoms with high surgical risk PBMC (level I recommendation) when • Symptomatic (stage D) • Favorable valve morphology, no left atrial clot, no or mild mitral regurgitation Mitral valve replacement (level I recommendation) when • Symptomatic (stage D) • Unfavorable valve morphology, left atrial clot, mitral regurgitation that is > mild • Not NYHA class III/IV symptoms with high surgical risk
Very severe	Mitral valve area ≤ 1.0 cm^2 Mean pressure gradient > 10 mm Hg Half-life ≥ 220 msec	Periodic monitoring • Asymptomatic (stage C) • Unfavorable valve morphology, left atrial clot, mitral regurgitation that is > mild PBMC (level 1 recommendation) when • Asymptomatic (stage C) • Favorable valve morphology, no left atrial clot, no or mild mitral regurgitation *or* • Symptomatic (stage D) • Favorable valve morphology, no left atrial clot, no or mild mitral regurgitation Mitral valve replacement (level 1 recommendation) when • Symptomatic (stage D) • Unfavorable valve morphology, left atrial clot, mitral regurgitation that is > mild • Not NYHA class III/IV symptoms with high surgical risk

[1] Unfavorable valve morphology: < 2+ mitral regurgitation, no left atrial clot, mitral leaflets without severe calcification, lack of severe subvalvular mitral calcification.

AF, atrial fibrillation; NYHA, New York Heart Association; PBMC, percutaneous balloon mitral commissurotomy; PCWP, pulmonary capillary wedge pressure.

When to Refer

- Patients with mitral stenosis should be monitored with yearly examinations, and echocardiograms should be performed more frequently as the severity of the obstruction increases.
- All patients should initially be seen by a cardiologist, who can then decide how often the patient needs cardiology follow-up and whether intervention is indicated.

MITRAL REGURGITATION

ESSENTIALS OF DIAGNOSIS

- May be asymptomatic for years (or for life).
- Severe mitral regurgitation may cause left-sided HF and lead to pulmonary hypertension and right-sided HF.
- For chronic primary mitral regurgitation, surgery is indicated for symptoms or when the LVEF is < 60% or the echocardiographic LV end-systolic dimension is > 4.0 cm. Surgery also indicated in patients who have a progressive increase in LV size or decline in LVEF.
- In patients with mitral prolapse and severe mitral regurgitation, earlier surgery is indicated if mitral repair can be performed successfully with a high degree of certainty.
- Transcatheter edge-to-edge repair, if possible, can be done in symptomatic patients at higher surgical risk regardless of whether the mitral regurgitation is primary or secondary.
- Patients with functional chronic mitral regurgitation may improve with biventricular pacing and guideline-directed management and therapy.

General Considerations

Mitral regurgitation results in a volume load on the heart (increases preload) and reduces afterload. The result is an enlarged LV with an increased EF. Over time, the stress of the volume overload reduces myocardial contractile function; when this occurs, there is a drop in EF and a rise in end-systolic volume.

Clinical Findings

A. Symptoms and Signs

In **acute mitral regurgitation**, the LA size is not large, and LA pressure rises abruptly, leading to pulmonary edema if severe. When **chronic,** the LA enlarges progressively and the increased volume can be handled without a major rise in the LA pressure; the pressure in pulmonary veins and capillaries may rise only during exertion. Exertional dyspnea and fatigue progress gradually over many years.

Mitral regurgitation leads to chronic LA and LV enlargement and may result in subsequent atrial fibrillation and eventually LV dysfunction. Clinically, mitral regurgitation is characterized by a pansystolic murmur maximal at the apex, radiating to the axilla and occasionally to the base. The murmur does *not* change in intensity after a premature beat because the LV to LA gradient is unaffected. In addition, a hyperdynamic LV impulse and a brisk carotid upstroke may be present along with a prominent third heart sound due to the increased volume returning to the LV in early diastole (Tables 10–1 and 10–2). In acute mitral regurgitation, the murmur intensity may be modest due to little difference between the LA and LV systolic pressures during ventricular systole. The mitral regurgitation murmur due to mitral valve prolapse tends to radiate anteriorly in the presence of posterior leaflet prolapse and posteriorly when the prolapse is primarily of the anterior leaflet. Mitral regurgitation may not be pansystolic in these patients but occur only after the mitral click (until late in the disease process when it then becomes progressively more holosystolic).

B. Diagnostic Studies

Echocardiographic information demonstrating the underlying pathologic process (rheumatic, calcific, prolapse, flail leaflet, endocarditis, cardiomyopathy), LV size and function, LA size, PA pressure, and RV function can be invaluable in planning treatment as well as in recognizing associated lesions. The valvular heart disease guidelines provide details of the classification and measures of severity for primary and secondary mitral valve regurgitation. Doppler techniques provide qualitative and semiquantitative estimates of the severity of mitral regurgitation. TEE may help reveal the cause of regurgitation and is especially useful in patients who have had mitral valve replacement, in suspected endocarditis, and in identifying candidates for valvular repair. Echocardiographic dimensions and measures of systolic function are critical in deciding the timing of surgery. Asymptomatic patients with severe mitral regurgitation (stage C1) but preserved LV dimensions should undergo at least yearly echocardiography. Exercise hemodynamics with either Doppler echocardiography or cardiac catheterization may be useful when the symptoms do not fit the anatomic severity of mitral regurgitation. BNP or NT-proBNP is useful in the early identification of LV dysfunction in the presence of mitral regurgitation and asymptomatic patients, and values that trend upward over time appear to have prognostic importance.

Cardiac MRI is occasionally useful, especially if specific myocardial causes are being sought (such as amyloid or myocarditis) or if myocardial viability assessment is needed prior to deciding whether to add coronary artery bypass grafting to mitral valve surgery.

Cardiac catheterization provides a further assessment of regurgitation and its hemodynamic impact along with LV function, resting cardiac output, and PA pressure. *The guidelines recommend coronary angiography to determine the presence of incidental CAD prior to valve surgery in all men over age 40 years and in menopausal women with coronary risk factors.* In younger patients, no coronary angiography is needed unless there is a clinical suspicion of coronary disease. Cardiac multidetector coronary CT may be adequate to screen patients with valvular heart disease for asymptomatic CAD. A normal CT coronary angiogram has a high predictive value for patients with normal or insignificant disease.

Treatment & Prognosis

A. Primary Mitral Regurgitation

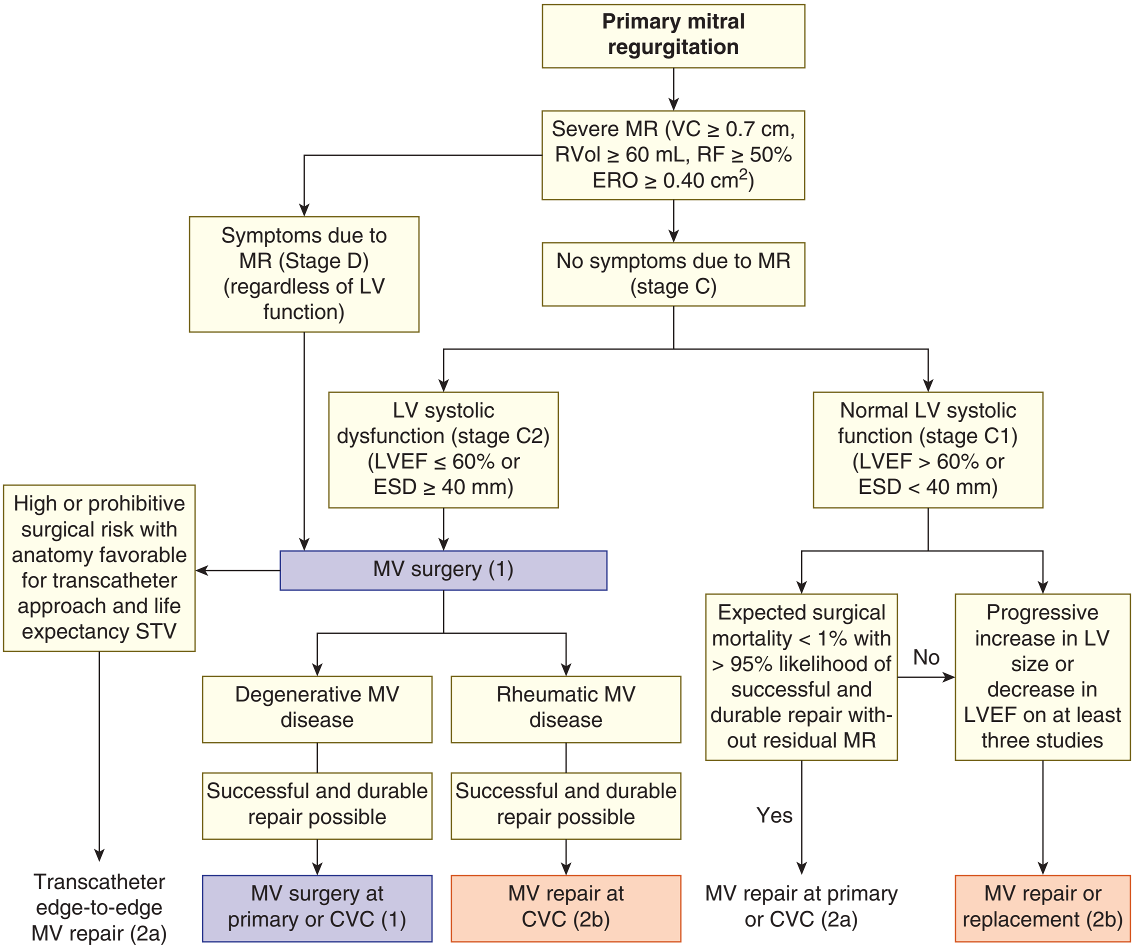
The degree of LV enlargement reflects the severity and chronicity of regurgitation. LV volume overload may ultimately lead to LV failure and reduced cardiac output. LA enlargement may be considerable in **chronic mitral**

regurgitation and a large amount of mitral regurgitation regurgitant volume may be tolerated. Patients with chronic lesions may thus remain asymptomatic for many years. Surgery is necessary when symptoms develop or when there is evidence for LV dysfunction, since progressive and irreversible deterioration of LV function can occur prior to the onset of symptoms. Early surgery is indicated even in asymptomatic patients with a reduced EF (< 60%) or marked LV dilation with reduced contractility (end-systolic dimension > 4.0 cm) (Figure 10–1).

It is a class IIa indication for mitral valve surgery when the LVEF is > 60% and the LV end-systolic dimension is still < 4.0 cm but serial imaging reveals a progressive increase in the LV end-systolic dimension or a serial decrease in the EF. Pulmonary hypertension development suggests the mitral regurgitation is severe and should prompt intervention.

Acute mitral regurgitation may develop abruptly, as with papillary muscle dysfunction following MI, valve perforation in infective endocarditis, in patients with hypertrophic cardiomyopathy (HCM), or when there are ruptured chordae tendineae in patients with mitral valve prolapse. Emergency surgery may be required.

Some patients may become hemodynamically unstable and require treatment with vasodilators or intra-aortic balloon counterpulsation that reduce the amount of retrograde regurgitant flow by lowering systemic vascular resistance and improving forward stroke volume. There is controversy regarding the role of afterload reduction in chronic mitral regurgitation, since the lesion inherently results in a reduction in afterload, and there are no data that chronic afterload reduction is effective in avoiding LV dysfunction or surgical intervention. A heightened sympathetic state has led some experts to suggest that β-blockade be considered routinely, though this also remains speculative. The mitral regurgitation in patients with tachycardia-related cardiomyopathy may improve with normalization of the heart rate.



Primary mitral regurgitation
Severe MR (VC ≥ 0.7 cm, RVol ≥ 60 mL, RF ≥ 50% ERO ≥ 0.40 cm²)
Symptoms due to MR (Stage D) (regardless of LV function)
No symptoms due to MR (stage C)
LV systolic dysfunction (stage C2) (LVEF ≤ 60% or ESD ≥ 40 mm)
Normal LV systolic function (stage C1) (LVEF > 60% or ESD < 40 mm)
High or prohibitive surgical risk with anatomy favorable for transcatheter approach and life expectancy STV
MV surgery (1)
Expected surgical mortality < 1% with > 95% likelihood of successful and durable repair without residual MR
No
Progressive increase in LV size or decrease in LVEF on at least three studies
Degenerative MV disease
Rheumatic MV disease
Successful and durable repair possible
Successful and durable repair possible
Yes
Transcatheter edge-to-edge MV repair (2a)
MV surgery at primary or CVC (1)
MV repair at CVC (2b)
MV repair at primary or CVC (2a)
MV repair or replacement (2b)

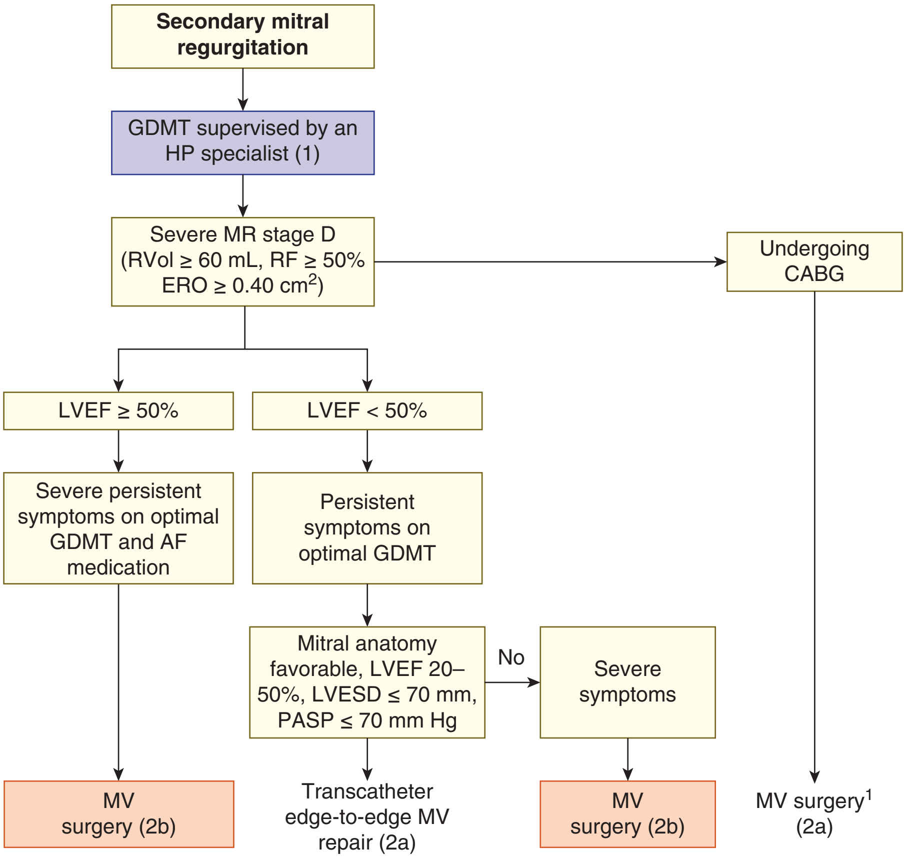
▲ **Figure 10–1.** Algorithm for intervention in primary mitral regurgitation. J Am Coll Cardiol. 2021; 77: e25–e197.)

B. Myocardial Disease and Mitral Regurgitation (Secondary Mitral Regurgitation)

When mitral regurgitation is due to cardiac dysfunction, it may subside as the infarction heals or LV dilation diminishes. The cause of the regurgitation in most of these situations is displacement of the papillary muscles and an enlarged mitral annulus rather than papillary muscle ischemia. The fundamental problem is the lack of leaflet coaptation during systole (due to either leaflet prolapse or retraction). In acute MI, rupture of the papillary muscle may occur with catastrophic results. Transient—but sometimes severe—mitral regurgitation may occur during episodes of myocardial ischemia and contribute to flash pulmonary edema. Patients with dilated cardiomyopathies of any origin may have **secondary mitral regurgitation** due to the papillary muscle displacement or dilation of the mitral annulus, or both. If mitral valve replacement is performed, preservation of the chordae to the native valve helps prevent further ventricular dilation following surgery. Initially, several groups reported good results with mitral valve repair in patients with LVEF < 30% and secondary mitral regurgitation. Guidelines advise that mitral valve repair/replacement can be attempted in severe mitral regurgitation patients with an EF < 30% or an LV end-systolic dimension > 5.5 cm, or both, as long as repair and preservation of the chordae are possible. Figure 10–2 outlines the recommendations for intervention in secondary mitral regurgitation.

Mitral valve replacement with chordal preservation is preferred over mitral valve repair in patients with chronic ischemic cardiomyopathy. There may also be a role for cardiac resynchronization therapy with biventricular pacemaker insertion, which has been found to reduce mitral regurgitation related to cardiomyopathy in many patients. Guidelines recommend biventricular pacing prior to surgical repair in symptomatic patients who have functional mitral regurgitation as long as other criteria (eg, a QRS of > 150 msec or left bundle branch block or both) are present.

There are several ongoing trials of percutaneous approaches to reducing mitral regurgitation. These approaches



Secondary mitral regurgitation
GDMT supervised by an HP specialist (1)
Severe MR stage D (RVol ≥ 60 mL, RF ≥ 50% ERO ≥ 0.40 cm²)
Undergoing CABG
LVEF ≥ 50%
LVEF < 50%
Severe persistent symptoms on optimal GDMT and AF medication
Persistent symptoms on optimal GDMT
Mitral anatomy favorable, LVEF 20–50%, LVESD ≤ 70 mm, PASP ≤ 70 mm Hg
No
Severe symptoms
MV surgery (2b)
Transcatheter edge-to-edge MV repair (2a)
MV surgery (2b)
MV surgery¹ (2a)

[1] Chordal-sparing MV replacement may be reasonable to choose over downsized annuloplasty repair.

Figure 10–2. Algorithm for intervention in secondary mitral regurgitation. AF, atrial fibrillation; CABG, coronary artery bypass graft; ERO, effective regurgitant orifice; GDMT, guideline-directed management and therapy; LVESD, LV end-systolic dimension; MR, mitral regurgitation; MV, mitral valve; PASP, pulmonary artery systolic pressure; RF, regurgitant fraction; RVol, regurgitant volume. (Reproduced with permission from Otto CM et al. 2020 ACC/AHA guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology. J Am Coll Cardiol. 2021; 77: e25–e1.)

include the use of a **mitral clip** (MitraClip) device to create a double-orifice mitral valve, various coronary catheter devices to reduce the mitral annular area, and devices to reduce the septal-lateral ventricular size and consequent mitral orifice size. Of these devices, the most success has been noted with the edge-to-edge MitraClip. Guidelines have accepted the use of the MitraClip in patients with secondary mitral regurgitation and high surgical risk. In addition, vascular plugging and occluder devices are being used in selected patients to occlude perivalvular leaks around prosthetic mitral valves. A transcatheter stented valve, which is used as a **transcatheter aortic valve replacement (TAVR)** device, can be used to open a degenerated mitral bioprosthetic valve in any position (aortic, mitral, tricuspid, or pulmonary). Transcatheter valve replacement has also been attempted in small series to repair mitral regurgitation following mitral valve repair with mixed results. Finally, the first cases of a stented mitral valve prosthesis to replace the entire mitral valve have been reported. Abbott has initiated the SUMMIT trial, a US-based pivotal trial utilizing the Tendyne percutaneous mitral valve replacement device. The mitral valve and aortic valve share a common "annulus" and some of the early attempts at percutaneous valve replacement have failed due to obstruction of the aortic outflow.

When to Refer

- All patients with more than mild mitral regurgitation should be referred to a cardiologist for an evaluation.
- Serial examinations and echocardiograms should be obtained and surgical referral made if there is an increase in the LV end-systolic dimensions, a fall in the LVEF to < 60%, symptoms, evidence for pulmonary hypertension, or the new onset of atrial fibrillation.
- There is evidence that mitral valve repair should be done early in the course of the disease to improve mortality and morbidity.
- Treatment in severe mitral regurgitation in a patient with a dilated cardiomyopathy may be of benefit.

AORTIC STENOSIS

ESSENTIALS OF DIAGNOSIS

- Congenital bicuspid aortic valve (usually asymptomatic until middle or old age).
- "Degenerative" or calcific aortic stenosis; similar risk factors as atherosclerosis
- Visual observation of immobile aortic valve plus a valve area of < 1.0 cm^2 define severe disease; low-gradient but severe aortic stenosis can thus be recognized when the stroke volume is reduced.
- Echocardiography/Doppler is diagnostic.
- Surgery typically indicated for symptoms. TAVR is approved for patients with calcific aortic stenosis.
- Intervention appropriate even in asymptomatic patients with super-severe aortic stenosis (mean gradient > 55 mm Hg) or when undergoing heart surgery for other reasons (eg, coronary artery bypass grafting [CABG]).
- BNP is a marker of early LV myocardial failure, and high levels (three times normal) suggest poor prognosis and can be an indication for intervention.

General Considerations

There are two common clinical scenarios in which aortic stenosis is prevalent. The first is due to a congenitally abnormal **unicuspid** or **bicuspid valve,** rather than tricuspid. Symptoms can occur in young or adolescent individuals if the stenosis is severe, but more often emerge at age 50–65 years when calcification and degeneration of the valve become manifest. A dilated ascending aorta, due to an intrinsic defect in the aortic root media and the hemodynamic effects of the eccentric aortic jet, may accompany the bicuspid valve in about half of these patients. Coarctation of the aorta is also seen in a number of patients with congenital aortic stenosis. Offspring of patients with a bicuspid valve have a much higher incidence of the disease in either the valve, the aorta, or both (up to 30% in some series).

A second, more common pathologic process, **degenerative** or **calcific aortic stenosis**, is thought to be related to calcium deposition due to processes similar to those that occur in atherosclerotic vascular disease. Approximately 25% of patients over age 65 years and 35% of those over age 70 years have echocardiographic evidence of aortic valve thickening (**sclerosis**). About 10–20% of these will progress to hemodynamically significant aortic stenosis over a period of 10–15 years.

Aortic stenosis has become the most common surgical valve lesion in developed countries, and many patients are older adults. The risk factors include hypertension, hypercholesterolemia, and smoking. HCM may also coexist with valvular aortic stenosis.

Clinical Findings

A. Symptoms and Signs

Slightly narrowed, thickened, or roughened valves **(aortic sclerosis)** or aortic dilation may contribute to the typical ejection murmur of aortic stenosis. In mild or moderate cases where the valve is still pliable, an ejection click may precede the murmur and the closure of the valve (S_2) is preserved. The characteristic systolic ejection murmur is heard at the aortic area and is usually transmitted to the neck and apex. In severe aortic stenosis, a palpable LV heave or thrill, a weak to absent aortic second sound, or reversed splitting of the second sound is present (see Table 10–2). In some cases, only the high-pitched components of the murmur are heard at the apex, and the murmur may sound like mitral regurgitation (the so-called **Gallavardin phenomenon**). When the valve area is < 0.8–1.0 cm^2 (normal, 3–4 cm^2), ventricular systole becomes prolonged and the typical carotid pulse pattern of delayed upstroke and low amplitude is present. A delayed upstroke, though, is an *unreliable* finding in older patients with extensive arteriosclerotic vascular disease and a stiff, noncompliant aorta. LVH increases progressively due to the pressure overload, eventually resulting in elevation of ventricular end-diastolic pressure. Cardiac output is maintained until the stenosis is severe. LV failure, angina pectoris, or syncope may be presenting symptoms of significant aortic stenosis; importantly, all symptoms tend to first occur with exertion.

B. Redefining Severe Aortic Stenosis

There are four different anatomic syndromes that occur in patients with severe aortic stenosis. The common underlying measure of **severe aortic stenosis** is an aortic valve area of < 1.0 cm^2 and echocardiographic evidence of an immobile aortic valve. In patients with a normal LVEF and normal cardiac output, the threshold for intervention is a peak aortic gradient of > 64 mm Hg and mean aortic gradient of > 40 mm Hg. In the same situation, **super-severe aortic stenosis** is defined as a mean gradient of > 55 mm Hg or peak aortic velocity > 5 m/sec by Doppler.

In some patients with an aortic valve area of < 1.0 cm^2 with a low cardiac output and stroke volume, the mean gradient may be < 40 mm Hg. This can occur when the LV systolic function is poor (**low-gradient severe aortic stenosis with low LVEF**) or when the LV systolic function is normal **(paradoxical low-flow severe aortic stenosis with a normal LVEF).** Low flow (low output) in these situations is defined by an echocardiographic stroke volume index of < 35 mL/min/m^2. Prognosis in patients with low gradient, low valve area, low output, and a normal LVEF aortic stenosis actually may be worse than in patients with the traditional high gradient, low valve area, normal output, and normal LVEF aortic stenosis. If low-flow severe aortic stenosis is present in the face of a low LVEF, provocative testing with dobutamine or nitroprusside is sometimes warranted to increase the stroke volume to discover if a mean aortic valve gradient of at least 40 mm Hg can be demonstrated without increasing the aortic valve area. If the aortic valve area can be made to increase and a mean gradient of > 40 mm Hg cannot be demonstrated by inotropic challenge, the presumption is that the low gradient is due to an associated cardiomyopathy and not the aortic valve stenosis. In this latter situation, intervention is not indicated. The guidelines acknowledge these four situations (Table 10–5). Intervention is indicated in super-severe aortic stenosis even without demonstrable symptoms (grade C) and in any of the other situations when symptoms are present: D1 defines the symptomatic high-gradient patient; D2 the symptomatic low-flow, low-gradient patient with low LVEF; and D3 the symptomatic low-flow, low-gradient patient with normal LVEF.

Symptoms of LV failure may be sudden in onset or may progress gradually. Angina pectoris frequently occurs in aortic stenosis due to underperfusion of the endocardium. Of patients with calcific aortic stenosis and angina, half have significant associated CAD. Syncope, a late finding, occurs with exertion as the LV pressure rises, stimulating the LV baroreceptors to cause peripheral vasodilation. This vasodilation results in the need for an increase in stroke volume, which increases the LV systolic pressure again, creating a cycle of vasodilation and stimulation of the baroreceptors that eventually results in a drop in systemic BP, as the stenotic valve prevents further increase in stroke volume. Less commonly, syncope may be due to arrhythmias (usually ventricular tachycardia but sometimes AV block as calcific invasion of the conduction system from the aortic valve may occur).

Table 10–5. Summary of AHA/ACC guideline definitions of symptomatic severe aortic stenosis.

Category of Severe Aortic Stenosis[1]	Properties
High Gradient	
High gradient	> 4.0 m/sec Doppler jet velocity > 40 mm Hg mean gradient
Super-severe	> 5.0 m/sec Doppler jet velocity > 55 mm Hg mean gradient
Low Gradient	
Low flow	Reduced LVEF (< 50%)
Low flow	Paradoxical with normal LVEF (> 50%)

[1] All categories of severe aortic stenosis have abnormal systolic opening of the aortic valve and an aortic valve area < 1.0 cm^2.

C. Diagnostic Studies

The ECG reveals LVH or secondary repolarization changes in most patients but can be normal in up to 10%. The CXR may show (1) a normal or enlarged cardiac silhouette, (2) calcification of the aortic valve, and (3) dilation or calcification (or both) of the ascending aorta. The echocardiogram provides useful data about aortic valve calcification and leaflet opening, the severity of LV wall thickness, and overall ventricular function, while Doppler can provide an excellent estimate of the aortic valve gradient. *Valve area estimation by echocardiography is a critical component of the diagnosis of aortic stenosis due to issues such as paradoxical low-flow aortic stenosis (low-gradient, low-flow, normal LVEF patients).* Likewise, the echocardiography/Doppler can estimate the stroke volume index used to define the low-flow state when the valve area is small but the gradient is < 40 mm Hg. Cardiac catheterization mostly provides an assessment of the hemodynamic consequence of the aortic stenosis, and the anatomy of the coronary arteries. Catheterization data can be important when there is a discrepancy between symptoms and the echocardiography/Doppler information of aortic stenosis severity. In younger patients and in patients with high aortic gradients, the aortic valve need not be crossed at catheterization. Aortic regurgitation can be semiquantified by aortic root angiography. Either BNP or NT-proBNP may provide additional prognostic data in the setting of poor LV function and aortic stenosis. A BNP > 550 pg/mL has been associated with a poor outcome in these patients regardless of the results of dobutamine testing. Guidelines suggest intervention when the NT-proBNP is three times normal (class IIa indication). Stress testing can be done cautiously in patients in whom the aortic stenosis severity does not match the reported symptoms to confirm the reported clinical status. It should *not* be done in patients with super-severe aortic stenosis.

Prognosis & Treatment

Valve intervention is warranted in all patients who have symptomatic severe aortic stenosis (Figure 10–3). There are also times when asymptomatic aortic stenosis should undergo intervention. Asymptomatic patients with severe aortic stenosis (aortic valve area < 1.0 cm^2) should generally undergo intervention according to the following guidelines: (1) they are undergoing other cardiac surgery (ie, CABG), (2) there is evidence for a reduced LVEF (< 50%), (3) when the mean gradient exceeds 55 mm Hg (peak velocity > 5 m/sec), (4) when there is exercise intolerance or when the BP falls > 10 mm Hg with exercise, (5) when there is severe valvular calcium, (6) when there is evidence of a rapid increase in the peak aortic gradient (> 0.3 m/sec/year), (7) when there has been a progressive decrease in the LVEF, or (8) when the NT-proBNP is three times normal. Following the onset of HF, angina, or syncope, the prognosis without surgery is poor (50% 3-year mortality rate). Medical treatment may stabilize patients in HF, but intervention is indicated for all symptomatic patients with evidence of significant aortic stenosis.

The surgical mortality rate for valve replacement is low, even in older adults, and ranges from 2% to 5%. This low risk is due to the dramatic hemodynamic improvement

that occurs with relief of the increased afterload. Mortality rates are substantially higher when there is an associated ischemic cardiomyopathy. Severe coronary lesions are usually bypassed at the same time as aortic valve replacement (AVR), although there are few data to suggest this practice affects outcome. In some cases, a staged procedure with stenting of the coronaries prior to surgery may be considered, especially if a percutaneous AVR approach is being considered. Around one-third to one-half of all patients with aortic stenosis have significant CAD, so this is a common concern. With the success of **TAVR** or **transcatheter aortic valve implantation (TAVI),** the treatment options have greatly expanded for many patients with severe aortic stenosis. For this reason, a **Heart Valve Team** approach bringing together invasive and noninvasive cardiologists, radiologists, anesthesiologists, and cardiac surgeons is mandatory; clinical factors (such as frailty) and anatomic features (such as a calcified aorta, vascular access, etc) can affect the decision making.

Medical therapy to reduce the progression of disease has *not* been effective to date. Statins have been assessed in four major clinical trials. None revealed any benefit on the progression of aortic stenosis or on clinical outcomes despite the association of aortic stenosis with atherosclerosis. If patients with aortic stenosis have concomitant CAD, the guidelines for the use of statins should be followed. Efforts to reduce stenosis progression by blockage of the renin-angiotensin system have also been ineffective, although they are recommended for patients who have undergone TAVR. Control of systemic hypertension is an important adjunct, and inadequate systemic BP control is all too common due to unreasonable concerns about providing too much afterload reduction in patients with aortic stenosis. Normal systemic BP is important to maintain as the LV is affected by the total afterload (systemic BP plus the aortic valve gradient).

The interventional options in patients with aortic valve stenosis has expanded with the use of TAVR and depend on the patient's lifestyle and age. The algorithm to decide when an AVR is appropriate in various situations is outlined in Figure 10–4.

TAVR has been shown to be equivalent to surgical AVR (SAVR) in all the randomized trials of symptomatic patients, including those at low risk for surgery (< 4%). Surgery is recommended for patients younger than 65 years or with a life expectancy of > 20 years. TAVR is recommended for all patients older than 80 years. Either SAVR or TAVR can be considered for all patients between 65 and 80 years. The decision about whether to perform SAVR or TAVR should be made by the Heart Team; anatomic issues (such as an enlarged aorta, a coronary that might be trapped by a leaflet when the valve is inserted, an annulus too large or too small, extensive LV outflow tract calcium, etc) are often the deciding factors for whether TAVR can be done.

In young and adolescent patients, percutaneous balloon valvuloplasty still has a very small role. Balloon valvuloplasty is associated with early restenosis in older adults and, thus, is rarely used except as a temporizing measure prior to a more permanent SAVR or TAVR. Data suggest aortic balloon valvuloplasty in older adults has an advantage only in those with preserved LV function, and such patients are usually excellent candidates for SAVR or TAVR.

The **Ross procedure** is generally still considered a viable option in younger patients with a bicuspid valve, and it is performed by moving the patient's own pulmonary valve and a portion of its root to the aortic position and replacing the pulmonary valve with a homograft (or rarely a bioprosthetic valve). The coronaries require reimplantation. However, dilation of the pulmonary valve autograft and consequent aortic regurgitation, plus early stenosis of the pulmonary homograft in the pulmonary position, has reduced the enthusiasm for this approach in most institutions. Guidelines suggest the Ross procedure should only be considered in those younger than 50 years. Middle-aged and younger adults generally can tolerate the anticoagulation therapy necessary for the use of mechanical aortic valves, so patients younger than 50 years generally undergo AVR with a bileaflet mechanical valve. If the aortic root is severely dilated as well (> 4.5 cm), then the valve may be housed in a Dacron sheath (**Bentall procedure**) and the root replaced along with the aortic valve. Alternatively, a human homograft root and valve replacement can be used. In patients older than 50 years, bioprosthetic (either porcine or bovine pericardial) valves with a life expectancy of about 10–15 years are routinely used instead of mechanical valves to avoid need for anticoagulation. Data favor the bovine pericardial valve over the porcine aortic valve. Bioprosthetic valve degeneration in the larger valves can be potentially repaired by percutaneous valve-in-valve TAVR. If the aortic annulus is small, a bioprosthetic valve with a short sheath can be sewn to the aortic wall (the stentless AVR) rather than sewing the prosthetic annulus to the aortic annulus. ("Annulus" is a relative term when speaking of the aortic valve, since there is no true annulus.) Another popular surgical option when the aorta is enlarged is the use of the **Wheat procedure;** it involves aortic root replacement above the coronary arteries and replacement of the aortic valve below the coronary arteries. The coronary arteries thus remain attached to the native aorta between the new graft and prosthetic valve rather than being reimplanted onto an artificial sheath or homograft. Newer aortic valve replacements can be placed quickly through a small incision and often require only three stitches to anchor (ie, the **Perceval** or **Intuity valve replacements**). These can shorten pump times at surgery.

In patients with a bicuspid aortic valve, there is an associated ascending aortic aneurysm in about half. If the maximal dimension of the aortic root is > 5.5 cm, it is recommended to proceed with root replacement regardless of the severity of the aortic valve disease. It is also appropriate to intervene when the maximal aortic root size is > 5.0 cm in diameter if there is a family history of aortic dissection or the aortic root size increases by > 0.5 cm in 1 year. The aortic valve may be replaced at the same time if at least moderate aortic stenosis is present or may be either left alone or repaired (valve sparing operation). If there is an indication for AVR and the root is > 4.5 cm in diameter, root replacement is also recommended at the time of SAVR.

The use of mechanical versus bioprosthetic AVR has changed over time. A bioprosthetic valve is acceptable for

patients at any age for whom anticoagulant therapy is contraindicated, not desired, or cannot be managed, and is preferred in patients over the age of 65. An aortic mechanical valve should be used in patients younger than 50 years of age who can take warfarin. Shared decision making is key especially for patients 50–65 years old. ***Anticoagulation** with warfarin is required with the use of mechanical aortic valves, and the INR should be maintained between 2.0 and 3.0 for bileaflet valves*. In general, mechanical aortic valves are less subject to thrombosis than mechanical mitral valves and do *not* require bridging with enoxaparin unless there are other thromboembolic risk factors or it is an older generation AVR. Low-dose aspirin (eg, 81 mg daily) is recommended if there is a low bleeding risk. Some newer bileaflet mechanical valves (On-X) allow for a lower INR range from 1.5 to 2.0. Clopidogrel is recommended for the first 6 months after TAVR in combination with lifelong low-dose aspirin therapy (**dual antiplatelet therapy**). DOACs are *not* recommended for any mechanical valves but may be used in patients with a bioprosthetic AVR if treating atrial fibrillation or venous thrombosis.

The use of TAVR has grown dramatically. The Edwards SAPIEN valve is a balloon-expandable valvular stent, while the CoreValve is a valvular stent that self-expands when pushed out of the catheter sheath. Five-year outcome data comparing SAVR with TAVR show no difference in death or stroke at five years with lower rates of atrial fibrillation and shorter length of procedure stay observed in patients undergoing TAVR. Cost remains a major issue. The cost of TAVR is similar to SAVR, mostly due to the cost of the valve itself. All of the professional societies stress the importance of a Heart Valve Team when considering aortic stenosis intervention.

TAVR is also being used more frequently in **"valve-in-valve" procedures** to reduce the gradient with bioprosthetic valve dysfunction in patients at high risk of repeat cardiac surgical valve replacement (regardless of whether in the aortic, mitral, tricuspid, or pulmonary position). While the results of TAVR in patients with bicuspid aortic valves (as opposed to tricuspid) have been less impressive, newer modifications have improved the success rates in these anatomic situations as well. This is supported by data from the TVT registry showing similar procedural and 1-year outcomes for patients with bicuspid or tricuspid aortic valve stenosis.

When to Refer

- All patients with echocardiographic evidence for mild to moderate aortic stenosis (estimated peak valve gradient > 30 mm Hg by echocardiography/Doppler) should be referred to a cardiologist for evaluation and to determine the frequency of follow-up.
- Any patients with symptoms suggestive of aortic stenosis (ie, exertional symptoms of chest pressure, shortness of breath, or presyncope) should be seen by a cardiologist.

Mack MJ et al; PARTNER 3 Investigators. Transcatheter aortic-valve replacement in low-risk patients at five years. N Engl J Med. 2023;389:1949. [PMID: 37874020]

AORTIC REGURGITATION

ESSENTIALS OF DIAGNOSIS

- Usually asymptomatic until middle age; presents with left-sided failure or rarely chest pain.
- Echocardiography/Doppler is diagnostic.
- Surgery for symptoms, EF < 50%, LV end-systolic dimension > 50 mm, or LV end-diastolic dimension > 65 mm.

General Considerations

Of all patients with isolated aortic valve disease, about 13% have predominately aortic regurgitation. Rheumatic aortic regurgitation has become much less common than in the preantibiotic era, and nonrheumatic causes now predominate. These include congenitally bicuspid valves, infective endocarditis, and hypertension. Many patients also have aortic regurgitation secondary to aortic root diseases, such as that associated with Marfan syndrome or aortic dissection. Rarely, inflammatory diseases, such as ankylosing spondylitis, may be implicated.

Clinical Findings

A. Symptoms and Signs

The clinical presentation is determined by the rapidity with which regurgitation develops. In **chronic aortic regurgitation,** the only sign for many years may be a soft aortic diastolic murmur. As the severity of the aortic regurgitation increases, diastolic BP falls, and the LV progressively enlarges. Most patients remain asymptomatic for long periods even at this point. LV failure is a late event and may be sudden in onset. Exertional dyspnea and fatigue are the most frequent symptoms, but paroxysmal nocturnal dyspnea and pulmonary edema may also occur. Angina pectoris or atypical chest pain may occasionally be present. Associated CAD and presyncope or syncope are less common than in aortic stenosis.

Hemodynamically, because of compensatory LV dilation, patients eject a large stroke volume, which is adequate to maintain forward cardiac output until late in the course of the disease. LV diastolic pressure may rise when HF occurs. Abnormal LV systolic function as manifested by reduced EF (< 50%) and increasing end-systolic LV volume (> 5.0 cm) are signs that surgical intervention is warranted.

The major physical findings in chronic aortic regurgitation relate to the high stroke volume being ejected into the systemic vascular system with rapid runoff as the regurgitation takes place (see Table 10–2). This results in a **wide arterial pulse pressure.** The pulse has a rapid rise and fall (**water-hammer pulse** or **Corrigan pulse**), with an elevated systolic and low diastolic pressure. The large stroke volume and flow back into the heart are also responsible for characteristic findings, such as **Quincke pulses** (nailbed capillary pulsations), **Duroziez sign** (to-and-fro murmur over a partially compressed femoral peripheral artery), and

Musset sign (head bob with each pulse). In younger patients, the increased stroke volume may summate with the pressure wave reflected from the periphery and create a higher than expected systolic pressure in the lower extremities compared with the central aorta. Since the peripheral bed is much larger in the leg than the arm, the BP in the leg may be over 40 mm Hg higher than in the arm (**Hill sign**) in severe aortic regurgitation. The apical impulse is prominent, laterally displaced, usually hyperdynamic, and may be sustained. A systolic flow murmur is usually present and may be quite soft and localized; the aortic diastolic murmur is usually high-pitched and decrescendo. A mid or late diastolic low-pitched mitral murmur (**Austin Flint murmur**) may be heard in advanced aortic regurgitation, owing to relative obstruction of mitral inflow produced by partial closure of the mitral valve by the rapidly rising LV diastolic pressure due to the aortic regurgitation.

In **acute aortic regurgitation** (usually from aortic dissection or infective endocarditis), LV failure is manifested primarily as pulmonary edema and may develop rapidly; surgery is urgently required in such cases. Patients with acute aortic regurgitation do not have the dilated LV of chronic aortic regurgitation and the extra LV volume is handled poorly. For the same reason, the diastolic murmur is shorter, may be minimal in intensity, and the pulse pressure may not be widened—making clinical diagnosis difficult. The mitral valve may close prematurely even before LV systole has been initiated (**preclosure**) due to the rapid rise in the LV diastolic pressure, and the first heart sound is thus diminished or inaudible. Preclosure of the mitral valve can be readily detected on echocardiography and is considered an indication for urgent surgical intervention.

B. Diagnostic Studies

The ECG usually shows moderate to severe LVH. Radiographs show cardiomegaly with LV prominence and sometimes a dilated aorta.

Echocardiography demonstrates the major diagnostic features, including whether the lesion includes the proximal aortic root and what valvular pathology is present. *Annual assessments of LV size and function are critical in determining the timing for valve replacement when the aortic regurgitation is severe.* The 2020 ACC/AHA valvular guideline provides criteria for assessing the severity of aortic regurgitation. Cardiac MRI and CT can estimate aortic root size, particularly when there is concern for an ascending aneurysm. MRI can provide a regurgitant fraction to help confirm severity. Cardiac catheterization may be unnecessary in younger patients, particularly those with acute aortic regurgitation, but can help define hemodynamics, aortic root abnormalities, and associated CAD preoperatively in older patients. Increasing data are emerging that serum BNP or NT-proBNP may be an early sign of LV dysfunction, and it is possible that these data will be added to recommendations for surgical intervention in the future.

▶ Treatment & Prognosis

Aortic regurgitation that appears or worsens during or after an episode of infective endocarditis or aortic dissection may lead to acute severe LV failure or subacute progression over weeks or months. The former usually presents as pulmonary edema; surgical replacement of the valve is indicated even during active infection. These patients may be transiently improved or stabilized by vasodilators.

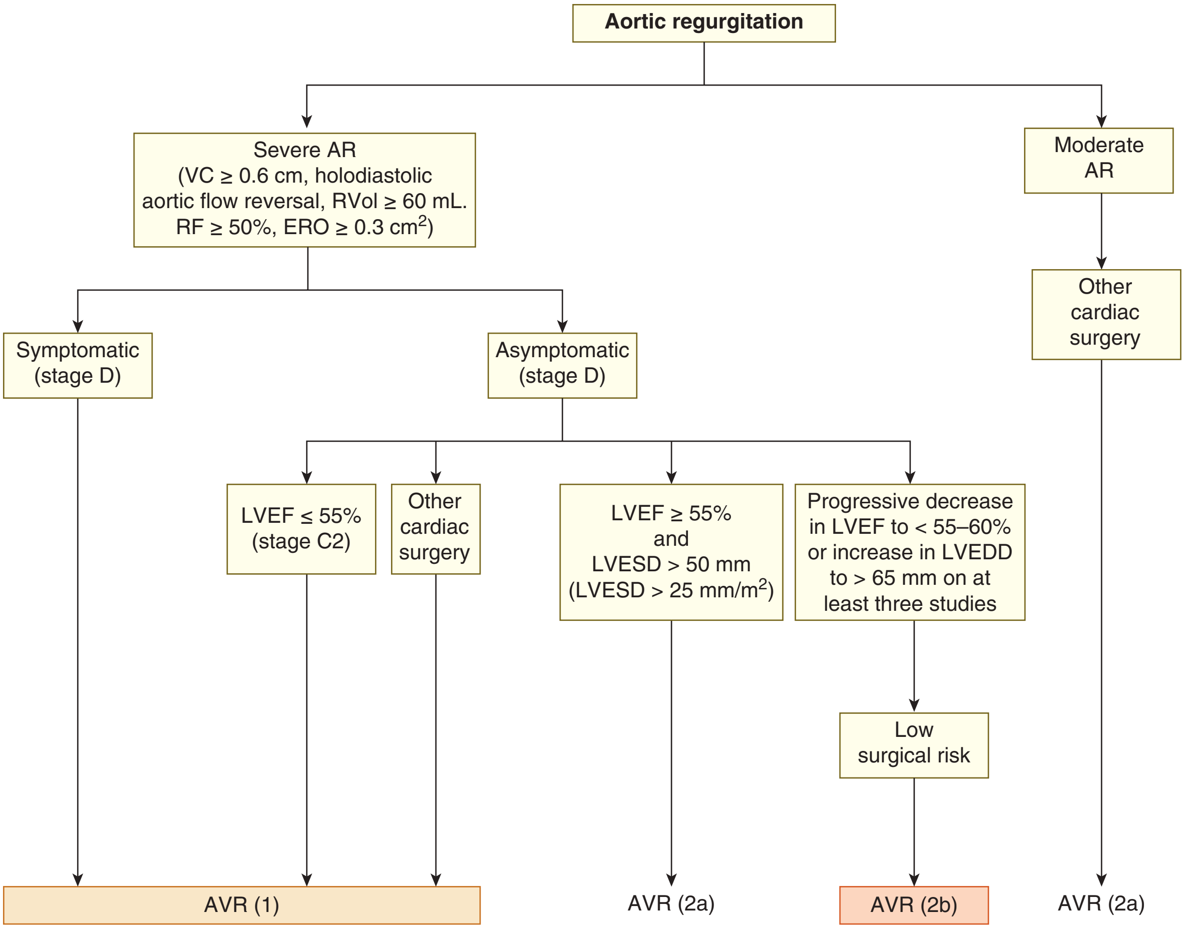
Chronic aortic regurgitation may be tolerated for many years, but the prognosis without surgery becomes poor when symptoms occur. Since aortic regurgitation places both a preload (volume) and afterload increase on the LV, medications that decrease afterload can reduce regurgitation severity, although there are no convincing data that afterload reduction alters mortality. *Recommendations advocate afterload reduction in aortic regurgitation only when there is associated systolic hypertension (systolic BP > 140 mm Hg).* Afterload reduction in normotensive patients does not appear warranted. ARBs, rather than β-blockers, are the preferred additions to the medical therapy in patients with an enlarged aorta, such as in Marfan syndrome, because of the theoretical ability of an ARB to reduce aortic stiffness (by blocking TGF-β) and to slow the rate of aortic dilation. However, clinical trials evaluating the efficacy of ARBs to reduce aortic stiffness and slow the rate of aortic dilation have not yielded a positive outcome to support their use.

Surgery is indicated once symptoms emerge or for any evidence of LV dysfunction (as exhibited by a reduction in the LVEF to < 55% or increase in the LV end-systolic diameter to > 50 mm by echocardiography). In addition, it is suggested that surgery should be considered even when the LV becomes excessively enlarged (LV end-diastolic diameter > 65 mm). Guidelines also suggest it be considered (class IIb) if serial imaging reveals a progressive increase in the size of the LV (Figure 10–5).

The issues with AVR covered in the above section concerning aortic stenosis pertain here. Early trials of TAVR had a high incidence of postprocedural residual aortic regurgitation (18.8% in one trial). Newer TAVR valves have greatly reduced residual aortic regurgitation when used in patients with pure native aortic regurgitation (4.2%). In multivariable analysis, postprocedural at least moderate aortic regurgitation was independently associated with 1-year all-cause mortality. Compared with the early-generation devices, TAVR using the new-generation devices was associated with improved procedural outcomes in treating patients with pure native aortic regurgitation. In patients with pure native aortic regurgitation, significant postprocedural aortic regurgitation was independently associated with increased mortality.

Aortic regurgitation due to a paravalvular prosthetic valve defect can occasionally be occluded with percutaneous occluder devices. *The choice of prosthetic valve for AVR depends on the patient's age and compatibility with warfarin anticoagulation similar to the choices for AVR in aortic stenosis.*

The operative mortality for AVR is usually in the 3–5% range. Aortic regurgitation due to aortic root disease requires repair or replacement of the root as well as surgical treatment of the aortic valve. Although valve-sparing operations have improved recently, most patients with root replacement undergo valve replacement at the same time.



Aortic regurgitation

▲ **Figure 10–5.** Algorithm for intervention in aortic regurgitation. AR, aortic regurgitation; AVR, aortic valve replacement; EDD, end-diastolic dimension; ERO, effective regurgitant orifice; LVESD, LV end-systolic dimension; RF, regurgitant fraction; RVol, regurgitant volume; VC, vena contracta. (Reproduced with permission from Otto CM et al. 2020 ACC/AHA guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology. J Am Coll Cardiol. 2021;77: e25–e197.)

Root replacement in association with valve replacement may require anastomosis of the coronary arteries, and thus the procedure is more complex than valve replacement alone. The **Wheat procedure** replaces the aortic root but spares the area where the coronaries attach to avoid the necessity for their reimplantation. Following any aortic valve surgery, LV size usually decreases and LV function generally improves even when the baseline EF is depressed.

Repair of the aortic root in patients with a bicuspid valve should be done once the root diameter exceeds 5.5 cm regardless of aortic valve disease severity. There are data that dissection is much more prevalent when the aortic root diameter exceeds 6.0 cm, and the general sense is not to let it approach that size. Patients with risk factors (family history of dissection or an increase in the diameter of the root > 0.5 cm in 1 year) should have the aorta repaired when the maximal dimension exceeds 5.0 cm. The following classifications summarize when to operate on the aortic root in patients with a bicuspid aortic valve based on the guidelines:

Class I indication (LOE C): aortic root diameter at sinuses or ascending aorta > 5.5 cm (regardless of need for AVR).

Class IIa indication (LOE C): aortic root diameter at sinuses or ascending aorta > 5.0 cm when there are associated risk factors (family history of dissection or increase in size > 0.5 cm in 1 year).

Class IIa indication (LOE C): aortic root diameter > 4.5 cm if patient undergoing AVR for valvular reasons.

▶ When to Refer

- Patients with audible aortic regurgitation should be seen, at least initially, by a cardiologist who can determine whether the patient needs follow-up.
- Patients with a dilated aortic root should be monitored by a cardiologist, since imaging studies other than the CXR or echocardiogram may be required to decide surgical timing.

TRICUSPID STENOSIS

ESSENTIALS OF DIAGNOSIS

- Female predominance.
- History of rheumatic heart disease most likely. Carcinoid disease and prosthetic valve degeneration are the most common etiologies in the United States.
- Echocardiography/Doppler is diagnostic.

General Considerations

Tricuspid stenosis is rare, affecting < 1% of the population in developed countries and < 3% worldwide. Native valve tricuspid valve stenosis is usually rheumatic in origin. In the United States, tricuspid stenosis is more commonly due to prior tricuspid valve repair or replacement or to the carcinoid syndrome. The incidence of tricuspid stenosis after tricuspid valve replacement increases considerably after 8 years post surgery. Tricuspid regurgitation frequently accompanies the lesion. It should be suspected when right HF appears in the course of mitral valve disease or in the postoperative period after tricuspid valve repair or replacement.

Clinical Findings

A. Symptoms and Signs

Tricuspid stenosis is characterized by right HF with hepatomegaly, ascites, and dependent edema. In sinus rhythm, a giant *a* wave is seen in the JVP, which is also elevated (see Table 10–2). The typical **diastolic rumble** along the lower left sternal border mimics mitral stenosis, though in tricuspid stenosis the rumble *increases with inspiration*. In sinus rhythm, a presystolic liver pulsation may be found. It should be considered when patients exhibit signs of carcinoid syndrome.

B. Diagnostic Studies

In the absence of atrial fibrillation, the ECG reveals RA enlargement. The CXR may show marked cardiomegaly with a normal PA size. A dilated superior vena cava and azygous vein may be evident.

The normal valve area of the tricuspid valve is 10 cm^2, so significant stenosis must be present to produce a gradient. Hemodynamically, a mean diastolic pressure gradient > 5 mm Hg is considered significant, although even a 2 mm Hg gradient can be considered abnormal. This can be demonstrated by echocardiography or cardiac catheterization. The 2017 update of the 2014 AHA/ACC guidelines suggests a tricuspid valve area of < 1.0 cm^2 and a pressure half-time longer than 190 msec should be defined as significant because the gradient may vary depending on the heart rate.

Treatment & Prognosis

Tricuspid stenosis may be progressive, eventually causing severe right-sided HF. Initial therapy is directed at reducing the fluid congestion, with diuretics the mainstay (see Chapter 11). When there is considerable bowel edema, torsemide or bumetanide may have an advantage over other loop diuretics, such as furosemide, because they are better absorbed from the gut. Aldosterone inhibitors also help, particularly if there is liver engorgement or ascites. Neither surgical nor percutaneous valvuloplasty is particularly effective for relief of tricuspid stenosis, as residual tricuspid regurgitation is common. Tricuspid valve replacement is the preferred surgical approach. Mechanical tricuspid valve replacement is rarely done because the low flow predisposes to thrombosis and because the mechanical valve cannot be crossed should the need arise for right heart catheterization or pacemaker implantation. Therefore, *bioprosthetic valves are almost always preferred.* Often tricuspid valve replacement is performed in conjunction with mitral valve replacement for rheumatic mitral stenosis or regurgitation. Percutaneous transcatheter valve replacement (stented valve) has been used in degenerative tricuspid prosthetic valve stenosis and a percutaneous tricuspid valve replacement device is being investigated. The indications for valve replacement in severe tricuspid stenosis are straightforward:

Class I indication (LOE C): at time of operation for left-sided valve disease.

Class I indication (LOE C): if symptomatic.

Class IIb indication (LOE C): rarely percutaneous balloon commissurotomy for isolated tricuspid stenosis in high-risk patients with no significant tricuspid regurgitation.

When to Refer

All patients with any evidence for tricuspid stenosis on an echocardiogram should be seen and monitored by a cardiologist to assess when intervention may be required.

TRICUSPID REGURGITATION

ESSENTIALS OF DIAGNOSIS

- Frequently occurs in patients with pulmonary or cardiac disease with pressure or volume overload on the RV.
- Tricuspid valve regurgitation from pacemaker lead placement is becoming more common.
- Echocardiography useful in determining cause (low- or high-pressure tricuspid regurgitation).

General Considerations

Tricuspid valvular regurgitation often occurs whenever there is RV dilation from any cause. As tricuspid regurgitation increases, the RV size increases further pulling the valve open due to chordal and papillary muscle displacement. This, in turn, worsens the severity of the tricuspid regurgitation. In addition, the tricuspid annulus is shaped like a horse's saddle.

With RV failure, the annulus flattens and becomes elliptical, further distorting the relationship between the leaflets and chordal attachments. In most cases, the cause of the tricuspid regurgitation is the RV geometry (functional) and not primary tricuspid valve disease. An enlarged, dilated RV may be present if there is RV systolic hypertension from valvular or subvalvular pulmonary valve stenosis, pulmonary hypertension for any reason, in severe pulmonary valve regurgitation, or in cardiomyopathy. The RV may also be injured from an MI or may be inherently dilated due to infiltrative diseases (RV dysplasia or sarcoidosis). RV dilation often occurs secondary to left HF. Inherent abnormalities of the tricuspid valve include **Ebstein anomaly** (displacement of the septal and posterior, but not the anterior, leaflets into the RV), tricuspid valve prolapse, carcinoid plaque formation, collagen disease inflammation, valvular tumors, or tricuspid endocarditis. In addition, pacemaker lead valvular injury is an increasingly frequent iatrogenic cause.

Clinical Findings

A. Symptoms and Signs

The symptoms and signs of tricuspid regurgitation are identical to those resulting from RV failure due to any cause. As a generality, the diagnosis can be made by careful inspection of the JVP. The JVP waveform should decline during ventricular systole (the *x* descent). The timing of this decline can be observed by palpating the opposite carotid artery. As tricuspid regurgitation worsens, more and more of this *x* descent valley in the JVP is filled with the regurgitant wave until all of the *x* descent is obliterated and a positive systolic waveform will be noted in the JVP. An associated tricuspid regurgitation murmur may or may not be audible and can be distinguished from mitral regurgitation by the left parasternal location and an increase with inspiration (**Carvallo sign**). An S_3 may accompany the murmur and is related to the high flow returning to the RV from the RA. Cyanosis may be present if the increased RA pressure stretches the atrial septum and opens a PFO or there is a true ASD (eg, in about 50% of patients with Ebstein anomaly). Severe tricuspid regurgitation results in hepatomegaly, edema, and ascites.

B. Diagnostic Studies

The ECG is usually nonspecific, though atrial flutter or atrial fibrillation is common. The CXR may reveal evidence of an enlarged RA or dilated azygous vein and pleural effusion. The echocardiogram helps assess severity of tricuspid regurgitation (criteria available in the 2014 AHA/ACC valvular heart disease guidelines). In addition, echocardiography/Doppler provides RV systolic pressure as well as RV size and function. A paradoxically moving interventricular septum may be present due to the volume overload on the RV. Catheterization confirms the presence of the regurgitant wave in the RA and elevated RA pressures. If the PA or RV systolic pressure is < 40 mm Hg, primary valvular tricuspid regurgitation should be suspected. In addition, in patients with severe tricuspid regurgitation and ascites, a hepatic wedge pressure can be performed at the time of the right heart catheterization. If there is a high gradient between the mean RA pressure and mean hepatic wedge, then cirrhosis is likely present. Normally, the gradient across the liver is < 5 mm Hg. Mild cirrhosis is suspected if gradient is 5–10 mm Hg, moderate disease if 10–15 mm Hg, and significant cirrhosis if > 15 mm Hg.

Treatment & Prognosis

Mild tricuspid regurgitation is common and generally can be well managed with diuretics. When severe tricuspid regurgitation is present, bowel edema may reduce the effectiveness of diuretics, such as furosemide, and intravenous diuretics should be used initially. Torsemide or bumetanide is better absorbed in this situation when oral diuretics are added. Aldosterone antagonists have a role as well, particularly if ascites is present. At times, the efficacy of loop diuretics can be enhanced by adding a thiazide diuretic (see Chapter 11).

Since most tricuspid regurgitation is secondary, definitive treatment usually requires elimination of the cause of the RV dysfunction. Surgical valve replacement in secondary (functional) tricuspid regurgitation is rarely if ever indicated until the cause of the RV dysfunction is resolved. If the problem is left heart disease, then treatment of the left heart issues may lower pulmonary pressures, reduce RV size, and resolve the tricuspid regurgitation. Treatment for primary and secondary causes of pulmonary hypertension will generally reduce the tricuspid regurgitation. Guidelines suggest that tricuspid valve surgery may be considered when the tricuspid annular dilation at end-diastole exceeds 4.0 cm and the patient is symptomatic. It is a class I recommendation that tricuspid annuloplasty be performed when significant tricuspid regurgitation is present and mitral valve replacement or repair is being performed for mitral regurgitation. Annuloplasty without insertion of a prosthetic ring (**DeVega annuloplasty**) may also be effective in reducing the tricuspid annular dilation. The valve leaflet itself can occasionally be primarily repaired in tricuspid valve endocarditis.

If there is an inherent defect in the tricuspid valve apparatus that cannot be repaired, then replacement of the tricuspid valve is warranted. A bioprosthetic valve, rather than a mechanical valve, is almost always used because the risk of mechanical valve thrombosis is increased if the INR is not stable. Anticoagulation is *not* required for bioprosthetic valves unless there is associated atrial fibrillation or flutter. Tricuspid regurgitation due to bioprosthetic degeneration has been shown to respond to transcatheter valve replacement. There are early reports of percutaneous tricuspid valve replacement for native valve tricuspid regurgitation being successful. Furthermore, the concept of transcatheter edge-to-edge repair, as is commonly utilized to treat mitral valve regurgitation, was recently shown to be safe and effective at reducing the degree of tricuspid regurgitation and improving quality of life in patients with severe functional tricuspid regurgitation randomized to treatment with the TriClip device versus medical therapy. Randomized clinical trial data in 2025 demonstrated an improvement in quality-of-life outcomes and improved heart failure symptoms in patients treated with transcatheter tricuspid valve replacement compared with standard medical therapy.

When to Refer

- Anyone with moderate or severe tricuspid regurgitation should be seen at least once by a cardiologist to determine whether studies and intervention are needed.
- Severe tricuspid regurgitation requires regular follow-up by a cardiologist.

PULMONARY VALVE REGURGITATION

ESSENTIALS OF DIAGNOSIS

- Most cases are due to pulmonary hypertension resulting in high-pressure pulmonary valve regurgitation.
- Echocardiogram is definitive in high-pressure but may be less definitive in low-pressure pulmonary valve regurgitation.

General Considerations

Pulmonary valve regurgitation can be divided into **high-pressure causes** (due to pulmonary hypertension) and **low-pressure causes** (usually due to a dilated pulmonary annulus, a congenitally abnormal [bicuspid or dysplastic] pulmonary valve, plaque from carcinoid disease, surgical pulmonary valve replacement, or the residual physiology following a surgical transannular patch used to reduce the outflow gradient in tetralogy of Fallot). Because the RV tolerates a volume load better than a pressure load, it tends to tolerate low-pressure pulmonary valve regurgitation for long periods of time without dysfunction.

Clinical Findings

Most patients are asymptomatic. Those with marked pulmonary valve regurgitation may exhibit symptoms of right heart volume overload. On examination, a hyperdynamic RV can usually be palpated (**RV lift**). If the PA is enlarged, it also may be palpated along the left sternal border. P_2 will be palpable in pulmonary hypertension and both systolic and diastolic thrills are occasionally noted. On auscultation, the second heart sound may be widely split due to prolonged RV systole or an associated right bundle branch block. A pulmonary valve systolic click may be noted as well as a right-sided gallop. If pulmonic stenosis is also present, the ejection click may decline with inspiration, while any associated systolic pulmonary murmur will increase. In high-pressure pulmonary valve regurgitation, the pulmonary diastolic (**Graham Steell**) murmur is readily audible. It is often contributed to by a dilated pulmonary annulus. The murmur increases with inspiration and diminishes with the Valsalva maneuver. In low-pressure pulmonary valve regurgitation, the PA diastolic pressure may be only a few mm Hg higher than the RV diastolic pressure, and there is little diastolic gradient to produce a murmur or characteristic echocardiography/Doppler findings. At times, only contrast angiography or MRI of the main PA will show the free-flowing pulmonary valve regurgitation in low-pressure pulmonary valve regurgitation. This situation is common in patients following repair of tetralogy of Fallot where, despite little murmur, there may effectively be no pulmonary valve present. This can be suspected by noting an enlarging RV.

The ECG is generally of little value, although right bundle branch block is common, and there may be ECG criteria for RVH. The CXR may show only the enlarged RV and PA. Echocardiography may demonstrate evidence of RV volume overload (paradoxical septal motion and an enlarged RV), and Doppler can determine peak systolic RV pressure and reveal any associated tricuspid regurgitation. The interventricular septum may appear flattened if there is pulmonary hypertension. The size of the main PA can be determined and color flow Doppler can demonstrate the pulmonary valve regurgitation, particularly in the high-pressure situation. Cardiac MRI and CT can be useful for assessing the size of the PA, for estimating regurgitant flow, for excluding other causes of pulmonary hypertension (eg, thromboembolic disease, peripheral PA stenosis), and for evaluating RV function. Cardiac catheterization is confirmatory only.

Treatment & Prognosis

Pulmonary valve regurgitation rarely needs specific therapy other than treatment of the primary cause. In low-pressure pulmonary valve regurgitation due to surgical transannular patch repair of tetralogy of Fallot, pulmonary valve replacement may be indicated if RV enlargement or dysfunction is present. In tetralogy of Fallot, the QRS will widen as RV function declines (a QRS > 180 msec, among other features, suggests a higher risk for sudden death) and increasing RV volumes should trigger an evaluation for potential severe pulmonary valve regurgitation. In carcinoid heart disease, pulmonary valve replacement with a porcine bioprosthesis may be undertaken, though the plaque from this disorder eventually coats the prosthetic pulmonary valve, limiting the life span of these valves. In high-pressure pulmonary valve regurgitation, treatment to control the cause of the pulmonary hypertension is key. *High-pressure pulmonary valve regurgitation is poorly tolerated and is a serious condition that needs a thorough evaluation for cause and choice of therapy*. Pulmonary valve replacement requires a bioprosthetic valve in most cases. Pulmonary valve regurgitation due to an RV to PA conduit or due to a pulmonary autograft replacement as part of the Ross procedure can be repaired with a percutaneous pulmonary valve (Melody valve). Bioprosthetic pulmonary valve regurgitation has also been treated using a percutaneous valve (Edwards SAPIEN). When the pulmonary valve is replaced percutaneously, the PA is often stented open to provide a platform for the percutaneous valve.

When to Refer

- Patients with pulmonary valve regurgitation that results in RV enlargement should be referred to a cardiologist regardless of the estimated pulmonary pressures.

MANAGEMENT OF ANTICOAGULATION FOR PATIENTS WITH PROSTHETIC HEART VALVES

The risk of thromboembolism is much lower with bioprosthetic valves than mechanical prosthetic valves. Mechanical mitral valve prostheses also pose a greater risk for thrombosis than mechanical aortic valves. For that reason, *the INR should be kept between 2.5 and 3.5 for mechanical mitral prosthetic valves but can be kept between 2.0 and 2.5 for most mechanical aortic prosthetic valves.* If there are additional risk factors in patients with a mechanical AVR (atrial fibrillation, previous thromboembolism, LV dysfunction, hypercoagulable state, or presence of older valve such as a ball-in-cage), then the INR for a mechanical AVR should be similar to a mechanical mitral valve replacement. Guidelines suggest the following as well: (1) a recommendation (class IIa) to expand the use of vitamin K antagonists (VKAs), such as warfarin, for up to 6 months after initial bioprosthetic valve replacement; (2) a lower target INR of 1.5–2.0 for a mechanical AVR using the On-X valve (class IIb); and (3) a consideration of VKA use with an INR of 2.5 for at least 3 months after TAVR (class IIa). Data from 2018 suggest that antiplatelet medications are inferior to warfarin for the prevention of thrombus in patients with the On-X mechanical valve. Concern regarding thrombus formation on bioprosthetic valves (including TAVR valves) also led to a class I recommendation to use multimodality imaging to identify such thrombus (class I). *The DOAC rivaroxaban has not been found to prevent stroke related to emboli from TAVR and it should not be used.* It is acceptable, though, to use DOACs for the treatment of atrial fibrillation in patients with bioprosthetic valves. For patients with a TAVR valve, it is reasonable to use dual antiplatelet therapy (clopidogrel and aspirin) for 3–6 months after the procedure. After that, lifelong low-dose aspirin should be used. As noted earlier, using warfarin for at least 3 months after TAVR is reasonable (class IIb), although that practice is widely variable. Randomized trials have *not* shown a benefit with DOACs after TAVR.

The European Registry of Pregnancy and Cardiac Disease (ROPAC) reported on a registry that compared pregnant persons who had undergone mechanical and bioprosthetic valve replacement to pregnant persons who had not. Maternal mortality was similar between the mechanical and bioprosthetic valve patients (1.5% and 1.4%, respectively) but was much higher than those without an artificial valve (0.2%). When patients with either mechanical or bioprosthetic valves were further assessed, it was found that pregnant persons with mechanical valves were more likely to suffer adverse events than women with bioprosthetic valves. Hemorrhagic events occurred in 23.1% versus 9.2%, miscarriage on warfarin occurred in 28.6% versus 9.2%, and late fetal death was noted in 7.1% versus 0.7%, respectively. These data suggest *a high risk for mortality and morbidity for pregnant patients with mechanical heart valves,* and in the WHO Classification of Maternal Cardiac Risk, the presence of a mechanical valve is considered a class III (out of IV) risk for pregnancy complications.

Stoppage of warfarin for noncardiac surgery is likewise dependent on which mechanical valve is involved, the patient-specific risk factors, and the procedure contemplated. The risk of thromboembolism is highest in the first few months after valve replacement. While the interruption of warfarin therapy is generally safe, most cases of valve thrombosis occur during periods of inadequate anticoagulation, so the time interval without coverage should be kept as short as possible. High-risk features include atrial fibrillation, a prior history of thromboembolism, HF or low LVEF, a hypercoagulable state, a mechanical valve in the mitral position, a known high-risk valve (ball-in-cage), or concomitant hypercoagulable state (such as with an associated cancer). The use of *bridging VKAs*, unfractionated heparin, low-molecular-weight heparin (LMWH), and antifibrinolytics in various clinical situations in patients with valvular heart disease is summarized in Table 10–6. In general, low-risk procedures (eg, pacemaker implantation, cataract removal, and routine dental work) require no stoppage of VKAs, while in other situations the warfarin can be stopped 3 days ahead of the procedure and resumed the night after the procedure (ie, in patients with bileaflet aortic valves) without any bridging unfractionated heparin or LMWH. It is reasonable to consider bridging based on the CHA2DS2-VASc score in patients with bioprosthetic heart valves or annuloplasty rings who take anticoagulants for atrial fibrillation. In high-risk patients, principally just those with a mechanical mitral valve, the warfarin should be stopped and bridging with either unfractionated heparin or LMWH begun once the INR falls below therapeutic levels. Fresh frozen plasma or prothrombin complex concentrate is reasonable in an emergency situation for acute reversal if serious bleeding occurs. *Most patients with a mechanical valve should not have the warfarin reversed with vitamin K, if it can be avoided, because this can result in a transient hypercoagulable state, and it may take many days to reach a therapeutic INR again.*

Warfarin causes fetal skeletal abnormalities in up to 2% of patients who become pregnant while taking the medication, so every effort is made to defer mechanical valve replacement in women until after childbearing age. However, if an individual with a mechanical valve becomes pregnant while taking warfarin, the risk of stopping warfarin may be higher for the mother than the risk of continuing warfarin for the fetus. The risk of warfarin to the fetal skeleton is greatest during the first trimester and, remarkably, is more related to dose than to the INR level. Guidelines suggest it is reasonable to continue warfarin for the first trimester if the dose is 5 mg/day or less. If the dose is > 5 mg/day, it is appropriate to consider either LMWH (as long as the anti-Xa is being monitored [range: 0.8 U/mL to 1.2 U/mL 4–6 hours post-dose]) or continuous intravenous unfractionated heparin (if the activated partial thromboplastin time [aPTT] can be monitored and is at least two times control). Guidelines suggest warfarin and low-dose

Table 10–6. Recommendations for administering vitamin K antagonist (VKA) therapy in patients undergoing procedures or patients with certain clinical conditions. (Listed in alphabetical order, within categories.)

Procedures	Recommendations
Bridging for mechanical heart valves	Required only for those at high risk for thromboembolism (generally only those with a mechanical mitral [not aortic] valve) Bridge with UFH or LMWH and stop UFH 4–6 hours before procedure or stop LMWH 24 hours before procedure Resume 48–72 hours after the procedure
General	Stop VKA 5 days prior and resume 12–24 hours after procedure
Clinical Situations	**Recommendations**
Aspirin use in patients with a bioprosthetic valve	
Bioprosthetic aortic or mitral valve replacement	Aspirin (50–100 mg) indefinitely. Reasonable to consider VKA to achieve INR 2.5 for first 3 months
Transcatheter valve replacement	Aspirin (50–100 mg) indefinitely
Mitral or aortic repair	Aspirin (50–100 mg) indefinitely
Atrial fibrillation and moderate or severe mitral stenosis	VKA (target INR 2.0–3.0) If patient prefers not to receive VKA, aspirin (50–100 mg) plus clopidogrel (75 mg)
Endocarditis	
Native valve or bioprosthetic valve endocarditis	No anticoagulation recommended
Mechanical valve endocarditis	Hold VKA until "safe to resume" (generally when mycotic aneurysm is ruled out or there is no need for urgent surgery)
Intermittent atrial fibrillation or history of systemic embolus and mitral stenosis	VKA (target INR 2.0–3.0)
Long-term anticoagulation after valve replacement	
Bioprosthetic valve in normal sinus rhythm	Aspirin (50–100 mg). Anticoagulation with a VKA to achieve an INR of 2.5 is reasonable for the first 3 months after surgical bioprosthetic MVR or AVR in patients at low risk for bleeding
Mechanical valve replacement	VKA (target INR 2.0–3.0 for mechanical aortic valve, target INR 1.5–2.5 for On-X aortic valve after the first 3 months with an initial target INR of 2.0–3.0, target INR 2.5–3.5 for mechanical mitral valve)
Pregnancy and a mechanical heart valve	Add aspirin (50–100 mg) for persons at high risk VKA may be used during first trimester and throughout pregnancy if dose of warfarin is $\le$ 5 mg/day If VKA dosage normally > 5 mg/day, then adjusted dose LMWH twice daily throughout pregnancy (follow anti-Xa 4 hours after dose, with target of 0.8 U/mL to 1.2 U/mL) or LMWH may be used only during the first trimester, then resume VKA during second and third trimesters *or* Adjusted dose UFH every 12 hours throughout pregnancy (aPTT > 2 times control) or UFH may be used only during the first trimester, then resume VKA during second and third trimester Discontinuation of VKA with initiation of UFH (2 times normal PTT) recommended before planned vaginal delivery
Prosthetic valve thrombosis	
Right-sided valve	Slow-infusion fibrinolytic therapy or intravenous heparin
Left-sided valve	Early surgery if thrombus large (> 0.8 cm^2), symptomatic from valvular obstruction, high surgical risk, or LA thrombus. Thrombolysis with heparin or slow-infusion fibrinolytic therapy may be tried initially if patient is stable If thrombus evident on bioprosthetic valve creating increased gradient, use of VKA reasonable to assess whether obstructive gradient can be improved
Sinus rhythm and mitral stenosis	If left atrial size > 5.5 cm, then consider VKA (target 2.0–3.0)

aPTT, activated partial thromboplastin time; AVR, aortic valve replacement; LMWH, low-molecular-weight heparin; MVR, mitral valve replacement; PTT, partial thromboplastin time. UFH, unfractionated heparin.

Adapted from Nishimura RA et al. 2014 AHA/ACC guidelines for the management of patients with valvular heart disease: executive summary. Circulation. 2014;129:2440–92; and Nishimura RA et al. 2017 AHA/ACC focused update of the 2014 AHA/ACC guideline for the management of patients with valvular heart disease. J Am Coll Cardiol. 2017;70:252–289.

aspirin are safe during the second and third trimester, and then should be stopped upon anticipation of delivery. At time of vaginal delivery, unfractionated intravenous heparin with aPTT at least two times control is desirable. DOACs (antithrombin or Xa inhibitors) should *not* be used in place of warfarin for mechanical prosthetic valves since there are no data that they are safe during pregnancy or safe for mechanical valves in general.

Management of suspected mechanical valve thrombosis depends on whether a left-sided or right-sided valve is involved, the size of the thrombus, and the patient's clinical condition. Simple fluoroscopy can help assess mechanical valve motion, although a TEE is indicated to assess thrombus size. *Therapeutic unfractionated heparin should be given to all patients with a thrombosed valve,* and this alone is generally effective. Fibrinolytic therapy is indicated if heparin therapy is ineffective and the clinical onset has been < 2 weeks, the thrombus is smaller than 0.8 cm^2, New York Heart Association (NYHA) class symptoms are mild (functional class I or II), or the valve is right-sided. Surgery is rarely indicated; it is reserved for those with left-sided mechanical valves in NYHA functional class III or IV HF or in whom TEE demonstrates a mobile thrombus larger than 0.8 cm^2. The use of urgent initial therapy for a thrombosed mechanical valve should include low-dose, slow-infusion fibrinolytic therapy or urgent surgery if the patient is symptomatic.

CORONARY HEART DISEASE (ATHEROSCLEROTIC CAD, ISCHEMIC HEART DISEASE)

CHD, or atherosclerotic CAD, is the number one cause of death in the United States and worldwide. Every minute in the United States, a person dies of CHD. About 37% of people who experience an acute coronary event, either angina or MI, will die of it in the same year. Death rates of CHD have declined every year since 1968, with about half of the decline from 1980 to 2000 due to treatments and half due to improved risk factors. CHD is still responsible for 1 in 4 of all deaths in the United States, totaling over 659,000 deaths annually. Each year, 805,000 individuals have a heart attack in the United States. CHD afflicts nearly 18.2 million Americans, and the prevalence rises steadily with age; thus, the aging of the US population promises to increase the overall burden of CHD.

Risk Factors for CAD

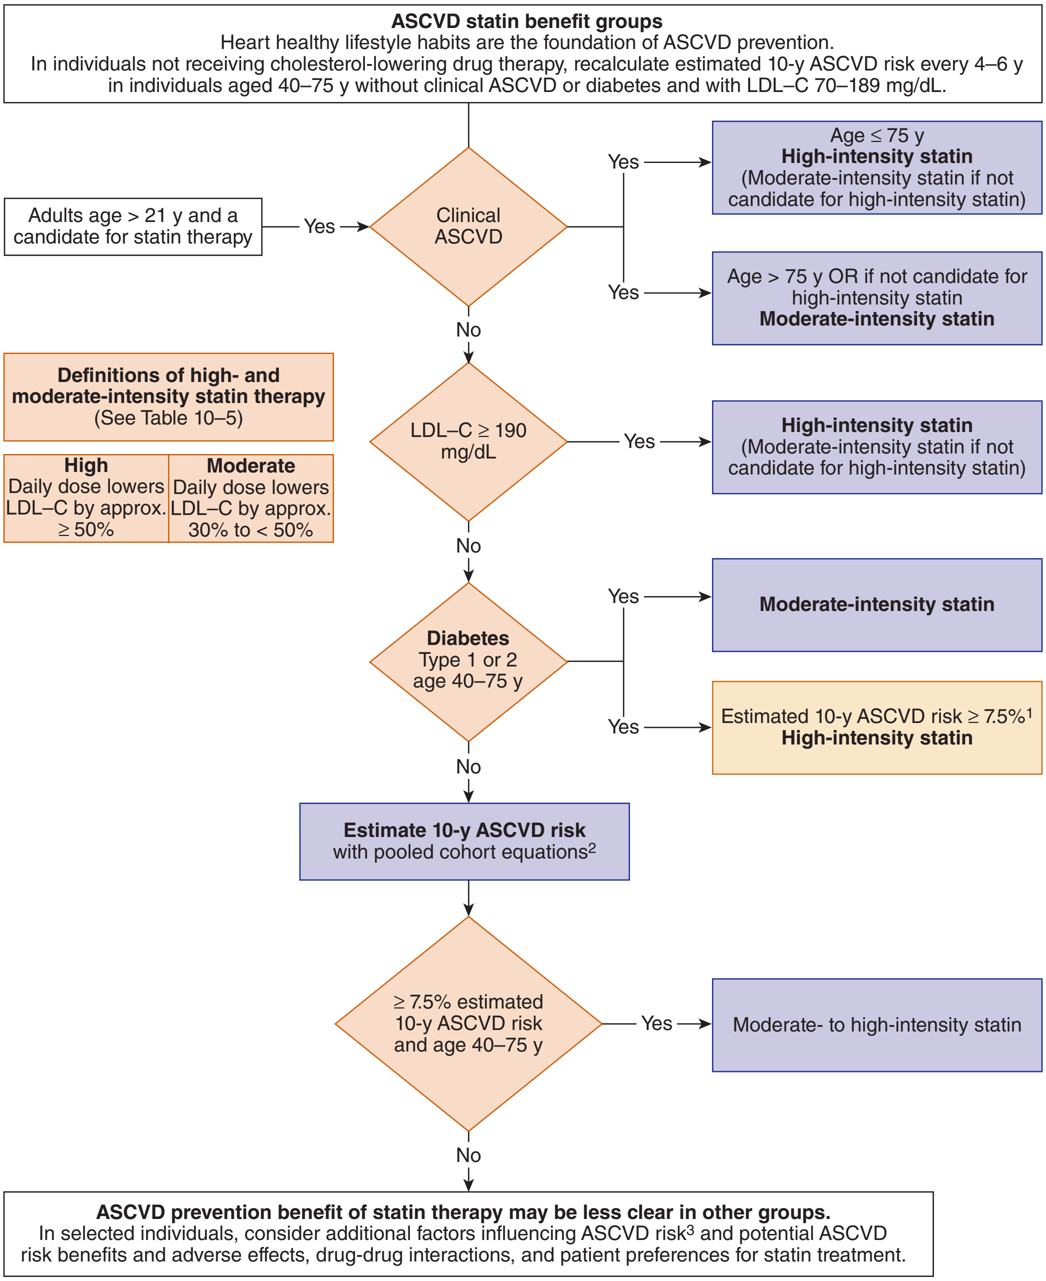
Most patients with CHD have some identifiable risk factor. These include a **positive family history** (the younger the onset in a first-degree relative, the greater the risk), **male sex, blood lipid abnormalities, diabetes mellitus, hypertension, physical inactivity, abdominal obesity, cigarette smoking, psychosocial factors,** and consumption of **too few fruits and vegetables** and **too much alcohol**. Many of these risk factors are modifiable. *Smoking remains the number one preventable cause of death and illness in the United States.* Although cigarette smoking rates have declined in the United States in recent decades, 11.5% of adults smoked cigarettes in 2021. According to the WHO, 1 year after quitting, the risk of CHD decreases by 50%. Various interventions have been shown to increase the likelihood of successful smoking cessation (see Chapter 1).

Hypercholesterolemia is an important modifiable risk factor for CHD. Risk increases progressively with higher levels of LDL cholesterol and declines with higher levels of HDL cholesterol. Composite risk scores, such as the **Framingham score** and the **10-year atherosclerotic CVD risk calculator** (http://my.americanheart.org/cvriskcalculator), provide estimates of the 10-year probability of development of CHD that can guide primary prevention strategies. The 2018 ACC/AHA Guideline on the Treatment of Blood Cholesterol to Reduce Atherosclerotic Cardiovascular Risk in Adults suggests statin therapy in four populations: patients with (1) clinical atherosclerotic disease, (2) LDL cholesterol 190 mg/dL or higher, (3) diabetes who are aged 40–75 years, and (4) an estimated 10-year atherosclerotic risk of 7.5% or more aged 40–75 years (Figure 10–6). Importantly, *the guidelines do not recommend treating to a target LDL cholesterol.* Patients in these categories should be treated with a moderate- or high-intensity statin, with high-intensity statin for populations with higher risk. Moderate-intensity statins are rosuvastatin 5–10 mg, atorvastatin 10–20 mg, simvastatin 20–40 mg, or pravastatin 40–80 mg. High-intensity statins are rosuvastatin 20–40 mg or atorvastatin 40–80 mg. The ACC/AHA atherosclerotic CVD estimator allows clinicians to determine the 10-year ASCVD risk to determine treatment decisions (http://tools.acc.org/ascvd-risk-estimator-plus/). The 2022 USPSTF Lipid Recommendations suggest statin therapy for primary prevention of CVD in those 40 to 75 years of age with one or more risk factors and a 10-year estimated CVD risk of 10% or greater.

The **metabolic syndrome** is defined as a constellation of three or more of the following: abdominal obesity, triglycerides 150 mg/dL or higher, HDL cholesterol < 40 mg/dL for men or < 50 mg/dL for women, fasting glucose 110 mg/dL or higher, and hypertension. This syndrome is increasing in prevalence at an alarming rate. Related to the metabolic syndrome, the **epidemic of obesity** in the United States is likewise a major factor contributing to CHD risk.

Myocardial Hibernation & Stunning

Areas of myocardium that are persistently underperfused but still viable may develop sustained contractile dysfunction. This phenomenon, which is termed **myocardial hibernation,** appears to represent an adaptive response that may be associated with depressed LV function. It is important to recognize this phenomenon, since this form of dysfunction is reversible following coronary revascularization. Hibernating myocardium can be identified by radionuclide testing, PET, contrast-enhanced MRI, or its retained response to inotropic stimulation with dobutamine. A related phenomenon, termed **myocardial stunning,** is the occurrence of persistent contractile dysfunction following prolonged or repetitive episodes of myocardial ischemia. Clinically, myocardial stunning is often seen after reperfusion of acute MI and is defined with improvement following revascularization.



ASCVD statin benefit groups
Heart healthy lifestyle habits are the foundation of ASCVD prevention.
In individuals not receiving cholesterol-lowering drug therapy, recalculate estimated 10-y ASCVD risk every 4–6 y in individuals aged 40–75 y without clinical ASCVD or diabetes and with LDL–C 70–189 mg/dL.
Adults age > 21 y and a candidate for statin therapy
Yes
Clinical ASCVD
Yes
Age ≤ 75 y
High-intensity statin
(Moderate-intensity statin if not candidate for high-intensity statin)
Yes
Age > 75 y OR if not candidate for high-intensity statin
Moderate-intensity statin
No
Definitions of high- and moderate-intensity statin therapy
(See Table 10–5)
High
Daily dose lowers LDL–C by approx. ≥ 50%
Moderate
Daily dose lowers LDL–C by approx. 30% to < 50%
LDL–C ≥ 190 mg/dL
Yes
High-intensity statin
(Moderate-intensity statin if not candidate for high-intensity statin)
No
Diabetes
Type 1 or 2
age 40–75 y
Yes
Moderate-intensity statin
Yes
Estimated 10-y ASCVD risk ≥ 7.5%[1]
High-intensity statin
No
Estimate 10-y ASCVD risk
with pooled cohort equations[2]
≥ 7.5% estimated 10-y ASCVD risk and age 40–75 y
Yes
Moderate- to high-intensity statin
No
ASCVD prevention benefit of statin therapy may be less clear in other groups.
In selected individuals, consider additional factors influencing ASCVD risk[3] and potential ASCVD risk benefits and adverse effects, drug-drug interactions, and patient preferences for statin treatment.

[1] Percent reduction in LDL–C can be used as an indication of response and adherence to therapy but is not in itself a treatment goal.

[2] The Pooled Cohort Equations can be used to estimate 10-year ASCVD risk in individuals with and without diabetes. A downloadable spreadsheet enabling estimation of 10-year and lifetime risk for ASCVD and a web-based calculator are available at http://my.americanheart.org/cvriskcalculator and http://www.cardiosource.org/science-and-quality/practice-guidelines-and-quality-standards/2013-prevention-guideline-tools.aspx.

[3] Primary LDL–C ≥ 160 mg/dL or other evidence of genetic hyperlipidemias, family history of premature ASCVD with onset < 55 years of age in a first-degree male relative or < 65 years of age in a first-degree female relative, high-sensitivity C-reactive protein > 2 mg/L, CAC score ≥ 300 Agatston units or ≥ 75 percentile for age, sex, and ethnicity, ankle-brachial index < 0.9, or elevated lifetime risk of ASCVD.

Primary & Secondary Prevention of CHD

Although many risk factors for CHD are not modifiable, it is now clear that interventions, such as smoking cessation, treatment of dyslipidemia, and lowering of BP can both prevent coronary disease and delay its progression and complications after it is manifest.

Lowering LDL levels delays the progression of atherosclerosis and in some cases may produce *regression*. Even in the absence of regression, fewer new lesions develop, endothelial function may be restored, and coronary event rates are markedly reduced in patients with clinical evidence of vascular disease.

A series of clinical trials has demonstrated the efficacy of **hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins)** in preventing death, coronary events, and strokes. Beneficial results have been found in patients who have already experienced coronary events (secondary prevention), those at particularly high risk for events (patients with diabetes and patients with peripheral artery disease), those with elevated cholesterol without multiple risk factors, and those without vascular disease or diabetes with elevated high-sensitivity CRP (hsCRP) with normal LDL levels. The benefits of statin therapy at moderate and high doses (see Risk Factors for CAD) are recommended by the cholesterol treatment guidelines. The IMPROVE-IT study showed that **ezetimibe**, 10 mg daily, combined with simvastatin was modestly better than simvastatin alone in reducing the risk of MI and ischemic stroke, but *not* mortality, in stabilized patients following an ACS. This was associated with a reduction of LDL to 53.7 mg/dL compared to 69.7 mg/dL. With this data, ezetimibe can be used in combination with statin therapy in patients who are not at target cholesterol level for secondary prevention (for individuals at high risk for cardiovascular events with an LDL > 70 on maximal intensity statin therapy [IIa recommendation]) or cannot tolerate high-dose statin therapy.

Benefits occurred regardless of age, race, baseline cholesterol levels, or the presence of hypertension. It is clear that for patients with vascular disease, statins provide benefit for those with normal cholesterol levels, and that more aggressive statin use is associated with greater benefits. *All patients at significant risk for vascular events should receive a statin regardless of their cholesterol levels, and many experts recommend that with those who have prior cardiovascular events should have their LDL lowered below 70 mg/dL.*

Monoclonal antibodies that inhibit **proprotein convertase subtilisin/kexin type 9 (PCSK9)** reduce LDL cholesterol levels significantly beyond levels associated with traditional statin therapy. These therapies have been studied in randomized trials of patients with maximally tolerated statin therapy (and for patients with statin intolerance) and have lowered LDL with signals of improved cardiovascular outcomes. The FOURIER trial showed that the PCSK9 inhibitor evolocumab, added to a statin, reduced the composite of atherothrombotic outcomes by 20% but did *not* reduce mortality. The ODYSSEY Outcomes trial demonstrated alirocumab reduced cardiovascular events in patients with ACSs. *Alirocumab and evolocumab have been approved by the FDA for patients on maximally tolerated statin therapy with familial hypercholesterolemia and atherosclerotic vascular disease, or both, and who require additional lowering of LDL.* These medications cost several thousand dollars per year in the United States. Alirocumab has also been approved by the FDA for secondary prevention of cardiovascular events. Inclisiran (a small interfering RNA that goes to the liver and prevents the production of PCSK9) has been studied as a twice yearly injection showing reduction in LDL and was approved by the FDA in early 2022.

The placebo-controlled, double-blind CLEAR Outcomes trial randomized 13,970 patients with a history of or at high-risk of ASCVD and an LDL-C > 100 mg/dL to bempedoic acid therapy or placebo. Treatment with bempedoic acid, an ATP citrate lyase inhibitor, resulted in reduction in the composite primary endpoint of cardiovascular death, nonfatal MI, nonfatal stroke, or coronary revascularization procedure. This important investigation provides another option to reduce major adverse cardiac events in at-risk patients who cannot tolerate or prefer not to take statin therapy.

Fish oil supplements have *not* been shown consistently to provide benefit for reducing risk. The AHA does *not* recommend omega-3 fatty acids for primary prevention of CVD in high-risk patients or in primary prevention of stroke. The AHA states treatment is reasonable for secondary prevention of CHD and sudden cardiac death among patients with prevalent CHD. Icosapent ethyl, a concentrated eicosapentaenoic acid at a high dose, was shown to be beneficial in the REDUCE-IT trial. Patients with established CVD or with diabetes and other risk factors, with fasting triglyceride level of 135–499 mg/dL, who were on statins were randomized to 2 g of icosapent ethyl twice daily or placebo. There was a 26% relative risk reduction in cardiovascular death, MI, and stroke, as well as a 20% relative risk reduction in cardiovascular death. Icosapent ethyl is approved by the FDA as an adjunct to maximally tolerated statin therapy to reduce the risk of MI, stroke, coronary revascularization, or unstable angina requiring hospitalization in patients with triglycerides of 150 mg/dL or more and either established CVD or diabetes mellitus and two or more additional risk factors. The role of high-dose omega-3 fatty acids was studied compared to corn oil and not shown to reduce cardiovascular events, leading to increased interest in comparative studies.

Treatment to raise HDL levels has failed to show benefit. The AIM High trial found no benefit from the addition of niacin in patients with vascular disease and a serum LDL near 70 mg/dL who were receiving statin therapy. The HPS2-THRIVE trial found no benefit but rather substantial harm of extended-release niacin (2 g) plus laropiprant (an antiflushing agent) for preventing vascular events in a population of over 25,000 patients with vascular disease who were taking simvastatin.

For primary prevention, *aspirin has little overall benefit, including for patients with established diabetes, and is* not *recommended for most patients.* In 2022, the USPSTF issued guidance on the use of aspirin for primary prevention of cardiovascular events. The document recommended that patient aged 40–59 years with a 10-year ASCVD risk of 10% or greater should have a shared-decision making conversation regarding the potential risk and benefits of initiating aspirin therapy for primary prevention. In addition, the document recommended that patients 60 years of age and older should not initiate aspirin for primary prevention of CVD.

Antiplatelet therapy is a very effective measure for secondary prevention and patients with established vascular disease should be treated with aspirin. The exact dose of aspirin in chronic CAD (81 mg vs 325 mg) was evaluated in a large pragmatic trial (ADAPTABLE). The unique pragmatic clinical trial design demonstrated that 81 mg aspirin was associated with a favorable cardiovascular event risk and bleeding risk compared with 325 mg daily.

While clopidogrel was found to be effective at preventing vascular events for 9–12 months after ACSs, and there are some benefits in prolonging dual antiplatelet therapy after coronary stenting, clopidogrel was *not* found to be effective at preventing vascular events in combination with aspirin with longer-term treatment in the CHARISMA trial. This trial included patients with clinically evident stable atherothrombosis or with multiple risk factors; all were treated with aspirin and observed for a median of 28 months.

In the COMPASS trial, rivaroxaban, a direct factor Xa inhibitor, at a dose of 2.5 mg twice daily in addition to 100 mg of aspirin, was shown to reduce cardiovascular death, MI, and stroke by a relative risk reduction of 24% compared to 100 mg aspirin monotherapy in stable patients with CAD and peripheral artery disease. Bleeding was modestly increased. All-cause mortality was also reduced by 18%. This regimen is approved by the FDA and is used for long-term management of patients with CAD and peripheral artery disease and should be considered in this group at high risk for adverse cardiac events with a low bleeding risk profile.

The HOPE and the EUROPA trials demonstrated that ACE inhibitors (ramipril 10 mg/day and perindopril 8 mg/day, respectively) reduced fatal and nonfatal vascular events (cardiovascular deaths, nonfatal MIs, and nonfatal strokes) by 20–25% in patients at high risk, including patients with diabetes with additional risk factors or patients with clinical coronary, cerebral, or peripheral arterial atherosclerotic disease. An overview of these trials has demonstrated that while low-risk patients may *not* derive substantial benefits from ACE inhibitors, *most patients with vascular disease, even in the absence of HF or LV dysfunction, should be treated with an ACE inhibitor.*

An interesting approach to secondary prevention of cardiovascular events was investigated in the SECURE trial. Utilizing a polypill (aspirin, ramipril, and atorvastatin) or standard medical therapy with multiple agents, 2499 patients with a history of an MI in the prior 6 months were randomized to polypill treatment or a standard approach with multiple agents and followed for 3 years. Medication adherence was statistically higher in the polypill cohort and this was associated with a statistically significant lower rate of major adverse cardiac events.

Over one-third of patients with vascular disease have type 2 diabetes. In addition to controlling risk factors, using high-intensity statins and ACE inhibitors or ARBs, *there is proven benefit to reduce cardiovascular events by using oral SGLT-2 inhibitors (specifically, empagliflozin, dapagliflozin, or canagliflozin) or injectable GLP1-receptor agonists (liraglutide, semaglutide, dulaglutide).* The cardiovascular benefits appear to be independent from the modest glucose lowering effects, and SGLT-2 inhibitors have benefits for patients with HF regardless of whether they have diabetes or HF with reduced versus preserved EF (see Chapter 11). Importantly, the SELECT RCT enrolled 17,604 patients with *a BMI > 27 and no history of diabetes mellitus* and showed a statistically significant decrease in the composite primary endpoint of cardiovascular death, nonfatal MI, or nonfatal stroke in the group treated with semaglutide.

Another approach to secondary prevention of cardiovascular events has evolved from clinical trials evaluating colchicine, which is commonly utilized to treat gout, at a lower dose of 0.5 mg daily. This regimen resulted in a 23% reduction in major adverse cardiac events in post-MI patients and 31% in stable CAD patients. The European Society of Cardiology adopted colchicine into the secondary prevention guidelines in 2021. The US FDA approved colchicine for secondary prevention in June 2023. However, a 2024 large randomized trial demonstrated that routine colchicine administration to patients presenting with a myocardial infarction and undergoing percutaneous coronary intervention did *not* reduce the composite endpoint of cardiovascular death, stroke, myocardial infarction, or coronary revascularization over 3 years of follow-up.

CHRONIC STABLE ANGINA PECTORIS (Chronic Coronary Syndromes)

ESSENTIALS OF DIAGNOSIS

- Precordial chest pain, usually precipitated by stress or exertion, relieved rapidly by rest or nitrates.
- ECG or scintigraphic evidence of ischemia during pain or stress testing.
- Angiographic demonstration of significant obstruction of major coronary vessels.

General Considerations

Angina pectoris is the manifestation of stable CAD or chronic coronary syndromes, and it is usually due to atherosclerotic heart disease. Coronary vasospasm may occur at the site of a lesion or, less frequently, in apparently normal vessels. Other unusual causes of coronary artery obstruction, such as congenital anomalies, emboli, arteritis, or dissection, may cause ischemia or infarction. Angina may also occur in the absence of coronary artery obstruction as a result of severe myocardial hypertrophy, severe aortic stenosis or regurgitation, or in response to increased metabolic demands, as in hyperthyroidism, marked anemia, or paroxysmal tachycardias with rapid ventricular rates.

Clinical Findings

A. Symptoms

The diagnosis of angina pectoris principally depends on the history, which should specifically include the following information: circumstances that precipitate and relieve angina, characteristics of the discomfort, location and radiation, duration of attacks, and effect of nitroglycerin.

1. Circumstances that precipitate and relieve angina— Angina occurs most commonly during activity and is relieved by resting. Patients may prefer to remain upright rather than lie down, as increased preload in recumbency increases myocardial work. The amount of activity required to produce angina may be relatively consistent under comparable physical and emotional circumstances or may vary from day to day. The threshold for angina is usually lower after meals, during excitement, or on exposure to cold. It is often lower in the morning or after strong emotion; the latter can provoke attacks in the absence of exertion. In addition, discomfort may occur during sexual activity, at rest, or at night as a result of coronary spasm.

2. Characteristics of the discomfort—Patients often do not refer to angina as "pain" but as a sensation of tightness, squeezing, burning, pressing, choking, aching, bursting, "gas," indigestion, or an ill-characterized discomfort. It is often characterized by *clenching a fist* over the mid chest. The distress of angina is rarely sharply localized and is not spasmodic.

3. Location and radiation—The distribution of the distress may vary widely in different patients but is usually the same for each patient unless unstable angina or MI supervenes. In most cases, the discomfort is felt behind or slightly to the left of the mid sternum. When it begins farther to the left or, uncommonly, on the right, it characteristically moves centrally substernally. Although angina may radiate to any dermatome from C8 to T4, it radiates most often to the left shoulder and upper arm, frequently moving down the inner volar aspect of the arm to the elbow, forearm, wrist, or fourth and fifth fingers. It may also radiate to the right shoulder or arm, the lower jaw, the neck, or even the back.

4. Duration of attacks—Angina is generally of short duration and subsides completely without residual discomfort. If the attack is precipitated by exertion and the patient promptly stops to rest, it usually lasts under 3 minutes. Attacks following a heavy meal or brought on by anger often last 15–20 minutes. Attacks lasting > 30 minutes are unusual and suggest the development of an ACS with unstable angina, MI, or an alternative diagnosis.

5. Effect of nitroglycerin—The diagnosis of angina pectoris is supported if sublingual nitroglycerin promptly and invariably shortens an attack and if prophylactic nitrates permit greater exertion or prevent angina entirely.

B. Signs

Examination during angina frequently reveals a significant elevation in systolic and diastolic BP, although hypotension may also occur, and may reflect more severe ischemia or inferior ischemia (especially with bradycardia) due to a **Bezold-Jarisch reflex**. Occasionally, a gallop rhythm and an apical systolic murmur due to transient mitral regurgitation from papillary muscle dysfunction are present during pain only. Supraventricular or ventricular arrhythmias may be present, either as the precipitating factor or as a result of ischemia.

It is important to detect signs of diseases that may contribute to or accompany atherosclerotic heart disease, eg, diabetes mellitus (retinopathy or neuropathy), xanthelasma tendinous xanthomas, hypertension, thyrotoxicosis, myxedema, or peripheral artery disease. Aortic stenosis or regurgitation, HCM, and mitral valve prolapse should be sought, since they may produce angina or other forms of chest pain.

C. Laboratory Findings

Other than standard laboratory tests to evaluate for ACS (troponin and CK-MB) and factors contributing to ischemia (such as anemia) and to screen for risk factors that may increase the probability of true CHD (such as hyperlipidemia and diabetes mellitus), blood tests are not helpful to diagnose chronic angina.

D. ECG

The resting ECG is often normal in patients with a history of angina. In the remainder, abnormalities include old MI, nonspecific ST–T changes, and changes of LVH. During anginal episodes, as well as during asymptomatic ischemia, *the characteristic ECG change is horizontal or downsloping*

ST-segment depression that reverses after the ischemia disappears. T wave flattening or inversion may also occur. Less frequently, transient ST-segment elevation is observed; this finding suggests severe (transmural) ischemia from coronary occlusion, and it can occur with coronary spasm.

E. Pretest Probability

The history as detailed above, the physical examination findings, and laboratory and ECG findings are used to develop a pretest probability of CAD as the cause of the clinical symptoms. Other important factors to include in calculating the pretest probability of CAD are patient age, sex, and clinical symptoms. Patients with low to intermediate pretest probability for CAD should undergo noninvasive stress testing whereas patients with high pretest probability are generally referred for cardiac catheterization. National review of diagnostic cardiac catheterization findings in patients without known CAD undergoing angiography has shown that between 38% and 40% of patients do not have obstructive disease.

F. Exercise ECG

Exercise ECG testing is the most commonly used noninvasive procedure for evaluating inducible ischemia in the patient with angina. Exercise ECG testing is often combined with imaging studies (nuclear or echocardiography), but in low-risk patients without baseline ST-segment abnormalities or in whom anatomic localization is not necessary, the exercise ECG remains the recommended initial procedure because of considerations of cost, convenience, and long-standing prognostic data.

Exercise testing can be done on a motorized treadmill or with a bicycle ergometer. A variety of exercise protocols are utilized, the most common being the **Bruce protocol,** which increases the treadmill speed and elevation every 3 minutes until limited by symptoms. At least two ECG leads should be monitored continuously.

1. Precautions and risks—The risk of exercise testing is about one infarction or death per 1000 tests, but individuals who have pain at rest or minimal activity are at higher risk and should not be tested. *Many of the traditional exclusions, such as recent MI or HF, are no longer used if the patient is stable and ambulatory, but symptomatic aortic stenosis remains a relative contraindication.*

2. Indications—Exercise testing is used (1) to confirm the diagnosis of angina; (2) to determine the severity of limitation of activity due to angina; (3) to assess prognosis in patients with known coronary disease, including those recovering from MI, by detecting groups at high or low risk; and (4) to evaluate responses to therapy. Because false-positive tests often exceed true positives, leading to much patient anxiety and self-imposed or mandated disability, *exercise testing of asymptomatic individuals should be done only for those whose occupations place them or others at special risk (eg, airline pilots).*

3. Interpretation—The usual ECG criterion for a positive test is 1-mm (0.1-mV) *horizontal or downsloping ST-segment depression* (beyond baseline) measured 80 msec after the J point. By this criterion, 60–80% of patients with anatomically significant coronary disease will have a positive test, but 10–30% of those without significant disease will also be positive. False positives are uncommon when a 2-mm depression is present. Additional information is inferred from the time of onset and duration of the ECG changes, their magnitude and configuration, BP and heart rate changes, the duration of exercise, and the presence of associated symptoms. In general, patients exhibiting more severe ST-segment depression (> 2 mm) at low workloads (< 6 minutes on the Bruce protocol) or heart rates (< 70% of age-predicted maximum)—especially when the duration of exercise and rise in BP are limited or when hypotension occurs during the test—have more severe disease and a poorer prognosis. Depending on symptom status, age, and other factors, such patients should be referred for coronary arteriography and possible revascularization. On the other hand, less impressive positive tests in asymptomatic patients are often “false positives.” Therefore, exercise testing results that do not conform to the clinical suspicion should be confirmed by stress imaging.

G. Myocardial Stress Imaging

Myocardial stress imaging (scintigraphy, echocardiography, or MRI) is indicated (1) when the resting ECG makes an exercise ECG difficult to interpret (eg, left bundle branch block, baseline ST–T changes, low voltage); (2) for confirmation of the results of the exercise ECG when they are contrary to the clinical impression (eg, a positive test in an asymptomatic patient); (3) to localize the region of ischemia; (4) to distinguish ischemic from infarcted myocardium; (5) to assess the completeness of revascularization following bypass surgery or coronary angioplasty; or (6) as a prognostic indicator in patients with known coronary disease. Published criteria summarize these indications for stress testing.

1. Myocardial perfusion scintigraphy—This test, also known as **radionuclide imaging,** provides images in which radionuclide uptake is proportionate to blood flow at the time of injection. Isotopes used include thallium-201, technetium-99m sestamibi, and tetrofosmin.

Stress imaging is positive in about 75–90% of patients with anatomically significant coronary disease and in 20–30% of those without it. Occasionally, other conditions, including infiltrative diseases (sarcoidosis, amyloidosis), left bundle branch block, and dilated cardiomyopathy, may produce resting or persistent perfusion defects. False-positive radionuclide tests may occur as a result of diaphragmatic attenuation or, in women, attenuation through breast tissue. Tomographic imaging (single-photon emission CT [SPECT]) can reduce the severity of artifacts.

2. Radionuclide angiography—This procedure, also known as **multi-gated acquisition scan,** or **MUGA scan,** uses radionuclide tracers to image the LV and measures its EF and wall motion. In coronary disease, resting abnormalities usually represent infarction, and those that occur only with exercise usually indicate stress-induced ischemia. Exercise radionuclide angiography has approximately the same sensitivity as myocardial perfusion scintigraphy, but it is less specific in older individuals and those with other forms of heart disease. In addition, because of the precision around LVEF, the test is also used for monitoring patients exposed to cardiotoxic therapies (such as some chemotherapeutic agents).

3. Stress echocardiography—Echocardiograms performed during supine exercise or immediately following upright exercise may demonstrate exercise-induced *segmental wall motion abnormalities* as an indicator of ischemia. In experienced laboratories, the test accuracy is comparable to that obtained with scintigraphy—though a higher proportion of tests is technically inadequate. While exercise is the preferred stress because of other information derived, pharmacologic stress with **high-dose dobutamine** (20–40 mcg/kg/min) can be used as an alternative to exercise.

H. Other Imaging

1. PET—PET and SPECT scanning can accurately distinguish transiently dysfunctional ("stunned") myocardium from scar tissue.

2. CT and MRI scanning—CT scanning can image the heart and, with contrast medium and multislice technology, the coronary arteries. *Multislice CT angiography may be useful in evaluating patients with low likelihood of significant CAD to rule out disease.* Its use has been associated with lower 5-year mortality compared to standard care in patients with stable chest pain. With lower radiation exposure than radionuclide SPECT imaging, CT angiography may also be useful for evaluating chest pain and suspected ACS. In the large randomized comparative effectiveness PROMISE trial, patients with stable chest pain undergoing anatomic imaging with CT angiography had similar outcomes to patients undergoing functional testing (stress ECG, stress radionuclide, or stress echocardiography). CT angiography with noninvasive functional assessment of coronary stenosis (fractional flow reserve), termed **CT-FFR,** has also been evaluated in patients with low-intermediate likelihood of CAD. CT-FFR has been shown to reduce the number of patients without coronary disease requiring invasive angiography. CT-FFR has been approved for clinical use and is being used in clinical practice in the United States and Europe. The use of CT-FFR has been endorsed with a level IIa recommendation for intermediate-risk patients with chest pain and no prior history of CAD with a 40–90% stenosis on CT imaging to guide need for revascularization in the 2021 ACC/AHA Guideline for the Evaluation and Diagnosis of Chest Pain.

Electron beam CT (EBCT) (coronary calcium score) can quantify coronary artery calcification, which is highly correlated with atheromatous plaque and has high sensitivity, but low specificity, for obstructive coronary disease. This test has not traditionally been used in symptomatic patients. According to the AHA, persons who are at low risk (< 10% 10-year risk) or at high risk (> 20% 10-year risk) for obstructive coronary disease do not benefit from coronary calcium assessment (class III, level of evidence: B). However, in clinically selected, intermediate-risk patients (5–7.5% atherosclerotic CVD), it may be reasonable to determine the atherosclerosis burden using EBCT in order to refine clinical risk prediction and to select patients for more aggressive target values for lipid-lowering therapies (class IIb, level of evidence: B).

Cardiac MRI using gadolinium provides high-resolution images of the heart and great vessels without radiation exposure or use of iodinated contrast media. Gadolinium has been associated with a rare but fatal complication in patients with severe kidney disease, called **necrotizing systemic fibrosis.** Gadolinium can demonstrate perfusion using dobutamine or adenosine to produce *pharmacologic stress*. Advances have been made in imaging the proximal coronary arteries. Perhaps the most clinically used indication of cardiac MRI is for identification of **myocardial fibrosis,** either from MI or infiltration, done with gadolinium contrast. This allows high-resolution imaging of myocardial viability and infiltrative cardiomyopathies.

I. Ambulatory ECG Monitoring

Ambulatory ECG recorders can monitor for ischemic ST-segment depression, but this modality is rarely used for ischemia detection. In patients with CAD, these episodes usually signify ischemia, even when asymptomatic ("silent").

J. Coronary Angiography

Selective coronary arteriography is the definitive diagnostic procedure for CAD. It can be performed with low mortality (about 0.1%) and morbidity (1–5%), but due to the invasive nature and cost, it is recommended only in patients with a high pretest probability of CAD.

Coronary arteriography should be performed in the following circumstances if percutaneous transluminal coronary angioplasty or bypass surgery is a consideration:

1. Life-limiting stable angina despite an adequate medical regimen.
2. Clinical presentation (unstable angina, postinfarction angina, etc) or noninvasive testing suggests high-risk disease (see "Prevention of Further Attacks," section K, "Revascularization").
3. Concomitant aortic valve disease and angina pectoris, to determine whether the angina is due to accompanying coronary disease.
4. Asymptomatic older patients undergoing valve surgery so that concomitant bypass may be done if the anatomy is propitious.
5. Recurrence of symptoms after coronary revascularization to determine whether bypass grafts or native vessels are occluded.
6. Cardiac failure where a surgically correctable lesion, such as LV aneurysm, mitral regurgitation, or reversible ischemic dysfunction, is suspected.
7. Persons who have experienced sudden death, symptomatic, or life-threatening arrhythmias when CAD may be a correctable cause.
8. Chest pain of uncertain cause or cardiomyopathy of unknown cause.
9. Emergently performed cardiac catheterization with intention to perform primary percutaneous coronary intervention (PCI) in patients with suspected acute MI.

A narrowing of > 50% of the luminal diameter is considered hemodynamically (and clinically) significant, although most lesions producing ischemia are associated with narrowing in excess of 70%. In those with strongly positive exercise ECGs or scintigraphic studies, three-vessel or left main disease may be present in 75–95% depending on the criteria used. **Intravascular ultrasound (IVUS)** is useful as an adjunct for assessing the results of angioplasty or stenting. In addition, IVUS is the invasive diagnostic method of choice for ostial left main lesions and coronary dissections. In **fractional flow reserve (FFR),** a pressure wire is used to measure the relative change in pressure across a coronary lesion after adenosine-induced hyperemia. Revascularization based on abnormal FFR improves clinical outcomes compared to revascularization of all angiographically stenotic lesions. Fractional flow reserve is an important invasive tool to aid with ischemia-driven revascularization and has become the standard tool to evaluate borderline lesions in cases in which the clinical team is evaluating the clinical and hemodynamic significance of a coronary stenosis. Additionally, pressures distally/pressures proximally during a wave-free period in diastole have been shown to demonstrate similar clinical outcomes to fractional flow reserve, without the use of adenosine.

LV angiography is usually performed at the same time as coronary arteriography. Global and regional LV function are visualized, as well as mitral regurgitation if present. LV function is a major determinant of prognosis in CHD.

Differential Diagnosis

When atypical features are present—such as prolonged duration (hours or days) or darting, or knifelike pains at the apex or over the precordium—ischemia is less likely.

Anterior chest wall syndrome is characterized by a sharply localized tenderness of the intercostal muscles. Inflammation of the chondrocostal junctions may result in diffuse chest pain that is also reproduced by local pressure **(Tietze syndrome).** Intercostal neuritis (due to herpes zoster or diabetes mellitus, for example) also mimics angina.

Cervical or thoracic spine disease involving the dorsal roots produces sudden sharp, severe chest pain suggesting angina in location and “radiation” but related to specific movements of the neck or spine, recumbency, and straining or lifting. Pain due to cervical or thoracic disk disease involves the outer or dorsal aspect of the arm and the thumb and index fingers rather than the ring and little fingers.

Reflux esophagitis, peptic ulcer, chronic cholecystitis, esophageal spasm, and functional GI disease may produce pain suggestive of angina pectoris. The picture may be especially confusing because ischemic pain may also be associated with upper GI symptoms, and esophageal motility disorders may be improved by nitrates and calcium channel blockers. Assessment of esophageal motility may be helpful.

Degenerative and inflammatory lesions of the left shoulder and thoracic outlet syndromes may cause chest pain due to nerve irritation or muscular compression; the symptoms are usually precipitated by movement of the arm and shoulder and are associated with paresthesias.

Pneumonia, PE, and spontaneous pneumothorax may cause chest pain as well as dyspnea. Dissection of the thoracic aorta can cause severe chest pain that is commonly felt in the back; it is sudden in onset, reaches maximum intensity immediately, and may be associated with changes in pulses. Other cardiac disorders, such as mitral valve prolapse, HCM, myocarditis, pericarditis, aortic valve disease, or RVH, may cause atypical chest pain or even myocardial ischemia.

Treatment

Sublingual nitroglycerin is the medication of choice for acute management; it acts in about 1–2 minutes. As soon as the attack begins, one fresh tablet is placed under the tongue. This may be repeated at 3- to 5-minute intervals, but if pain is not relieved or improving after 5 minutes, the patient should call 9-1-1; *pain not responding to three tablets or lasting > 20 minutes may represent evolving infarction*. The dosage (0.3, 0.4, or 0.6 mg) and the number of tablets to be used before seeking further medical attention must be individualized. Nitroglycerin buccal spray is also available as a metered (0.4 mg) delivery system. It has the advantage of being more convenient for patients who have difficulty handling the pills and of being more stable.

Prevention of Further Attacks

A. Aggravating Factors

Angina may be aggravated by hypertension, LV failure, arrhythmia (usually tachycardias), strenuous activity, cold temperatures, and emotional states. These factors should be identified and treated when possible.

B. Nitroglycerin

Nitroglycerin, 0.3–0.6 mg sublingually or 0.4–0.8 mg translingually by spray, should be taken 5 minutes before any activity likely to precipitate angina. Sublingual isosorbide dinitrate (2.5–5 mg) is only slightly longer-acting than sublingual nitroglycerin.

C. Long-Acting Nitrates

Longer-acting nitrate preparations include isosorbide dinitrate, 10–40 mg orally three times daily; isosorbide mononitrate, 10–40 mg orally twice daily or 60–120 mg once daily in a sustained-release preparation; oral sustained-release nitroglycerin preparations, 6.25–12.5 mg two to four times daily; nitroglycerin ointment, 2% ointment, 0.5–2 inches (7.5–30 mg in the morning and 6 hours later); and transdermal nitroglycerin patches that deliver nitroglycerin at rates of 0.2, 0.4, and 0.6 mg/hour rate (0.1–0.8 mg/hour), and should be taken off after 12–14 hours of use for a 10- to 12-hour patch-free interval daily. The main limitation to long-term nitrate therapy is *tolerance*, which can be limited by using a regimen that includes a minimum 8- to 10-hour period per day without nitrates. Isosorbide dinitrate can be given three times daily, with the last dose after dinner, or longer-acting isosorbide mononitrate once daily. Transdermal nitrate preparations should be removed overnight in most patients.

Nitrate therapy is often limited by headache. Other side effects include nausea, light-headedness, and hypotension. Importantly, phosphodiesterase inhibitors used commonly for erectile dysfunction should not be taken within 24 hours of nitrate use.

D. β-Blockers

β-Blockers are the only antianginal agents that have been demonstrated to prolong life in patients with coronary disease (post-MI). *β-Blockers should be considered for first-line therapy in most patients with chronic angina* and are recommended as such by the stable ischemic heart disease guidelines.

β-Blockers with intrinsic sympathomimetic activity, such as pindolol, are less desirable because they may exacerbate angina in some individuals and have not been effective in secondary prevention trials. Otherwise, despite differences in cardioselectivity, vasodilation, and lipid solubility all β-blockers seem to be equally efficacious in the treatment of stable ischemic heart disease. The pharmacology and side effects of the β-blockers are discussed in Chapter 13 (see Tables 13–10 and 13–11). The dosages of all these medications when given for angina are similar. The major contraindications are severe bronchospastic disease, bradyarrhythmias, and decompensated HF.

E. Ranolazine

Ranolazine is indicated for chronic angina. Ranolazine has no effect on heart rate and BP, and it has been shown in clinical trials to prolong exercise duration and time to angina, both as monotherapy and when administered with conventional antianginal therapy. It is safe to use with erectile dysfunction medications. The usual dose is 500 mg orally twice a day. Because it can cause QT prolongation, it is contraindicated in patients with existing QT prolongation; in patients taking QT prolonging medications, such as class I or III antiarrhythmics (eg, quinidine, dofetilide, sotalol); and in those taking potent and moderate CYP450 3A inhibitors (eg, clarithromycin and rifampin). Of interest, in spite of the QT prolongation, there is a significantly lower rate of ventricular arrhythmias with its use following ACSs, as shown in the MERLIN trial.

F. Calcium Channel Blocking Agents

Unlike the β-blockers, calcium channel blockers have *not* been shown to reduce mortality postinfarction and in some cases have increased ischemia and mortality rates. This appears to be the case with some dihydropyridines (eg, nifedipine) and with diltiazem and verapamil in patients with clinical HF or moderate to severe LV dysfunction. Meta-analyses have suggested that short-acting nifedipine in moderate to high doses causes an *increase* in mortality. It is uncertain whether these findings are relevant to longer-acting dihydropyridines. Nevertheless, considering the uncertainties and the lack of demonstrated favorable effect on outcomes, calcium channel blockers should be considered third-line anti-ischemic medications in the postinfarction patient. Similarly, these agents, with the exception of amlodipine (which proved safe in patients with HF in the PRAISE-2 trial), should be avoided in patients with HF or low EFs.

The pharmacologic effects and side effects of the calcium channel blockers are discussed in Chapter 13 and summarized in Table 13–8. Diltiazem, amlodipine, and verapamil are preferable because they produce less reflex tachycardia and because the former, at least, may cause fewer side effects. Nifedipine, nicardipine, and amlodipine are also approved agents for angina. Isradipine, felodipine, and nisoldipine are not approved for angina but probably are as effective as the other dihydropyridines.

G. Ivabradine

Ivabradine selectively blocks the I_f current and specifically lowers heart rate. It has been shown to reduce angina in patients with chronic stable angina and is approved in Europe. However, the SIGNIFY trial found no overall difference in clinical outcomes in patients without HF and angina and that there may have been harm for patients with significant angina with regard to outcomes of cardiovascular death and MI.

H. Alternative and Combination Therapies

Patients who do not respond to one class of antianginal medication often respond to another. It may, therefore, be worthwhile to use an alternative agent before progressing to combinations. *The stable ischemic heart disease guidelines recommend starting with a β-blocker as initial therapy, followed by long-acting nitrates, calcium channel blockers, or ranolazine.* A few patients will have further response to a regimen including all four agents.

I. Platelet-Inhibiting Agents

Several studies have demonstrated the benefit of antiplatelet medications for patients with stable and unstable vascular disease. Therefore, *unless contraindicated, aspirin (81 mg orally daily) should be prescribed for all patients with angina.* A $P2Y_{12}$ inhibitor **clopidogrel,** 75 mg orally daily, reduces vascular events in patients with stable vascular disease (as an alternative to aspirin) and in patients with ACSs (in addition to aspirin). Thus, it is also a good alternative in aspirin-intolerant patients. Clopidogrel in addition to aspirin did not reduce MI, stroke, or cardiovascular death in the CHARISMA trial of patients with CVD or multiple risk factors, with about a 50% increase in bleeding. However, it might be reasonable to use combination clopidogrel and aspirin for certain high-risk patients with established coronary disease, as tested in the Dual Antiplatelet Therapy (DAPT) trial. Specifically, *prolonged use of dual antiplatelet therapy with aspirin and clopidogrel may be beneficial in patients post–percutaneous stenting with drug-eluting stents who have a low bleeding risk.*

Ticagrelor, a $P2Y_{12}$ inhibitor, has been shown to reduce cardiovascular events in patients with ACSs. Additionally, in patients with prior MI, long-term treatment with ticagrelor plus aspirin reduced cardiovascular events compared to aspirin alone. In patients with peripheral artery disease, ticagrelor monotherapy did *not* reduce cardiovascular events compared to clopidogrel.

Vorapaxar is an inhibitor of the protease-activated receptor-1. It was shown to reduce cardiovascular events for patients with stable atherosclerosis with a history of MI or peripheral artery disease in the TRA 2P trial. It is contraindicated for patients with a history of stroke or TIA due to increased risk of intracranial hemorrhage.

Rivaroxaban, a direct factor Xa inhibitor, when used at a dose of 2.5 mg twice daily in addition to low-dose aspirin, was found to reduce cardiovascular events including cardiovascular death, MI, or stroke when compared to aspirin monotherapy in patients with known CAD or peripheral artery disease. This agent is approved and provides another option for patients.

Guidelines recommend ***dual antiplatelet therapy*** *(aspirin and $P2Y_{12}$ therapy) in patients with recent MI (within 1 year) or recent stenting (within 6 months) and for prolonged therapy (> 1 year) in patients at high ischemic risk (multivessel coronary disease or polyvascular disease) and low bleeding risk.*

J. Risk Reduction

Patients with coronary disease should undergo aggressive **risk factor modification.** This approach, with a particular focus on statin treatment, treating hypertension, stopping smoking, and exercise and weight control (especially for patients with metabolic syndrome or at risk for diabetes), may markedly improve outcomes. For patients with diabetes and CVD, there is uncertainty about the optimal target blood sugar control. The ADVANCE trial suggested some benefit for tight blood sugar control with target HbA_{1C} of 6.5% or less, but the ACCORD trial found that routine aggressive targeting for blood sugar control to HbA_{1C} to < 6.0% in patients with diabetes and coronary disease was associated with *increased* mortality. Therefore, *tight blood sugar control should be avoided particularly in patients with a history of severe hypoglycemia, long-standing diabetes, and advanced vascular disease.* Aggressive BP control (target systolic BP < 120 mm Hg) in the ACCORD trial was *not* associated with reduction in CHD events despite reducing stroke. In contrast, the SPRINT trial, which did not include patients with diabetes, demonstrated a reduction in cardiovascular events in patients with a reduction in death from any cause and reduction in MI with a goal systolic BP of < 120 mm Hg versus of goal of < 140 mm Hg. Some increase in adverse events was noted. Based on this and the totality of results, *the AHA has recommended defining hypertension at the 130 mm Hg level.*

K. Revascularization

1. Indications—There is general agreement that otherwise healthy patients in the following groups should undergo revascularization: (1) patients with unacceptable symptoms despite medical therapy to its tolerable limits; (2) patients with left main coronary artery stenosis > 50% with or without symptoms; (3) patients with three-vessel disease with LV dysfunction (EF < 50% or previous transmural infarction); (4) patients with unstable angina who after symptom control by medical therapy continue to exhibit ischemia on exercise testing or monitoring; and (5) post-MI patients with continuing angina or severe ischemia on noninvasive testing. The use of revascularization for patients with ACSs and acute ST-segment elevation MI (STEMI) is discussed below.

Data from the COURAGE trial have shown that for patients with chronic angina and disease suitable for PCI, PCI in addition to stringent guideline-directed medical therapy aimed at both risk reduction and anti-anginal care offers no mortality benefit beyond excellent medical therapy alone, and relatively moderate long-term symptomatic improvement. Therefore, *for patients with mild to moderate CAD and limited symptoms, revascularization may not provide significant functional status quality-of-life benefit.* For patients with moderate to significant coronary stenosis, such as those who have two-vessel disease associated with underlying LV dysfunction, anatomically critical lesions (> 90% proximal stenoses, especially of the proximal left anterior descending artery), or physiologic evidence of severe ischemia (early positive exercise tests, large exercise-induced thallium scintigraphic defects, or frequent episodes of ischemia on ambulatory monitoring), a heart team consisting of revascularization physicians (interventional cardiologists and surgeons) may be required to review and provide patients with the best revascularization options. More recently, another study examined the role of PCI revascularization along with optimal guideline-directed medical therapy versus optimal guideline-directed medical therapy alone in 700 randomized patients with ischemic cardiomyopathy (EF < 35%) and myocardial viability. Compared with optimal medical therapy alone, PCI did *not* improve mortality, rate of hospitalization for HF, or EF.

The ISCHEMIA trial found that for patients with moderate to severe ischemia on stress testing, coronary angiography and revascularization did not reduce the risk of cardiovascular death, MI, hospitalization for unstable angina, HF, or resuscitated cardiac arrest. Thus, in the context of optimal medical therapy to prevent cardiovascular events, a higher threshold for whom to evaluate with stress tests and coronary angiography may be reasonable.

2. Type of procedure

A. PERCUTANEOUS CORONARY INTERVENTION INCLUDING STENTING—PCI, including balloon angioplasty and coronary stenting, can effectively open stenotic coronary arteries. Coronary stenting, with either bare metal stents or drug-eluting stents, has substantially reduced restenosis. Stenting can also be used selectively for left main coronary stenosis, particularly when CABG is contraindicated or deemed high risk.

PCI is possible but often less successful in bypass graft stenoses. Experienced operators are able to successfully dilate > 90% of lesions attempted. The major early complication is intimal dissection with vessel occlusion, although this is rare with coronary stenting. The use of intravenous platelet glycoprotein IIb/IIIa inhibitors (abciximab, eptifibatide, tirofiban) substantially reduces the rate of periprocedural MI, and placement of intracoronary stents markedly improves initial and long-term angiographic results, especially with complex and long lesions. After PCI, all patients should have CK-MB and troponin measured. The definition of a *periprocedural infarction* has been debated, with many experts advocating for a clinical definition that incorporates different enzyme cutpoints, angiographic findings, and electrocardiographic evidence. Acute thrombosis after stent placement can largely be prevented by aggressive antithrombotic therapy (long-term aspirin, 81–325 mg, plus clopidogrel, 300–600 mg loading dose followed by 75 mg daily, for between 30 days and 1 year, and with acute use of platelet glycoprotein IIb/IIIa inhibitors).

A major limitation with PCI has been restenosis, which occurs in the first 6 months in < 10% of vessels treated with drug-eluting stents, 15–30% of vessels treated with bare metal stents, and 30–40% of vessels without stenting. Factors associated with higher restenosis rates include diabetes, small luminal diameter, longer and more complex lesions, and lesions at coronary ostia or in the left anterior descending coronary artery. Drug-eluting stents that elute antiproliferative agents, such as sirolimus, everolimus, zotarolimus, or paclitaxel, have substantially reduced restenosis. In-stent restenosis is often treated with restenting with drug-eluting stents, and rarely with brachytherapy. The nearly 2 million PCIs performed worldwide per year far exceed the number of CABG operations, but the rationale for many of the procedures performed in patients with stable angina should be for angina symptom reduction. Moreover, data published in 2021 reported that 706,263 PCIs were performed in the United States from 2018 to 2019.

The role of routine functional stress testing following PCI to improve patient outcomes was analyzed in a randomized study of 1706 patients. There was no difference in all-cause death, MI, or hospitalization for unstable angina between the those assigned to surveillance stress testing at 1 year following PCI or those receiving standard care, strongly arguing *against* a role for routine stress testing in asymptomatic patients post-PCI.

The COURAGE trial and the ORBITA sham-controlled trial have confirmed earlier studies in showing that, even for patients with moderate anginal symptoms and positive stress tests, PCI provides no benefit over medical therapy with respect to death or MI. PCI was more effective at relieving angina, although most patients in the medical group had improvement in symptoms. PCI was also not more effective than optimal medical therapy for exercise time in patients with one vessel coronary disease. Thus, *in patients with mild or moderate stable symptoms, aggressive lipid-lowering and antianginal therapy may be a preferable initial strategy, reserving PCI for patients with significant and refractory symptoms or for those who are unable to take the prescribed medicines.*

Several studies of PCI, including those with drug-eluting stents, versus CABG in patients with multivessel disease have been reported. The SYNTAX trial as well as previously performed trials with drug-eluting stent use in PCI patients show comparable mortality and infarction rates over follow-up periods of 1–3 years but a high rate (approximately 40%) of repeat procedures following PCI. Stroke rates are higher with CABG. As a result, the choice of revascularization procedure may depend on details of coronary anatomy and is often a matter of patient preference. However, it should be noted that < 20% of patients with multivessel disease meet the entry criteria for the clinical trials, so these results cannot be generalized to all multivessel disease patients. Outcomes with percutaneous revascularization in patients with diabetes have generally been inferior to those with CABG. The FREEDOM trial demonstrated that *CABG surgery was superior to PCI with regard to death, MI, and stroke for patients with diabetes and multivessel coronary disease* at 5 years across all subgroups of SYNTAX score anatomy.

B. Coronary artery bypass grafting—CABG can be accomplished with a very low mortality rate (1–3%) in otherwise healthy patients with preserved cardiac function. However, the mortality rate of this procedure rises to 4–8% in older individuals and in patients who have had a prior CABG.

Grafts using one or both **internal mammary arteries** (usually to the left anterior descending artery or its branches) provide the best long-term results in terms of patency and flow. Segments of the saphenous vein (or, less optimally, other veins) or the radial artery interposed between the aorta and the coronary arteries distal to the obstructions are also used. One to five distal anastomoses are commonly performed.

Minimally invasive surgical techniques may involve a limited sternotomy, lateral thoracotomy (MIDCAB), or thoracoscopy (port-access). They are more technically demanding, usually not suitable for more than two grafts, and do not have established durability. Bypass surgery can be performed both on circulatory support (on-pump) and without direct circulatory support (off-pump). Randomized trial data have *not* shown a benefit with off-pump bypass surgery, but minimally invasive surgical techniques allow earlier postoperative mobilization and discharge.

The operative mortality rate is increased in patients with poor LV function (LVEF < 35%) or those requiring additional procedures (valve replacement or ventricular aneurysmectomy). Patients over 70 years of age, patients undergoing repeat procedures, or those with important noncardiac disease (especially CKD and diabetes) or poor general health also have higher operative mortality and morbidity rates, and full recovery is slow. Thus, CABG should be reserved for more severely symptomatic patients in this group. Early (1–6 months) graft patency rates average 85–90% (higher for internal mammary grafts), and subsequent graft closure rates are about 4% annually. Early graft failure is common in vessels with poor distal flow, while late closure is more frequent in patients who continue smoking and those with untreated hyperlipidemia. Antiplatelet therapy with aspirin improves graft patency rates. Smoking cessation and vigorous treatment of blood lipid abnormalities (particularly with statins) are necessary. Repeat revascularization may be necessary because of recurrent symptoms due to progressive native vessel disease and graft occlusions. Reoperation is technically demanding and less often fully successful than the initial operation. In addition, in patients with ischemic mitral regurgitation, mitral repair at the time of a CABG does *not* offer any clinical benefit.

L. Mechanical Extracorporeal Counterpulsation

Extracorporeal counterpulsation entails repetitive inflation of a high-pressure chamber surrounding the lower half of the body during the diastolic phase of the cardiac cycle for daily 1-hour sessions over a period of 7 weeks. Randomized trials have shown that extracorporeal counterpulsation reduces angina, thus it may be considered for relief of refractory angina in patients with stable coronary disease.

M. Neuromodulation

Spinal cord stimulation can be used to relieve chronic refractory angina. Spinal cord stimulators are subcutaneously implantable via a minimally invasive procedure under local anesthesia.

Prognosis

The prognosis of angina pectoris has improved with development of therapies aimed at secondary prevention. Mortality rates vary depending on the number of vessels diseased, the severity of obstruction, the status of LV function, and the presence of complex arrhythmias. Mortality rates are progressively higher in patients with one-, two-, and three-vessel disease and those with left main coronary artery obstruction (ranging from 1% per year to 25% per year). *The outlook in individual patients is unpredictable, and nearly half of the deaths are sudden.* Therefore, risk stratification is attempted. Patients with accelerating symptoms have a poorer outlook. Among stable patients, those whose exercise tolerance is severely limited by ischemia (< 6 minutes on the Bruce treadmill protocol) and those with extensive ischemia by exercise ECG or scintigraphy have more severe anatomic disease and a poorer prognosis. The **Duke Treadmill Score,** based on a standard Bruce protocol exercise treadmill test, provides an estimate of risk of death at 1 year. The score uses time on the treadmill, amount of ST-segment depression, and presence of angina (Table 10–7).

Table 10–7. Duke Treadmill Score: calculation and interpretation.

Time in minutes on Bruce protocol		= ______________
–5 × amount of depression (in mm)		= ______________
–4 × angina index 0 = no angina on test 1 = angina, not limiting 2 = limiting angina		= ______________
Total Summed Score	**Risk Group**	**Annual Mortality**
≥ 5	Low	0.25%
–10 to 4	Intermediate	1.25%
≤ –11	High	5.25%

When to Refer

All patients with new or worsening symptoms believed to represent progressive angina or a positive stress test for myocardial ischemia with continued angina despite medical therapy (or both) should be referred to a cardiologist.

When to Admit

- Patients with elevated cardiac biomarkers, ischemic ECG findings, or hemodynamic instability.
- Patients with new or worsened symptoms, possibly thought to be ischemic, but who lack high-risk features can be observed with serial ECGs and biomarkers and discharged if stress testing shows low-risk findings.

CORONARY VASOSPASM & ANGINA OR MI WITH NORMAL CORONARY ARTERIOGRAMS

ESSENTIALS OF DIAGNOSIS

- Precordial chest pain, often occurring at rest during stress or without known precipitant, relieved rapidly by nitrates.
- ECG evidence of ischemia during pain, sometimes with ST-segment elevation.
- Angiographic demonstration of:
- No significant obstruction of major coronary vessels.
- Coronary spasm that responds to intracoronary nitroglycerin or calcium channel blockers.

General Considerations

Although most symptoms of myocardial ischemia result from fixed stenosis of the coronary arteries, intraplaque hemorrhage, or thrombosis at the site of lesions, some ischemic events may be precipitated or exacerbated by coronary vasoconstriction.

Spasm of the large coronary arteries with resulting decreased coronary blood flow may occur spontaneously or may be induced by exposure to cold, emotional stress, or vasoconstricting medications, such as ergot-derivative medications. Spasm may occur both in normal and in stenosed coronary arteries. Even MI may occur as a result of spasm in the absence of visible obstructive CHD, although most instances of such coronary spasm occur in the presence of coronary stenosis.

Cocaine can induce myocardial ischemia and infarction by causing coronary artery vasoconstriction or by increasing myocardial energy requirements. It also may contribute to accelerated atherosclerosis and thrombosis. The ischemia in **Prinzmetal (variant) angina** usually results from coronary vasoconstriction. It tends to involve the right coronary artery and there may be no fixed stenoses. Myocardial ischemia may also occur in patients with normal coronary arteries as a result of disease of the coronary microcirculation or abnormal vascular reactivity. MI without obstructive coronary disease is more frequent in women and has been shown to be due to atherosclerosis or ruptured plaques in 80% of cases. The 2020 ESC guidelines recommend cardiac MRI to aid in determining the cause of MI without obstructive coronary disease.

Clinical Findings

Ischemia may be silent or result in angina pectoris.

Prinzmetal (variant) angina is a clinical syndrome in which chest pain occurs without the usual precipitating factors and is associated with ST-segment elevation rather than depression. It often affects women under 50 years of age. It characteristically occurs in the early morning, awakening patients from sleep, and is apt to be associated with arrhythmias or conduction defects. It may be diagnosed by challenge with ergonovine (a vasoconstrictor), although the results of such provocation are not specific and it entails risk.

Treatment

Patients with chest pain associated with ST-segment elevation should undergo coronary arteriography to determine whether fixed stenotic lesions are present. If they are, aggressive medical therapy or revascularization is indicated, since the presence of these lesions may represent an unstable phase of the disease. If significant lesions are not seen, there may still be endothelial disruption and plaque rupture. If spasm is suspected, avoidance of precipitants, such as cigarette smoking and cocaine, is the top priority. Episodes of coronary spasm generally respond well to nitrates, and both nitrates and calcium channel blockers (including long-acting nifedipine, diltiazem, or amlodipine [see Table 13–8]) are effective prophylactically. By allowing unopposed α_1-mediated vasoconstriction, β-blockers have exacerbated coronary vasospasm, but they may have a role in management of patients in whom spasm is associated with fixed stenoses.

When to Refer

All patients with persistent symptoms of chest pain that may represent spasm should be referred to a cardiologist.

ACUTE CORONARY SYNDROMES WITHOUT ST-SEGMENT ELEVATION

ESSENTIALS OF DIAGNOSIS

- Distinction in ACS between patients with and without ST-segment elevation at presentation is essential to determine need for reperfusion therapy.
- Fibrinolytic therapy is harmful in ACS without ST-segment elevation, unlike with ST-segment elevation, where acute reperfusion saves lives.
- Antiplatelet and anticoagulation therapies and coronary intervention are mainstays of treatment.

General Considerations

***ACSs** comprise the spectrum of unstable cardiac ischemia from unstable angina to acute MI.* ACSs are classified based on the presenting ECG as either **ST-segment elevation MI (STEMI)** or **non–ST-segment elevation MI (NSTEMI)**. This allows for immediate classification and guides determination of whether patients should be considered for acute reperfusion therapy. The evolution of cardiac biomarkers then allows determination of whether MI has occurred.

ACSs represent a *dynamic state* in which patients frequently shift from one category to another, as new ST elevation can develop after presentation and cardiac biomarkers can become abnormal with recurrent ischemic episodes.

Clinical Findings

A. Symptoms and Signs

Patients with ACSs generally have symptoms and signs of myocardial ischemia either at rest or with minimal exertion. These symptoms and signs are similar to the chronic angina symptoms described above, consisting of substernal chest pain or discomfort that may radiate to the jaw, left shoulder or arm. Dyspnea, nausea, diaphoresis, or syncope may either accompany the chest discomfort or may be the only symptom of ACS. *About one-third of patients with MI have no chest pain per se*—these patients tend to be older, female, have diabetes, and be at higher risk for subsequent mortality. Patients with ACSs have signs of HF in about 10% of cases, and this is also associated with higher risk of death.

Many hospitals have developed **chest pain observation units** to provide a systematic approach toward serial risk stratification to improve the triage process. In many cases, those who have not experienced new chest pain and have insignificant ECG changes and no cardiac biomarker elevation undergo treadmill exercise tests or imaging procedures to exclude ischemia at the end of an 8- to 24-hour period and are discharged directly from the emergency department if these tests are negative.

B. Laboratory Findings

Depending on the time from symptom onset to presentation, initial laboratory findings may be normal. The markers of cardiac myocyte necrosis (**myoglobin**, **CK-MB,** and **troponin I and T**) may all be used to identify acute MI, although *high-sensitivity troponin is the recommended biomarker to diagnose acute MI* (see Laboratory Findings, Acute Myocardial Infarction with ST-Segment Elevation). In patients with STEMI, these initial markers are often within normal limits as the patient is being rushed to immediate reperfusion. In patients without ST-segment elevation, it is the presence of abnormal CK-MB or troponin values that are associated with myocyte necrosis and the diagnosis of MI. High-sensitivity troponin assays allow rapid assessment of MI in emergency departments by using 1- or 2-hour rule out algorithms. The universal definition of MI is a rise of cardiac biomarkers with at least one value above the 99th percentile of the upper reference limit together with evidence of myocardial ischemia with at least one of the following: symptoms of ischemia, ECG changes of new ischemia, new Q waves, or imaging evidence of new loss of viable myocardium or new wall motion abnormality.

Serum creatinine is an important determinant of risk, and estimated creatinine clearance is important to guide dosing of certain antithrombotics, including eptifibatide and enoxaparin.

C. ECG

Many patients with ACSs will exhibit ECG changes during pain—either ST-segment elevation, ST-segment depression, or T wave flattening or inversion. Dynamic ST-segment shift is the most specific for ACS. ST-segment elevation in lead AVR suggests left main or three-vessel disease.

Treatment

A. General Measures

Treatment of ACSs without ST elevation should be multifaceted. Patients who are at medium or high risk should be hospitalized, maintained at bed rest or at very limited activity for the first 24 hours, monitored, and given supplemental oxygen. Sedation with a benzodiazepine agent may help if anxiety is present.

B. Specific Measures

Figure 10–7 provides an algorithm for initial management of NSTEMI.

C. Antiplatelet and Anticoagulation Therapy

Patients should receive a combination of antiplatelet and anticoagulant agents on presentation. *Fibrinolytic therapy should be avoided in patients without ST-segment elevation since they generally do not have an acute coronary occlusion, and the risk of such therapy appears to outweigh the benefit.*

1. Antiplatelet therapy—

A. ASPIRIN—Aspirin, 162–325 mg loading dose, then 81 mg daily, should be commenced immediately and continued for the first month. The 2020 ESC guidelines for longer-term aspirin treatment recommend aspirin 75–100 mg/day as preferable to higher doses with or without coronary stenting.

B. $P2Y_{12}$ INHIBITORS—ACC/AHA guidelines call for either a $P2Y_{12}$ inhibitor (clopidogrel, prasugrel [at the time of PCI], or ticagrelor) as a class I recommendation. The ESC guidelines provide a stronger recommendation for a $P2Y_{12}$ inhibitor upfront, as a class IA recommendation for all patients. Both sets of guidelines recommend postponing elective CABG surgery for at least 5 days after the last dose of clopidogrel or ticagrelor and at least 7 days after the last dose of prasugrel, due to risk of bleeding.

The Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) trial demonstrated a 20% reduction in the composite end point of cardiovascular death, MI, and stroke with the addition of clopidogrel (300-mg loading dose, 75 mg/day for 9–12 months) to aspirin in patients with non–ST-segment elevation ACSs. The large CURRENT trial showed that "double-dose" clopidogrel (600-mg initial oral loading dose, followed by 150 mg orally daily) for 7 days reduced stent thrombosis with a modest increase in major (but not fatal) bleeding and, therefore, it is an option for patients with ACS undergoing PCI.

The ESC guidelines recommend ticagrelor for all patients at moderate to high risk for ACS (class I recommendation). Prasugrel is recommended for patients who have not yet received another $P2Y_{12}$ inhibitor, for whom a PCI is planned, and who are not at high risk for life-threatening bleeding. Clopidogrel is reserved for patients who cannot receive either ticagrelor or prasugrel. Some studies have shown an association between assays of residual platelet function and thrombotic risk during $P2Y_{12}$ inhibitor therapy, and both the European and the US guidelines do not recommend routine platelet function testing to guide therapy (class IIb recommendation).

Prasugrel is both more potent and has a faster onset of action than clopidogrel. The TRITON trial compared prasugrel with clopidogrel in patients with STEMI or NSTEMI in whom PCI was planned; prasugrel resulted in a 19% relative reduction in death from cardiovascular causes, MI, or stroke, at the expense of an increase in serious bleeding (including fatal bleeding). Stent thrombosis was reduced by half. Because patients with prior stroke or TIA had higher risk of intracranial hemorrhage, prasugrel is contraindicated in such patients. Bleeding was also higher in patients with low body weight (< 60 kg) and age ≥ 75 years, and caution should be used in these populations. For patients with STEMI treated with PCI, prasugrel appears to be especially effective (compared to clopidogrel) without a substantial increase in bleeding. For patients who will not receive revascularization, prasugrel, when compared to clopidogrel, had no overall benefit in the TRILOGY trial (the dose of prasugrel was lowered for older adults). Prasugrel appears to be at least comparable to ticagrelor for patients with STEMI regarding safety and efficacy based on the ISAR-REACT 5 trial.

• Enoxaparin (Class I; LOE: A) or
• Fondaparinux[†](Class I; LOE: B)
Initiate DAPT and Anticoagulant Therapy
1. ASA (Class I; LOE: A)
2. $P2Y_{12}$ inhibitor (in addition to ASA) (Class I; LOE: B):
• Clopidogrel or
• Ticagrelor
3. Anticoagulant:
• UFH (Class I; LOE: B) or
• Enoxaparin (Class I; LOE: A) or
• Fondaparinux[†](Class I; LOE: B) or
• Bivalirudin (Class I; LOE: B)
Can consider GPI in addition to ASA and $P2Y_{12}$ inhibitor in high-risk (eg, troponin positive) patients (Class IIb; LOE: B)
• Eptifibatide
• Tirofiban
Medical therapy chosen based on cath findings
Therapy Effective
Therapy Ineffective
PCI With Stenting
Initiate/continue antiplatelet and anticoagulant therapy
1. ASA (Class I; LOE: B)
2. $P2Y_{12}$ inhibitor (in addition to ASA):
• Clopidogrel (Class I; LOE: B) or
• Prasugrel (Class I; LOE: B) or
• Ticagrelor (Class I; LOE: B)
3. GPI (if not treated with bivalirudin at time of PCI)
• High-risk features, not adequately pretreated with clopidogrel (Class I; LOE: A)
• High-risk features adequately pretreated with clopidogrel (Class IIa; LOE: B)
4. Anticoagulant:
• Enoxaparin (Class I; LOE: A) or
• Bivalirudin (Class I; LOE: B) or
• Fondaparinux[†] as the sole anticoagulant (Class III: Harm; LOE: B) or
• UFH (Class I; LOE: B)
CABG
Initiate/continue ASA therapy and discontinue $P2Y_{12}$ and/or GPI therapy
1. ASA (Class I; LOE: B)
2. Discontinue clopidogrel/ticagrelor 5 d before, and prasugrel at least 7 d before elective CABG
3. Discontinue clopidogrel/ticagrelor up to 24 h before urgent CABG (Class I; LOE: B). May perform urgent CABG <5 d after clopidogrel/ticagrelor and <7 d after prasugrel discontinued
4. Discontinue eptifibatide/tirofiban at least 2–4 h before, and abciximab ≥12 h before CABG (Class I; LOE: B)
Late Hospital/Posthospital Care
1. ASA indefinitely (Class I; LOE: A)
2. $P2Y_{12}$ inhibitor (clopidogrel or ticagrelor), in addition to ASA, up to 12 mo if medically treated (Class I; LOE: B)
3. $P2Y_{12}$ inhibitor (clopidogrel, prasugrel, or ticagrelor), in addition to ASA, at least 12 mo if treated with coronary stenting (Class I; LOE: B)

Figure 10–7. Algorithm for management of patients with definite or likely NSTE-ACS.

* *See corresponding full-sentence recommendations and their explanatory footnotes.

[†]In patients who have been treated with fondaparinux (as upfront therapy) who are undergoing PCI, an additional anticoagulant with anti-IIa activity should be administered at the time of PCI because of the risk of catheter thrombosis. ASA indicates aspirin; CABG, coronary artery bypass graft; cath, catheter; COR, Class of Recommendation; DAPT, dual antiplatelet therapy; GPI, glycoprotein IIb/IIIa inhibitor; LOE, Level of Evidence; NSTE-ACS, non–ST-elevation ACS; PCI, percutaneous coronary intervention; pts, patients; and UFH, unfractionated heparin. (Reproduced with permission from Amsterdam EA, Wenger NK, Brindis RG, et al. 2014 AHA/ACC Guideline for the Management of Patients with Non-ST-Elevation Acute Coronary Syndromes: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [published correction appears in J Am Coll Cardiol. 2014;64(24):2713–2714.)

Ticagrelor has a faster onset of action than clopidogrel and a more consistent and potent effect. The PLATO trial showed that when ticagrelor was started at the time of presentation in ACS patients (UA/NSTEMI and STEMI), it reduced cardiovascular death, MI, and stroke by 16% when compared with clopidogrel. In addition, there was a 22% relative risk reduction in mortality with ticagrelor. The overall rates of bleeding were similar between ticagrelor and clopidogrel, although non–CABG-related bleeding was modestly higher. The finding of a lesser treatment effect in the United States may have been related to use of higher-dose aspirin, and thus when using ticagrelor, low-dose aspirin (81 mg/day) is recommended.

c. Glycoprotein IIb/IIIa inhibitors—Small-molecule inhibitors of the platelet glycoprotein IIb/IIIa receptor are useful adjuncts in high-risk patients (usually defined by fluctuating ST-segment depression or positive biomarkers) with ACSs, particularly when they are undergoing PCI. Tirofiban, 25 mcg/kg over 3 minutes, followed by 0.15 mcg/kg/min, and eptifibatide, 180 mcg/kg bolus followed by a continuous infusion of 2 mcg/kg/min, have both been shown to be effective. Downward dose adjustments of the infusions are required in patients with reduced kidney function. The bolus or loading dose remains unadjusted. For example, if the estimated creatinine clearance is below 50 mL/min, the eptifibatide infusion should be cut in half to 1 mcg/kg/min.

2. Anticoagulant therapy

a. Heparin—Several trials have shown that LMWH (enoxaparin 1 mg/kg subcutaneously every 12 hours) is somewhat more effective than unfractionated heparin in preventing recurrent ischemic events in the setting of ACSs. However, the SYNERGY trial showed that unfractionated heparin and enoxaparin had similar rates of death or (re)infarction in the setting of frequent early coronary intervention.

b. Fondaparinux—Fondaparinux, a specific factor Xa inhibitor given in a dose of 2.5 mg subcutaneously once a day, was found in the OASIS-5 trial to be equally effective as enoxaparin among 20,000 patients at preventing early death, MI, and refractory ischemia, and resulted in a 50% reduction in major bleeding. This reduction in major bleeding translated into a significant reduction in mortality (and in death or MI) at 30 days. While catheter-related thrombosis was more common during coronary intervention procedures with fondaparinux, the FUTURA trial found that it can be controlled by adding unfractionated heparin (in a dose of 85 U/kg without glycoprotein IIb/IIIa inhibitors, and 60 U/kg with glycoprotein IIb/IIIa inhibitors) during the procedure. Guidelines recommend fondaparinux, describing it as especially favorable for patients who are initially treated medically and who are at high risk for bleeding, such as older adults.

c. Direct thrombin inhibitors—The ACUITY trial showed that bivalirudin appears to be a reasonable alternative to heparin (unfractionated heparin or enoxaparin) plus a glycoprotein IIb/IIIa antagonist for many patients with ACSs who are undergoing early coronary intervention. Bivalirudin (without routine glycoprotein IIb/IIIa inhibitor) is associated with substantially less bleeding than heparin plus glycoprotein IIb/IIIa inhibitor, although it may have numerically increased cardiovascular events. The ISAR-REACT-4 trial showed that bivalirudin has similar efficacy compared to abciximab but better bleeding outcomes in NSTEMI patients. Bivalirudin does not have an FDA-approved indication for NSTEMI care.

D. Temporary Discontinuation of Antiplatelet Therapy for Procedures

Patients who have had recent coronary stents are at risk for thrombotic events, including stent thrombosis, if $P2Y_{12}$ inhibitors are discontinued for procedures (eg, dental procedures or colonoscopy). If possible, these procedures should be delayed until the end of the necessary treatment period with $P2Y_{12}$ inhibitors, which generally is at least 1 month with bare metal stents and 3–6 months with drug-eluting stents. With current generation drug-eluting stents, elective stenting patients with bleeding risk may have $P2Y_{12}$ inhibitors stopped before 3 months. Before that time, if a procedure is necessary, risk and benefit of continuing the antiplatelet therapy through the time of the procedure should be assessed. Aspirin should generally be continued throughout the period of the procedure. Patients with polymer-free drug coated stents who are at high risk for bleeding and receiving a short course of dual antiplatelet therapy had fewer cardiovascular and bleeding events. Likewise, in the MASTER-DAPT trial, patients at high risk for bleeding treated for 1 month with DAPT had noninferior outcomes with respect to major adverse cardiac events compared with longer duration DAPT with lower rates of bleeding. *A cardiologist should be consulted before temporary discontinuation of these agents.*

E. Nitroglycerin

Nitrates are first-line therapy for patients with ACSs presenting with chest pain. Nonparenteral therapy with sublingual or oral agents or nitroglycerin ointment is usually sufficient. If pain persists or recurs, intravenous nitroglycerin should be started. The usual initial dosage is 10 mcg/min. The dosage should be titrated upward by 10–20 mcg/min (to a maximum of 200 mcg/min) until angina disappears or mean arterial pressure drops by 10%. Careful—usually continuous—BP monitoring is required when intravenous nitroglycerin is used. Avoid hypotension (systolic BP < 100 mm Hg). Tolerance to continuous nitrate infusion is common.

F. β-Blockers

β-Blockers are an important part of the initial treatment of unstable angina unless otherwise contraindicated. The pharmacology of these agents is discussed in Chapter 13 and summarized in Tables 13–10 and 13–11. Use of agents with intrinsic sympathomimetic activity should be avoided in this setting. Oral medication is adequate in most patients, but intravenous treatment with metoprolol, given as three 5-mg doses 5 minutes apart as tolerated and in the absence of HF, achieves a more rapid effect. Oral therapy should be titrated upward as BP permits.

G. Calcium Channel Blockers

Calcium channel blockers have *not* been shown to favorably affect outcome in unstable angina, and they should be used primarily as third-line therapy in patients with continuing angina who are taking nitrates and β-blockers or those who are not candidates for these medications. In the presence of nitrates and without accompanying β-blockers, diltiazem or verapamil is preferred, since nifedipine and the other dihydropyridines are more likely to cause reflex tachycardia or hypotension. The initial dosage should be low, but upward titration should proceed steadily (see Table 13–8).

H. Statins

The PROVE-IT trial provides evidence for starting a statin in the days immediately following an ACS. In this trial, more intensive therapy with atorvastatin 80 mg/day, regardless of total or LDL cholesterol level, improved outcome compared to pravastatin 40 mg/day, with the curves of death or major cardiovascular event separating as early as 3 months after starting therapy. *High-intensity statins are recommended for all patients with ACSs.*

▶ Indications for Coronary Angiography

For patients with ACS, including NSTEMI, risk stratification is important for determining intensity of care. Several therapies, including glycoprotein IIb/IIIa inhibitors, LMWH heparin, and early invasive catheterization, have been shown to have the greatest benefit in higher-risk patients with ACS. As outlined in the ACC/AHA guidelines, patients with any high-risk feature (Table 10–8) generally warrant an early invasive strategy with catheterization and revascularization. For patients without these high-risk features, either an invasive or noninvasive approach, using exercise (or pharmacologic stress for patients unable to exercise) stress testing to identify patients who have residual ischemia, are at high risk, or both, can be used. Moreover, based on the ICTUS trial, a strategy based on selective coronary angiography and revascularization for instability or inducible ischemia, or both, even for patients with positive troponin, is acceptable (ACC/AHA class IIb recommendation).

Two risk-stratification tools are available that can be used at the bedside, the **GRACE Risk Score** (http://www.outcomes-umassmed.org/grace) and the **TIMI Risk Score** (http://www.timi.org). The GRACE Risk Score, which applies to patients with or without ST elevation, was developed in a more generalizable registry population and has better discrimination of risk. It includes age (as a continuous variable), Killip class, BP, ST-segment deviation, cardiac arrest at presentation, serum creatinine, elevated creatine kinase (CK)-MB or troponin, and heart rate. The TIMI Risk Score includes seven variables: age 65 years or older, three or more cardiac risk factors, prior coronary stenosis of 50% or more, ST-segment deviation, two anginal events in prior 24 hours, aspirin in prior 7 days, and elevated cardiac markers.

Table 10–8. Indications for catheterization and percutaneous coronary intervention.[1]

ACSs (unstable angina and non–ST-elevation MI)	
Class I	Early invasive strategy for any of the following high-risk indicators:
	Recurrent angina/ischemia at rest or with low-level activity
	Elevated troponin
	ST-segment depression
	Recurrent ischemia with evidence of HF
	High-risk stress test result
	EF < 40%
	Hemodynamic instability
	Sustained ventricular tachycardia
	PCI within 6 months
	Prior CABG
	In the absence of these findings, either an early conservative or early invasive strategy
Class IIa	Early invasive strategy for patients with repeated presentations for ACS despite therapy
Class III	Extensive comorbidities in patients in whom benefits of revascularization are not likely to outweigh the risks
	Acute chest pain with low likelihood of ACS
Acute MI after fibrinolytic therapy	
Class I	Cardiogenic shock or acute severe HF that develops after initial presentation
	Intermediate- or high-risk findings on predischarge noninvasive ischemia testing
	Spontaneous or easily provoked myocardial ischemia
Class IIa	Failed reperfusion or reocclusion after fibrinolytic therapy
	Stable[2] patients after successful fibrinolysis, before discharge and ideally between 3 and 24 hours

[1] Class I indicates treatment is useful and effective, IIa indicates weight of evidence is in favor of usefulness/efficacy, class IIb indicates weight of evidence is less well established, and class III indicates intervention is not useful/effective and may be harmful. Level of evidence A recommendations are derived from large-scale randomized trials, and B recommendations are derived from smaller randomized trials or carefully conducted observational analyses.

[2] Although individual circumstances will vary, clinical stability is defined by the absence of low output, hypotension, persistent tachycardia, apparent shock, high-grade ventricular or symptomatic supraventricular tachyarrhythmias, and spontaneous recurrent ischemia.

ACCF/AHA, American College of Cardiology Foundation/American Heart Association; CABG, coronary artery bypass grafting; PCI, percutaneous coronary intervention.

Data from O'Gara PT et al. 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. Circulation. 2013;127:e362–e425.

When to Refer

- All patients with acute MI should be referred to a cardiologist.
- Patients who are taking a P2Y$_{12}$ inhibitor following coronary stenting should consult a cardiologist before discontinuing treatment for nonemergency procedures.

ACUTE MI WITH ST-SEGMENT ELEVATION

ESSENTIALS OF DIAGNOSIS

- Sudden but not instantaneous development of prolonged (> 30 minutes) anterior chest discomfort (sometimes felt as "gas" or pressure).
- Sometimes painless, masquerading as acute HF, syncope, stroke, or shock.
- ECG: ST-segment elevation or left bundle branch block.
- Immediate reperfusion treatment is warranted.
- Primary PCI within 90 minutes of first medical contact is the goal and is superior to fibrinolytic therapy.
- Fibrinolytic therapy within 30 minutes of hospital presentation is the goal and reduces mortality if given within 12 hours of onset of symptoms.

General Considerations

STEMI results, in most cases, from an occlusive coronary thrombus at the site of a preexisting (though not necessarily severe) atherosclerotic plaque. More rarely, infarction may result from prolonged vasospasm, inadequate myocardial blood flow (eg, hypotension), or excessive metabolic demand. Very rarely, MI may be caused by embolic occlusion, vasculitis, aortic root or coronary artery dissection, or aortitis. Cocaine, a cause of infarction, should be considered in young individuals without risk factors. A condition that may mimic STEMI is stress cardiomyopathy (also referred to as **takotsubo** or **apical ballooning syndrome**). *ST elevation connotes an acute coronary occlusion and warrants immediate reperfusion therapy with activation of emergency services.*

Clinical Findings

A. Symptoms

1. Premonitory pain—There is usually a worsening in the pattern of angina preceding the onset of symptoms of MI; classically the onset of angina occurs with minimal exertion or at rest.

2. Pain of infarction—*Unlike anginal episodes, most infarctions occur at rest,* and more commonly in the early morning. The pain is similar to angina in location and radiation but it may be more severe, and it builds up rapidly or in waves to maximum intensity over a few minutes or longer. Nitroglycerin has little effect; even opioids may not relieve the pain.

3. Associated symptoms—Patients may break out in a cold sweat, feel weak and apprehensive, and move about, seeking a position of comfort. They prefer not to lie quietly. Light-headedness, syncope, dyspnea, orthopnea, cough, wheezing, nausea and vomiting, or abdominal bloating may be present singly or in any combination.

4. Painless infarction—One-third of patients with acute MI present *without* chest pain, and these patients tend to be undertreated and have poor outcomes. Older patients, women, and patients with diabetes mellitus are more likely to present without chest pain. As many as 25% of infarctions are detected on routine ECG without any recallable acute episode.

5. Sudden death and early arrhythmias—Of all deaths from MI, about half occur before the patients arrive at the hospital, with death presumably caused by ventricular fibrillation.

B. Signs

1. General—Patients may appear anxious and sometimes are sweating profusely. The heart rate may range from marked bradycardia (most commonly in inferior infarction) to tachycardia, low cardiac output, or arrhythmia. The BP may be high, especially in patients with previous hypertension, or low in patients with shock. Respiratory distress usually indicates HF. Fever, usually low grade, may appear after 12 hours and persist for several days.

2. Chest—The **Killip classification** is the standard way to classify HF in patients with acute MI and has powerful prognostic value. Killip class I is absence of rales and S$_3$, class II is rales that do not clear with coughing over one-third or less of the lung fields or presence of an S$_3$, class III is rales that do not clear with coughing over more than one-third of the lung fields, and class IV is cardiogenic shock (rales, hypotension, and signs of hypoperfusion).

3. Heart—The cardiac examination may be unimpressive or very abnormal. Jugular venous distention reflects RA hypertension, and a Kussmaul sign (failure of decrease of jugular venous pressure with inspiration) is suggestive of RV infarction. Soft heart sounds may indicate LV dysfunction. Atrial gallops (S$_4$) are the rule, whereas ventricular gallops (S$_3$) are less common and indicate significant LV dysfunction. Mitral regurgitation murmurs are not uncommon and may indicate papillary muscle dysfunction or, rarely, rupture. Pericardial friction rubs are uncommon in the first 24 hours but may appear later.

4. Extremities—Edema is usually not present. Cyanosis and cold temperature indicate low output. The peripheral pulses should be noted, since later shock or emboli may alter the examination.

C. Laboratory Findings

Cardiac-specific markers of myocardial damage include quantitative determinations of CK-MB, highly sensitive and conventional troponin I, and troponin T. Each of these tests may become positive as early as 4–6 hours after the onset of an MI and should be abnormal by 8–12 hours. Troponins are more sensitive and specific than CK-MB. “Highly sensitive” or “fourth-generation” troponin assays were approved in 2017. They are the standard assays in most of Europe, with a 10- to 100-fold lower limit of detection, allowing MI to be detected earlier, using the change in value over 3 hours.

Circulating levels of troponins may remain elevated for 5–7 days or longer and therefore are generally not useful for evaluating suspected early reinfarction. Elevated CK-MB generally normalizes within 24 hours, thus being more helpful for evaluation of reinfarction. Low-level elevations of troponin in patients with severe CKD may not be related to acute coronary disease but rather a function of the physiologic washout of the marker. While many conditions including chronic HF are associated with elevated levels of the high-sensitivity troponin assays, these assays may be especially useful when negative to exclude MI in patients reporting chest pain.

D. ECG

The extent of the ECG abnormalities, especially the sum of the total amount of *ST-segment deviation*, is a good indicator of the extent of acute infarction and risk of subsequent adverse events. The classic evolution of changes is from peaked (“hyperacute”) T waves, to ST-segment elevation, to Q wave development, to T wave inversion. This may occur over a few hours to several days. *The evolution of new Q waves (longer than 30 msec in duration and 25% of the R wave amplitude) is diagnostic, but Q waves do not occur in 30–50% of acute infarctions* (**non–Q wave infarctions,** which are typically *not* associated with ST elevation). Left bundle branch block, especially when new (or not known to be old), in a patient with symptoms of an acute MI is considered to be a **“STEMI equivalent”**; reperfusion therapy is indicated for the affected patient. Concordant ST elevation (ie, ST elevation in leads with an overall positive QRS complex) with left bundle branch block is a specific finding indicating STEMI.

E. Chest Radiography

The CXR may demonstrate signs of HF, but these changes often lag behind the clinical findings. Signs of aortic dissection, including mediastinal widening, should be sought as a possible alternative diagnosis.

F. Echocardiography

Echocardiography provides convenient *bedside assessment* of LV global and regional function. This can help with the diagnosis and management of infarction; echocardiography has been used successfully to make judgments about admission and management of patients with suspected infarction, including in patients with ST-segment elevation or left bundle branch block of uncertain significance, since normal wall motion makes an infarction unlikely. Doppler echocardiography is generally the most convenient procedure for diagnosing postinfarction mitral regurgitation or VSD.

G. Other Noninvasive Studies

Diagnosis of MI and extent of MI can be assessed by various imaging studies in addition to echocardiography. **MRI with gadolinium contrast enhancement** is the most sensitive test to detect and quantitate extent of infarction, with the ability to detect as little as 2 g of MI. **Technetium-99m pyrophosphate scintigraphy,** when injected at least 18 hours postinfarction, complexes with calcium in necrotic myocardium to provide a “hot spot” image of the infarction. This test is insensitive to small infarctions, and false-positive studies occur, so its use is limited to patients in whom the diagnosis by ECG and enzymes is not possible—principally those who present several days after the event or have intraoperative infarctions. **Scintigraphy with thallium-201** or **technetium-based perfusion tracers** will demonstrate “cold spots” in regions of diminished perfusion, which usually represent infarction when the radiotracer is administered at rest, but abnormalities do not distinguish recent from old damage. All of these tests may be considered after the patient has had revascularization.

H. Hemodynamic Measurements

These can be helpful in managing the patient with suspected cardiogenic shock. Use of PA catheters, however, has generally *not* been associated with better outcomes and should be limited to patients with severe hemodynamic compromise for whom the information would be anticipated to change management.

▶ Treatment

A. Aspirin, P2Y$_{12}$ Inhibitors (Prasugrel, Ticagrelor, and Clopidogrel)

All patients with definite or suspected acute MI should receive aspirin at a dose of 162 mg or 325 mg at once regardless of whether fibrinolytic therapy is being considered or the patient has been taking aspirin. Chewable aspirin provides more rapid blood levels. Patients with a definite aspirin allergy should be treated with a P2Y$_{12}$ inhibitor (clopidogrel, prasugrel, or ticagrelor).

P2Y$_{12}$ inhibitors, in combination with aspirin, have been shown to provide important benefits in patients with acute STEMI. Thus, guidelines call for a *P2Y$_{12}$ inhibitor to be added to aspirin for all patients with STEMI, regardless of whether reperfusion is given, and continued for at least 14 days,* *and generally for 1 year.* The preferred P2Y$_{12}$ inhibitors are prasugrel (60 mg orally on day 1, then 10 mg daily) or ticagrelor (180 mg orally on day 1, then 90 mg twice daily). Both of these medications demonstrated superior outcomes to clopidogrel in clinical studies of primary PCI. Clopidogrel should be administered as a loading dose of 300–600 mg orally for faster onset of action than the 75 mg maintenance dose. With fibrinolytic therapy, ticagrelor appears to be a reasonable alternative to clopidogrel, at least after an initial clopidogrel dose. Prasugrel is contraindicated in patients with a history of stroke or who are older than 75 years.

B. Reperfusion Therapy

Patients with STEMI who seek medical attention within 12 hours of the onset of symptoms should be treated with reperfusion therapy, either primary PCI or fibrinolytic therapy. Patients without ST-segment elevation (previously labeled "non–Q wave" infarctions) do not benefit, and may derive harm, from thrombolysis.

1. Primary percutaneous coronary intervention—Immediate coronary angiography and primary PCI (including stenting) of the infarct-related artery have been shown to be *superior* to thrombolysis when done by experienced operators in high-volume centers with rapid time from first medical contact to intervention ("door-to-balloon"). US and European guidelines call for first medical contact or *door-to-balloon times of 90 minutes or less.* Several trials have shown that if efficient transfer systems are in place, transfer of patients with acute MI from hospitals without primary PCI capability to hospitals with primary PCI capability with first door-to-device times of 120 minutes or less can improve outcome compared with fibrinolytic therapy at the presenting hospital, although this requires sophisticated systems to ensure rapid identification, transfer, and expertise in PCI. Because PCI also carries a lower risk of hemorrhagic complications, including intracranial hemorrhage, it may be the preferred strategy in many older patients and others with contraindications to fibrinolytic therapy (see Table 10–9 for factors to consider in choosing fibrinolytic therapy or primary PCI).

A. Stenting—*PCI with stenting is standard for patients with acute MI.* Although randomized trials have shown a benefit with regard to fewer repeat interventions for restenosis with the use of **drug-eluting stents** in STEMI patients, and current generation drug-eluting stents have similar or lower rates of stent thrombosis than bare metal stents, **bare metal stents** may still be used for selected patients without the ability to obtain and comply with P2Y$_{12}$ inhibitor therapy. In the subgroup of patients with cardiogenic shock, early catheterization and percutaneous

or surgical revascularization are the preferred management and have been shown to reduce mortality.

Glycoprotein IIb/IIIa inhibitors, and specifically abciximab, have been shown to reduce major thrombotic events, and possibly mortality, when added to heparin for patients undergoing primary PCI.

“Facilitated” PCI, whereby a combination of medications (full- or reduced-dose fibrinolytic agents, with or without glycoprotein IIb/IIIa inhibitors) is given followed by immediate PCI, is *not* recommended. *Patients should be treated either with primary PCI or with fibrinolytic agents (and immediate rescue PCI for reperfusion failure), if it can be done promptly* as outlined in the ACC/AHA and European guidelines. Timely access to most appropriate reperfusion, including primary PCI, can be expanded with development of regional systems of care, including emergency medical systems and networks of hospitals. Patients treated with fibrinolytic therapy appear to have improved outcomes if transferred for routine coronary angiography and PCI within 24 hours. The AHA has a program called “Mission: Lifeline” to support the development of regional systems of care (http://www.heart.org/missionlifeline).

B. Antiplatelet therapy after drug-eluting or bare metal stents—*In patients with an ACS,* ***dual antiplatelet therapy*** *is indicated for 1 year in all patients (including those with medical therapy and those patients undergoing revascularization irrespective of stent type). The DAPT (Dual Antiplatelet Therapy) study showed fewer* death, MI, and stroke events with longer (up to 30 months) dual antiplatelet therapy for patients who had received drug-eluting stents, but it also showed more bleeding and a tendency for higher mortality. Treatment with clopidogrel for longer than 1 year after drug-eluting stents, therefore, should be individualized based on thrombotic and bleeding risks. For patients undergoing elective or stable PCI (not in the context of ACS), the duration of dual antiplatelet therapy is recommended for at least 1 month for patients receiving bare metal stents and for at least 3 months for patients receiving drug-eluting stents. These recommendations are based both on the durations of therapies during the studies evaluating the stents, and the pathophysiologic understanding of the timing of endothelialization following bare metal versus drug-eluting stent implantation.

2. Fibrinolytic therapy—

A. Benefit—Fibrinolytic therapy reduces mortality and limits infarct size in patients with STEMI (defined as 0.1 mV or more in two inferior or lateral leads or two contiguous precordial leads) or with left bundle branch block (not known to be old). The greatest benefit occurs if treatment is initiated within the first 3 hours after the onset of presentation, when up to a 50% reduction in mortality rate can be achieved. The magnitude of benefit declines rapidly thereafter, but a 10% relative mortality reduction can be achieved up to 12 hours after the onset of chest pain. The survival benefit is greatest in patients with large—usually anterior—infarctions. *Primary PCI (including stenting) of the infarct-related artery, however, is superior to thrombolysis when done by experienced operators with rapid time from first medical contact to intervention (“door-to-balloon”).*

B. Contraindications—Major bleeding complications occur in 0.5–5% of patients, the most serious of which is intracranial hemorrhage. The major risk factors for intracranial bleeding are age 75 years or older, hypertension at presentation (especially over 180/110 mm Hg), low body weight (< 70 kg), and the use of fibrin-specific fibrinolytic agents (alteplase, reteplase, tenecteplase). Although patients over age 75 years have a much higher mortality rate with acute MI and therefore may derive greater benefit, the risk of severe bleeding is also higher, particularly among patients with risk factors for intracranial hemorrhage, such as severe hypertension or recent stroke. Patients presenting > 12 hours after the onset of chest pain may also derive a small benefit, particularly if pain and ST-segment elevation persist, but rarely does this benefit outweigh the attendant risk.

Absolute contraindications to fibrinolytic therapy include previous hemorrhagic stroke, other strokes or cerebrovascular events within 1 year, known intracranial neoplasm, recent head trauma (including minor trauma), active internal bleeding (excluding menstruation), or suspected aortic dissection. *Relative contraindications* are BP > 180/110 mm Hg at presentation, other intracerebral pathology not listed above as a contraindication, known bleeding diathesis, trauma within 2–4 weeks, major surgery within 3 weeks, prolonged (> 10 minutes) or traumatic CPR, recent (within 2–4 weeks) internal bleeding, noncompressible vascular punctures, active diabetic retinopathy, pregnancy, active peptic ulcer disease, a history of severe hypertension, current use of anticoagulants (INR > 2.0–3.0), and (for streptokinase) prior allergic reaction or exposure to streptokinase or anistreplase within 2 years.

C. Fibrinolytic agents—Four fibrinolytic agents are available for acute MI and are characterized in Table 10–9.

(1) Selection of a fibrinolytic agent—In the United States, most patients are treated with alteplase, reteplase, or tenecteplase. The differences in efficacy between them are small compared with the potential benefit of treating a greater proportion of appropriate candidates in a more prompt manner. The principal objective should be to administer a thrombolytic agent within 30 minutes of presentation—or even during transport. The ability to administer tenecteplase as a single bolus is an attractive feature that may facilitate earlier treatment. The combination of a reduced-dose thrombolytic given with a platelet glycoprotein IIb/IIIa inhibitor does not reduce mortality but does cause a modest increase in bleeding complications.

(2) Postfibrinolytic management—After completion of the fibrinolytic infusion, aspirin (81–325 mg/day) and anticoagulation should be continued until revascularization or for the duration of the hospital stay (or up to 8 days). Anticoagulation with LMWH (enoxaparin or fondaparinux) is preferable to unfractionated heparin.

(A) Low-molecular-weight heparin—In the EXTRACT trial, enoxaparin significantly reduced death and MI at day 30 (compared with unfractionated heparin), at the expense of a modest increase in bleeding. In patients younger than age 75, enoxaparin was given as a 30-mg intravenous bolus and 1 mg/kg subcutaneously every

12 hours; in patients aged 75 years and older, it was given with no bolus and 0.75 mg/kg subcutaneously every 12 hours. This appeared to attenuate the risk of intracranial hemorrhage in older adults that had been seen with full-dose enoxaparin. Another antithrombotic option is fondaparinux, given at a dose of 2.5 mg subcutaneously once a day. There is no benefit of fondaparinux among patients undergoing primary PCI, and fondaparinux is *not* recommended as a sole anticoagulant during PCI due to risk of catheter thrombosis.

(B) UNFRACTIONATED HEPARIN—Anticoagulation with intravenous heparin (initial dose of 60 U/kg bolus to a maximum of 4000 units, followed by an infusion of 12 U/kg/hour to a maximum of 1000 U/hour, then adjusted to maintain an aPTT of 50–75 seconds beginning with an aPTT drawn 3 hours after thrombolytic) is continued for at least 48 hours after alteplase, reteplase, or tenecteplase, and with continuation of an anticoagulant until revascularization (if performed) or until hospital discharge (or day 8).

(C) PROPHYLACTIC THERAPY AGAINST BLEEDING—For all patients with STEMI treated with intensive antithrombotic therapy, prophylactic treatment with PPIs, or antacids and an H_2-blocker, is advisable. However, certain PPIs, such as omeprazole and esomeprazole, may decrease the clinical effect of clopidogrel; in such cases, pantoprazole, lansoprazole, and dexlansoprazole may be better PPI options.

3. Assessment of myocardial reperfusion, recurrent ischemic pain, reinfarction—Myocardial reperfusion can be recognized clinically by the early cessation of pain and the resolution of ST-segment elevation. Although at least 50% resolution of ST-segment elevation by 90 minutes may occur without coronary reperfusion, *ST resolution is a strong predictor of better outcome*. Even with anticoagulation, 10–20% of reperfused vessels will reocclude during hospitalization, although reocclusion and reinfarction appear to be reduced following intervention. **Reinfarction**, indicated by recurrence of pain and ST-segment elevation, can be treated by readministration of a thrombolytic agent or immediate angiography and PCI.

C. General Measures

Cardiac care unit monitoring should be instituted as soon as possible. Patients without complications can be transferred to a telemetry unit after 24 hours. Activity should initially be limited to bed rest but can be advanced within 24 hours. Progressive ambulation should be started after 24–72 hours if tolerated. For patients without complications, discharge by day 4 appears to be appropriate. Low-flow oxygen therapy (2–4 L/min) should be given if oxygen saturation is reduced, but there is no value to routine use of oxygen.

D. Analgesia

An initial attempt should be made to relieve pain with sublingual nitroglycerin. However, if no response occurs after two or three tablets, intravenous opioids provide the most rapid and effective analgesia and may also reduce pulmonary congestion. Morphine sulfate, 4–8 mg, or meperidine, 50–75 mg, should be given. Subsequent small doses can be given every 15 minutes until pain abates.

NSAIDs, other than aspirin, should be avoided during hospitalization for STEMI due to increased risk of mortality, myocardial rupture, hypertension, HF, and kidney injury with their use.

E. β-Adrenergic Blocking Agents

Trials have shown modest short-term benefit from β-blockers started during the first 24 hours after acute MI if there are no contraindications (metoprolol 25–50 mg orally twice daily). Aggressive β-blockade can increase shock, with overall harm in patients with HF. Thus, early β-blockade should be avoided in patients with any degree of HF, evidence of low-output state, increased risk of cardiogenic shock, or other relative contraindications to β-blockade. Carvedilol (beginning at 6.25 mg twice a day, titrated to 25 mg twice a day) was shown to be beneficial in the CAPRICORN trial following the acute phase of large MI.

F. Nitrates

Nitroglycerin is the agent of choice for continued or recurrent ischemic pain and is useful in lowering BP or relieving pulmonary congestion. However, routine nitrate administration is *not* recommended, since no improvement in outcome has been observed in the ISIS-4 or GISSI-3 trials. Nitrates should be avoided in patients who received phosphodiesterase inhibitors (sildenafil, vardenafil, and tadalafil) in the prior 24 hours.

G. ACE Inhibitors

A series of trials (SAVE, AIRE, SMILE, TRACE, GISSI-III, and ISIS-4) have shown both short- and long-term improvement in survival with ACE inhibitor therapy. The benefits are greatest in patients with an EF of 40% or less, large infarctions, or clinical evidence of HF. Because substantial amounts of the survival benefit occur on the first day, ACE inhibitor treatment should be commenced early in patients without hypotension, especially patients with large or anterior MI. Given the benefits of ACE inhibitors for patients with vascular disease, it is reasonable to *use ACE inhibitors for all patients following STEMI who do not have contraindications.*

H. Angiotensin Receptor Blockers

Although there has been inconsistency in the effects of different ARBs on mortality for patients post-MI with HF, LV dysfunction, or both, the VALIANT trial showed that valsartan 160 mg orally twice a day is *equivalent* to captopril in reducing mortality. Thus, valsartan should be used for all patients with ACE inhibitor intolerance and is a reasonable, albeit more expensive, alternative to captopril. The combination of captopril and valsartan (at a reduced dose) was *no better than either agent alone* and resulted in more side effects.

I. Aldosterone Antagonists

The RALES trial showed that 25 mg of spironolactone can reduce the mortality rate of patients with advanced HF, and the EPHESUS trial showed a 15% relative risk reduction in mortality with eplerenone 25 mg daily for patients post-MI with LV dysfunction (LVEF of 40% or less) and either clinical HF or diabetes. Kidney dysfunction and hyperkalemia are contraindications, and patients must be monitored carefully for development of hyperkalemia.

J. Calcium Channel Blockers

There are no studies to support the routine use of calcium channel blockers in most patients with acute MI—and indeed, they have the potential to exacerbate ischemia and cause death from reflex tachycardia or myocardial depression. *Long-acting calcium channel blockers should generally be reserved for management of hypertension or ischemia as second- or third-line medications after β-blockers and nitrates.*

K. Long-Term Antithrombotic Therapy

Discharge on aspirin, 81–325 mg/day, since it is highly effective, inexpensive, and well tolerated, is a key quality indicator of MI care. Patients who received a coronary stent should also receive a $P2Y_{12}$ inhibitor (see Antiplatelet therapy after drug-eluting or bare metal stents, above).

Patients who have received a coronary stent and who require warfarin anticoagulation present a particular challenge, since **"triple therapy"** with aspirin, clopidogrel, and warfarin has a high risk of bleeding. Triple therapy should be (1) limited to patients with a clear indication for warfarin (such as $CHADS_2$ score of 2 or more or a mechanical prosthetic valve), (2) used for the shortest period of time (such as 1 month after placement of bare metal stent; drug-eluting stents that would require longer clopidogrel duration should be avoided if possible), (3) used with low-dose aspirin and with strategies to reduce risk of bleeding (eg, PPIs for patients with a history of GI bleeding), and (4) used with consideration of a lower target anticoagulation intensity (INR 2.0–2.5, at least for the indication of atrial fibrillation) during the period of concomitant treatment with aspirin and $P2Y_{12}$ therapy. The PIONEER trial studied three treatment regimens for patients with atrial fibrillation who had coronary stent placement with a primary outcome of bleeding: (1) rivaroxaban 2.5 mg twice daily plus clopidogrel, (2) rivaroxaban 15 mg once daily plus clopidogrel, and (3) warfarin plus aspirin plus clopidogrel. There was less bleeding in the patients who received rivaroxaban plus clopidogrel than in those who received "triple therapy," although the trial was not powered to assess efficacy, and thus the low dose of rivaroxaban may be inadequate. Consensus statements recommend oral anticoagulation (with either warfarin or a DOAC) be combined with clopidogrel and with a relatively short duration of aspirin (1–4 weeks) for the typical patient with atrial fibrillation and coronary stents. Dabigatran, 110 mg and 150 mg, was also studied in patients with atrial fibrillation who underwent PCI. Dual therapy with dabigatran and clopidogrel was shown to be beneficial for bleeding compared to triple therapy, with similar rates of thrombotic cardiovascular events. However, there were too few thrombotic events to be certain about efficacy of discontinuing the aspirin, and there was a suggestion that MI and stent thrombosis occurred more often with the 110-mg dose of dabigatran than with clopidogrel alone. *Given the trial evidence to date, for a typical patient, it is reasonable to use a DOAC and clopidogrel and to discontinue aspirin at the time of hospital discharge or 1–4 weeks after stenting.*

The AUGUSTUS trial, which tested apixaban versus warfarin and aspirin versus placebo in a factorial trial, found that apixaban resulted in 31% less major and clinically relevant nonmajor bleeding than warfarin for patients with atrial fibrillation and coronary stents or ACSs or both. Avoiding aspirin, after an average of 6 days after the PCI, resulted in less bleeding and a nonsignificant increase in stent thrombosis. It is reasonable to stop aspirin at hospital discharge or at day 7 for patients with atrial fibrillation who are taking apixaban or warfarin at the time of discharge, although continuing aspirin for 1 month may reduce stent thrombosis.

L. Coronary Angiography

For patients who do not reperfuse based on lack of at least 50% resolution of ST elevation, **rescue angioplasty** should be performed and has been shown to reduce the composite risk of death, reinfarction, stroke, or severe HF. Patients treated with coronary angiography and PCI 3–24 hours after fibrinolytic therapy showed improved outcomes. Patients with recurrent ischemic pain prior to discharge should undergo catheterization and, if indicated, revascularization. PCI of a totally occluded infarct-related artery > 24 hours after STEMI should generally not be performed in asymptomatic patients with one- or two-vessel disease without evidence of severe ischemia.

▶ When to Refer

All patients with acute MI should be referred to a cardiologist.

Writing Committee Members; Lawton JS et al. 2021 ACC/AHA/SCAI Guideline for Coronary Artery Revascularization: a report of the American College of Cardiology/American Heart Association Joint Committee on Clinical Practice Guidelines. J Am Coll Cardiol. 2022;79:e21. Erratum in: J Am Coll Cardiol. 2022;79:1547. [PMID: 34895950]

▶ Complications

A variety of complications can occur after MI even when treatment is initiated promptly.

A. Postinfarction Ischemia

In clinical trials of thrombolysis, recurrent ischemia occurred in about one-third of patients, was more common following NSTEMI than after STEMI, and had important short- and long-term prognostic implications. Vigorous medical therapy should be instituted, including nitrates and β-blockers as well as aspirin 81–325 mg/day, anticoagulant therapy (unfractionated heparin, enoxaparin, or fondaparinux), and clopidogrel (75 mg orally daily). Most patients with postinfarction angina—and all who are refractory to medical therapy—should undergo early catheterization and revascularization by PCI or CABG.

B. Arrhythmias

Abnormalities of rhythm and conduction are common.

1. Sinus bradycardia—This is most common in inferior infarctions or may be precipitated by medications. Observation or withdrawal of the offending agent is usually sufficient. If accompanied by signs of low cardiac output, atropine intravenously is usually effective. Temporary pacing is rarely required.

2. Supraventricular tachyarrhythmias—Sinus tachycardia is common and may reflect either increased adrenergic stimulation or hemodynamic compromise due to hypovolemia or pump failure. In the latter, β-blockade is contraindicated. Supraventricular premature beats are common and may be premonitory for atrial fibrillation. Electrolyte abnormalities and hypoxia should be corrected and causative agents (especially aminophylline) stopped. *Atrial fibrillation should be rapidly controlled or converted to sinus rhythm*. Intravenous β-blockers, such as metoprolol (2.5–5 mg intravenously every 2–5 minutes, maximum 15 mg over 10–minutes) or short-acting esmolol (50–200 mcg/kg/min), are the agents of choice if cardiac function is adequate. Intravenous diltiazem (5–15 mg/hour) may be used if β-blockers are contraindicated or ineffective. Electrical cardioversion (commencing with 100 J) may be necessary if atrial fibrillation is complicated by hypotension, HF, or ischemia, but the arrhythmia often recurs. Amiodarone (150 mg intravenous bolus and then 15–30 mg/hour intravenously, or rapid oral loading dose for cardioversion of 400 mg three times daily) may be helpful to restore or maintain sinus rhythm.

3. Ventricular arrhythmias—Ventricular arrhythmias are most common in the first few hours after infarction and are a marker of high risk. Ventricular premature beats may be premonitory for ventricular tachycardia or fibrillation, but generally should *not* be treated in the absence of frequent or sustained ventricular tachycardia. Lidocaine is *not* recommended as a prophylactic measure.

Sustained ventricular tachycardia should be treated with a 1 mg/kg bolus of lidocaine if the patient is stable or by electrical cardioversion (100–200 J) if not. If the arrhythmia cannot be suppressed with lidocaine, procainamide (100 mg boluses over 1–2 minutes every 5 minutes to a cumulative dose of 750–1000 mg) or intravenous amiodarone (150 mg over 10 minutes, which may be repeated as needed, followed by 360 mg over 6 hours and then 540 mg over 18 hours) should be initiated, followed by an infusion of 0.5 mg/min (720 mg/24 hours). Ventricular fibrillation is treated electrically (300–400 J). All patients taking antiarrhythmics should be monitored with telemetry or ECGs during initiation. Unresponsive ventricular fibrillation should be treated with additional amiodarone and repeat cardioversion while CPR is administered.

Accelerated idioventricular rhythm is a regular, wide-complex rhythm at a rate of 60–120/min. It may occur with or without reperfusion and should *not* be treated with antiarrhythmics, which could cause asystole.

4. Conduction disturbances—All degrees of AV block may occur in the course of acute MI. Block at the level of the AV node is more common than infranodal block and occurs in approximately 20% of inferior MIs. First-degree block is the most common and requires no treatment. Second-degree block is usually of the Mobitz type I form (Wenckebach), is often transient, and requires treatment only if associated with a heart rate slow enough to cause symptoms. Complete AV block occurs in up to 5% of acute inferior infarctions, usually is preceded by Mobitz I second-degree block, and generally resolves spontaneously, though it may persist for hours to several weeks. The escape rhythm originates in the distal AV node or AV junction and hence has a narrow QRS complex and is reliable, albeit often slow (30–50 beats/min). Treatment is often necessary because of resulting hypotension and low cardiac output. Intravenous atropine (1 mg) usually restores AV conduction temporarily, but if the escape complex is wide or if repeated atropine treatments are needed, temporary ventricular pacing is indicated. The prognosis for these patients is only slightly worse than for patients in whom AV block does not develop.

In anterior infarctions, the site of block is distal, below the AV node, and usually a result of extensive damage of the His-Purkinje system and bundle branches. New first-degree block (prolongation of the PR interval) is unusual in anterior infarction; Mobitz type II AV block or complete heart block may be preceded by intraventricular conduction defects or may occur abruptly. The escape rhythm, if present, is an unreliable wide-complex idioventricular rhythm. Urgent ventricular pacing is mandatory, but even with successful pacing, morbidity and mortality are high because of the extensive myocardial damage. New conduction abnormalities, such as right or left bundle branch block or fascicular blocks, may presage progression, often sudden, to second- or third-degree AV block. Temporary ventricular pacing is recommended for new-onset alternating bilateral bundle branch block, bifascicular block, or bundle branch block with worsening first-degree AV block. Patients with anterior infarction who progress to second- or third-degree block even transiently should be considered for insertion of a prophylactic permanent ventricular pacemaker before discharge.

C. Myocardial Dysfunction

Persons with hypotension not responsive to fluid resuscitation or refractory HF or cardiogenic shock should be considered for urgent echocardiography to assess left and right ventricular function and for mechanical complications, right heart catheterization, and continuous measurements of arterial pressure. These measurements permit the accurate assessment of volume status and may facilitate decisions about volume resuscitation, selective use of vasopressors and inotropes, and mechanical support.

1. Acute LV failure—Dyspnea, diffuse rales, and arterial hypoxemia usually indicate LV failure. General measures include supplemental oxygen to increase arterial saturation to above 95% and elevation of the trunk. Diuretics are usually the initial therapy unless RV infarction is present.

Intravenous furosemide (10–40 mg) or bumetanide (0.5–1 mg) is preferred because of the reliably rapid onset and short duration of action of these medications. Higher dosages can be given if an inadequate response occurs. Morphine sulfate (4 mg intravenously followed by increments of 2 mg) is valuable in acute pulmonary edema.

Diuretics are usually effective; however, because most patients with acute infarction are not volume overloaded, the hemodynamic response may be limited and may be associated with hypotension. In mild HF, sublingual isosorbide dinitrate (2.5–10 mg every 2 hours) or nitroglycerin ointment (6.25–25 mg every 4 hours) may be adequate to lower pulmonary capillary wedge pressure (PCWP). In more severe failure, especially if cardiac output is reduced and BP is normal or high, sodium nitroprusside may be the preferred agent. It should be initiated only with arterial pressure monitoring; the initial dosage should be low (0.25 mcg/kg/min) to avoid excessive hypotension, but the dosage can be increased by increments of 0.5 mcg/kg/min every 5–10 minutes up to 5–10 mcg/kg/min until the desired hemodynamic response is obtained. Excessive hypotension (mean BP < 65–75 mm Hg) or tachycardia (> 10/min increase) should be avoided.

Intravenous nitroglycerin (starting at 10 mcg/min) also may be effective but may lower PCWP with less hypotension. Oral or transdermal vasodilator therapy with nitrates or ACE inhibitors is often necessary after the initial 24–48 hours.

Inotropic agents should be avoided if possible, because they often increase heart rate and myocardial oxygen requirements and worsen clinical outcomes. Dobutamine has the best hemodynamic profile, increasing cardiac output and modestly lowering PCWP, usually without excessive tachycardia, hypotension, or arrhythmias. The initial dosage is 2.5 mcg/kg/min, and it may be increased by similar increments up to 15–20 mcg/kg/min at intervals of 5–10 minutes. Dopamine is more useful in the presence of hypotension, since it produces peripheral vasoconstriction, but it has a less beneficial effect on PCWP. Digoxin has not been helpful in acute infarction except to control the ventricular response in atrial fibrillation, but it may be beneficial if chronic HF persists.

2. Hypotension and shock—*Patients with hypotension (systolic BP < 90 mm Hg, individualized depending on prior BP) and signs of diminished perfusion (low urinary output, confusion, cold extremities) that does not respond to fluid resuscitation should be presumed to have cardiogenic shock and should be considered for urgent catheterization and revascularization*. Sparing use of **intra-aortic balloon pump (IABP)** support and hemodynamic monitoring with a **PA catheter** can be considered, although these later measures have *not* been shown to improve outcome. Up to 20% will have findings indicative of intravascular hypovolemia (due to diaphoresis, vomiting, decreased venous tone, medications—such as diuretics, nitrates, morphine, β-blockers, calcium channel blockers, and thrombolytic agents—and lack of oral intake). These should be treated with successive boluses of 100 mL of normal saline until PCWP reaches 15–18 mm Hg to determine whether cardiac output and BP respond. Pericardial tamponade due to hemorrhagic pericarditis (especially after thrombolytic therapy or CPR) or ventricular rupture should be considered and excluded by echocardiography if clinically indicated. RV infarction, characterized by a normal PCWP but elevated RA pressure, can produce hypotension. This is discussed below.

Most patients with cardiogenic shock will have moderate to severe LV systolic dysfunction, with a mean EF of 30% in the SHOCK trial. If hypotension is only modest (systolic pressure higher than 90 mm Hg) and the PCWP is elevated, diuretics should be administered. If the BP falls, inotropic support will need to be added. A large randomized trial showed *no benefit* of IABP support in cardiogenic shock.

Norepinephrine (0.1–0.5 mcg/kg/min) is generally considered to be the most appropriate inotrope/vasopressor for cardiogenic shock based on limited randomized clinical trial evidence suggesting less arrhythmias and improved outcomes compared with dopamine. Dopamine is nonetheless also an option and can be initiated at a rate of 2–4 mcg/kg/min and increased at 5-minute intervals to the appropriate hemodynamic end point. At dosages lower than 5 mcg/kg/min, it improves renal blood flow; at intermediate dosages (2.5–10 mcg/kg/min), it stimulates myocardial contractility; at higher dosages (> 8 mcg/kg/min), it is a potent α_1-adrenergic agonist. In general, BP and cardiac index rise, but PCWP does not fall. Dopamine may be combined with nitroprusside or dobutamine (see above for dosing), or the latter may be used in its place if hypotension is not severe.

Patients with cardiogenic shock not due to hypovolemia have a poor prognosis, with 30-day mortality rates of 40–80%. The IABP-SHOCK II trial found that the use of an IABP does *not* offer a mortality benefit at 30 days or 1 year, compared with routine care with rapid revascularization, and is likely not helpful. Surgically implanted (or percutaneous) ventricular assist devices may be used in refractory cases. Emergent cardiac catheterization and coronary angiography followed by percutaneous or surgical revascularization offer the best chance of survival. Additionally, revascularization in shock should be aimed at the culprit artery only, avoiding multivessel PCI.

D. RV Infarction

RV infarction is present in one-third of patients with inferior wall infarction but is clinically significant in < 50% of these. It presents as hypotension with relatively preserved LV function and *should be considered whenever patients with inferior infarction exhibit low BP, raised venous pressure, and clear lungs*. Hypotension is often exacerbated by medications that decrease intravascular volume or produce venodilation, such as diuretics, nitrates, and opioids. RA pressure and JVP are high, while PCWP is normal or low and the lungs are clear. The diagnosis is suggested by ST-segment elevation in right-sided anterior chest leads, particularly RV_4. The diagnosis can be confirmed by echocardiography or hemodynamic measurements. Treatment consists of fluid loading beginning with 500 mL of 0.9% saline over 2 hours to improve LV filling, and inotropic agents only if necessary.

E. Mechanical Defects

Partial or complete rupture of a papillary muscle or of the interventricular septum occurs in < 1% of acute MIs and carries a poor prognosis. These complications occur in both anterior and inferior infarctions, *usually 3–7 days after the acute event*. They are detected by the appearance of a new systolic murmur and clinical deterioration, often with pulmonary edema. The two lesions are distinguished by the location of the murmur (apical versus parasternal) and by Doppler echocardiography. Hemodynamic monitoring is essential for appropriate management and demonstrates an increase in oxygen saturation between the RA and PA in VSD and, often, a large *v* wave with mitral regurgitation. Treatment by nitroprusside and, preferably, **intra-aortic balloon counterpulsation (IABC)** reduces the regurgitation or shunt, but surgical correction is mandatory. In patients remaining hemodynamically unstable or requiring continuous parenteral pharmacologic treatment or counterpulsation, early surgery is recommended, though mortality rates are high (15% to nearly 100%, depending on residual ventricular function and clinical status). Patients who are stabilized medically can have delayed surgery with lower risks (10–25%), although this may be due to the death of sicker patients, some of whom may have been saved by earlier surgery.

F. Myocardial Rupture

Complete rupture of the LV free wall occurs in < 1% of patients and usually results in immediate death. It occurs 2–7 days postinfarction, usually involves the anterior wall, and is more frequent in older women. Incomplete or gradual rupture may be sealed off by the pericardium, creating a pseudoaneurysm. This may be recognized by echocardiography, radionuclide angiography, or LV angiography, often as an incidental finding. It demonstrates a narrow-neck connection to the LV. Early surgical repair is indicated, since delayed rupture is common.

G. LV Aneurysm

An LV aneurysm, a sharply delineated area of scar that bulges paradoxically during systole, develops in 10–20% of patients surviving an acute infarction. This usually follows anterior ST-segment elevation infarctions. Aneurysms are recognized by persistent ST-segment elevation (beyond 4–8 weeks), and a wide neck from the LV can be demonstrated by echocardiography, scintigraphy, or contrast angiography. They rarely rupture but may be associated with arterial emboli, ventricular arrhythmias, and HF. Surgical resection may be performed for these indications if other measures fail. The best results (mortality rates of 10–20%) are obtained when the residual myocardium contracts well and when significant coronary lesions supplying adjacent regions are bypassed.

H. Pericarditis

The pericardium is involved in approximately 50% of infarctions, but pericarditis is often not clinically significant. Twenty percent of patients with ST-segment elevation infarctions will have an audible friction rub if examined repetitively. Pericardial pain occurs in approximately the same proportion after 2–7 days and is recognized by its variation with respiration and position (improved by sitting). Often, no treatment is required, but aspirin (650 mg every 4–6 hours) will usually relieve the pain. Indomethacin and corticosteroids can cause impaired infarct healing and predispose to myocardial rupture, and therefore should generally be *avoided* in the early post-MI period. Likewise, anticoagulation should be used cautiously, since hemorrhagic pericarditis may result.

One week to 12 weeks after infarction, **Dressler syndrome** (post-MI syndrome) occurs in < 5% of patients. This is an autoimmune phenomenon and presents as pericarditis with associated fever, leukocytosis, and, occasionally, pericardial or pleural effusion. It may recur over months. Treatment is the same as for other forms of pericarditis. A short course of nonsteroidal agents or corticosteroids may help relieve symptoms, but the use of nonsteroidal agents in the first several weeks after MI may impair infarct healing.

I. Mural Thrombus

Mural thrombi are common in large anterior infarctions but not in infarctions at other locations. Arterial emboli occur in approximately 2% of patients with known infarction, usually within 6 weeks. Anticoagulation with heparin followed by short-term (3-month) warfarin therapy (or DOAC therapy based on limited case report experience) results in clot resolution and prevents most emboli and should be considered in all patients with large anterior infarctions and evidence of LV thrombi. Mural thrombi can be detected by echocardiography or cardiac MRI. If the thrombus is resolved at 3 months, then anticoagulation can be discontinued.

Postinfarction Management

After the first 24 hours, the focus of patient management is to prevent recurrent ischemia, improve infarct healing and prevent remodeling, and prevent recurrent vascular events. Patients with hemodynamic compromise, who are at high risk for death, need careful monitoring and management of volume status.

A. Risk Stratification

Risk stratification is important for the management of STEMI. GRACE and TIMI risk scores can be helpful tools. Patients with recurrent ischemia (spontaneous or provoked), hemodynamic instability, impaired LV function, HF, or serious ventricular arrhythmias should undergo cardiac catheterization (see Table 10–8). ACE inhibitor (or ARB) therapy is indicated in patients with clinical HF or LVEF of 40% or less. Aldosterone blockade is indicated for patients with an LVEF of 40% or less and either HF or diabetes mellitus.

For patients not undergoing cardiac catheterization, *submaximal* exercise (or pharmacologic stress testing for patients unable to exercise) before discharge or a *maximal* test after 3–6 weeks (the latter being more sensitive for ischemia) helps patients and clinicians plan the return to normal activity. Imaging in conjunction with stress testing adds additional sensitivity for ischemia and provides localizing information. Both exercise and pharmacologic stress imaging have successfully predicted subsequent outcomes. One of these tests should be used prior to discharge in patients who have received thrombolytic therapy as a means of selecting appropriate candidates for coronary angiography.

B. Secondary Prevention

Postinfarction management should begin with identification and modification of risk factors. Treatment of hyperlipidemia and smoking cessation both prevent recurrent infarction and death. Statin therapy should be started before the patient is discharged from the hospital to reduce recurrent atherothrombotic events. BP control as well as cardiac rehabilitation and exercise are also recommended. They can be of considerable psychological benefit and appear to improve prognosis.

β-Blockers improve survival rates, primarily by reducing the incidence of sudden death in high-risk subsets of patients, though their value may be less in patients without complications with small infarctions and normal exercise tests. While a variety of β-blockers have been shown to be beneficial, for patients with LV dysfunction managed with contemporary treatment, carvedilol titrated to 25 mg orally twice a day has been shown to reduce mortality. β-Blockers with intrinsic sympathomimetic activity have *not* proved beneficial in postinfarction patients.

Antiplatelet agents are beneficial; aspirin (75–100 mg daily, after the initial dose) and P2Y$_{12}$ inhibitor therapy for 1 year are recommended. Prasugrel provides further reduction in thrombotic outcomes compared with clopidogrel, at the cost of more bleeding, but is contraindicated for patients with prior stroke. Likewise, ticagrelor provides benefit over clopidogrel. Calcium channel blockers have *not* been shown to improve prognoses overall and should not be prescribed purely for secondary prevention. Antiarrhythmic therapy other than with β-blockers has *not* been shown to be effective except in patients with symptomatic arrhythmias. Amiodarone has been studied in several trials of postinfarct patients with either LV dysfunction or frequent ventricular ectopy. Although survival was not improved, amiodarone was not harmful—unlike other agents in this setting. Therefore, it is the *agent of choice for individuals with symptomatic postinfarction supraventricular arrhythmias*. While implantable defibrillators improve survival for patients with postinfarction LV dysfunction and HF, the DINAMIT trial found *no benefit to implantable defibrillators implanted in the 40 days following acute MI*.

C. ACE Inhibitors and ARBs in Patients with LV Dysfunction

Patients who sustain substantial myocardial damage often experience subsequent progressive LV dilation and dysfunction, leading to clinical HF and reduced long-term survival. In patients with EFs < 40%, long-term ACE inhibitor (or ARB) therapy prevents LV dilation and the onset of HF and prolongs survival. The HOPE trial, as well as an overview of trials of ACE inhibitors for secondary prevention, also demonstrated a reduction of approximately 20% in mortality rates and the occurrence of nonfatal MI and stroke with ramipril treatment of patients with coronary or peripheral vascular disease and without confirmed LV systolic dysfunction. Therefore, ACE inhibitor therapy should be strongly considered in this broader group of patients—and especially in patients with diabetes and those with even mild systolic hypertension, in whom the greatest benefit was observed (see Table 13–6).

D. Revascularization

The indications for CABG are similar to those for patients with chronic coronary syndromes, including left main stenosis and multivessel disease (particularly with type 2 diabetes or LV dysfunction, or both). For patients who have undergone primary PCI and have residual left main or multivessel disease, CABG may be appropriate, but the timing needs to take into account the high risk of stent thrombosis if P2Y$_{12}$ inhibitor therapy is interrupted. For patients with non-infarct-related CAD, stenting should generally be performed on these lesions prior to hospital discharge.

RHEUMATIC FEVER

ESSENTIALS OF DIAGNOSIS

- More common in developing countries (100 cases/100,000 population) than in the United States (~2 cases/100,000 population).
- Peak incidence between ages 5 and 15 years.
- Presence of two major Jones criteria or one major and two minor.
- May involve mitral and other valves acutely, rarely leading to HF.

General Considerations

Rheumatic fever is a systemic immune process that is a sequela of a β-hemolytic streptococcal infection of the pharynx. It is a major scourge in developing countries and responsible for 320,000 deaths in young people worldwide each year. Over 15 million people have evidence for rheumatic heart disease. Signs of **acute rheumatic fever** usually commence 2–3 weeks after infection but may appear as early as 1 week or as late as 5 weeks. The disease has become quite uncommon in the United States, except in immigrants. The peak incidence is between ages 5 and 15 years; rheumatic fever is rare before age 4 years or after age 40 years. Rheumatic carditis and valvulitis may be self-limited or may lead to slowly progressive valvular deformity. The characteristic lesion is a perivascular granulomatous reaction with valvulitis. The mitral valve is acutely attacked in 75–80% of cases, the aortic valve in 30%

(but rarely as the sole valve involved), and the tricuspid and pulmonary valves in under 5% of cases.

The clinical profile of the infection includes carditis in 50–70% and arthritis in 35–66%, followed by chorea (10–30%, predominantly in girls) then subcutaneous nodules (0–10%) and erythema marginatum (in < 6%). Echocardiography has been found to be superior to auscultation, and the 2015 guidelines introduced **subclinical carditis** to the Jones criteria to represent abnormal echocardiographic findings when auscultatory findings were either not present or not recognized.

Chronic rheumatic heart disease results from single or repeated attacks of rheumatic fever that produce rigidity and deformity of valve cusps, fusion of the commissures, or shortening and fusion of the chordae tendineae. Valvular stenosis or regurgitation results, and the two often coexist. In chronic rheumatic heart disease, the mitral valve alone is abnormal in 50–60% of cases; combined lesions of the aortic and mitral valves occur in 20%; pure aortic lesions are less common. Tricuspid involvement occurs in about 10% of cases, but only in association with mitral or aortic disease and is thought to be more common when recurrent infections have occurred. The pulmonary valve is rarely affected long term. *A history of rheumatic fever is obtainable in only 60% of patients with rheumatic heart disease.* While there has been progress against this disease, it remains a major cardiovascular problem in the poorest regions of the world.

▶ Clinical Findings

The presence of two major criteria—or one major and two minor criteria—establishes the diagnosis. While India, New Zealand, and Australia have all published revised guidelines since 2001, the 2015 recommendations have revised the Jones criteria in a scientific statement from the AHA where subclinical carditis is now recognized with the advent of echocardiography. The revised criteria also recognize that a lower threshold should be used to diagnosis acute rheumatic fever in populations with high risk.

A. Major Criteria

1. Carditis—Carditis is most likely to be evident in children and adolescents. Any of the following suggests the presence of carditis: (1) pericarditis; (2) cardiomegaly, detected by physical signs, radiography, or echocardiography; (3) HF, right- or left-sided—the former perhaps more prominent in children, with painful liver engorgement due to tricuspid regurgitation; and (4) mitral or aortic regurgitation murmurs, indicative of dilation of a valve ring with or without associated valvulitis or morphologic findings on echocardiography of rheumatic valvulitis. The **Carey–Coombs** short mid-diastolic mitral murmur may be present due to inflammation of the mitral valve. It is a class I (LOE B) indication to perform echocardiography/Doppler studies on all cases of suspected or confirmed acute rheumatic fever.

2. Erythema marginatum and subcutaneous nodules—Erythema marginatum begins as rapidly enlarging macules that may be less notable on darker skin tones and that assume the shape of rings or crescents with clear centers. They may be raised, confluent, and either transient or persistent and usually on the trunk or proximal extremities. Subcutaneous nodules are uncommon except in children. They are small (2 cm or less in diameter), firm, and nontender and are attached to fascia or tendon sheaths over bony prominences. They persist for days or weeks, are recurrent, and are indistinguishable from rheumatoid nodules. Neither the rash nor nodules ever occur as the sole manifestation of acute rheumatic fever.

3. Sydenham chorea—This is the most definitive manifestation of acute rheumatic fever. Defined as involuntary choreoathetoid movements primarily of the face, tongue, and upper extremities, Sydenham chorea may be the sole manifestation of rheumatic fever. Girls are more frequently affected than boys, and occurrence in adults is rare.

4. Polyarthritis—This is a migratory polyarthritis that involves the large joints sequentially. In adults and in certain populations with moderate to high risk, only a single joint may be affected. The arthritis lasts 1–5 weeks and subsides without residual deformity. Prompt response of arthritis to therapeutic doses of salicylates or nonsteroidal agents is characteristic.

B. Minor Criteria

These include fever, polyarthralgia, reversible prolongation of the PR interval, and an elevated ESR or CRP. A lower threshold is set for patients at high risk. The 2015 guidelines stipulate that evidence for a preceding streptococcal infection can be defined by an increase in or rising antistreptolysin O titer or streptococcal antibodies (anti-DNAase B), a positive throat culture for group A β-hemolytic *Streptococcus,* or a positive rapid group A streptococcal carbohydrate antigen test in a child with a high pretest probability of streptococcal pharyngitis.

▶ Treatment

A. General Measures

The patient should be kept at strict bed rest until the temperature returns to normal (without the use of antipyretic medications) and the ESR, plus the resting pulse rate, and the ECG have all returned to baseline.

B. Medical Measures

1. Salicylates—The salicylates markedly reduce fever and relieve joint pain and swelling. They have no effect on the natural course of the disease. Adults may require large doses of aspirin, 0.6–0.9 g every 4 hours; children are treated with lower doses.

2. Penicillin—Penicillin (benzathine penicillin, 1.2 million units intramuscularly once, or procaine penicillin, 600,000 units intramuscularly daily for 10 days) is used to eradicate streptococcal infection if present. Erythromycin may be substituted (40 mg/kg/day). A 2022 randomized study demonstrated reduced progression of latent rheumatic heart disease with benzathine penicillin during 2 years of follow-up.

3. Corticosteroids—There is no proof that cardiac damage is prevented or minimized by corticosteroids. A short course of corticosteroids (prednisone, 40–60 mg orally daily, with tapering over 2 weeks) usually causes rapid improvement of the joint symptoms and is indicated when response to salicylates has been inadequate.

Prevention of Recurrent Rheumatic Fever

Improvements in socioeconomic conditions and public health are critical to reducing bouts of rheumatic fever. The initial episode of rheumatic fever can usually be prevented by early treatment of streptococcal pharyngitis with penicillin (see Chapter 37). Prevention of recurrent episodes of rheumatic fever is critical. Recurrences of rheumatic fever are most common in patients who have had carditis during their initial episode and in children, 20% of whom will have a second episode within 5 years. The preferred method of prophylaxis is with benzathine penicillin G, 1.2 million units intramuscularly every 4 weeks. Oral penicillin (250 mg twice daily) is less reliable.

If the patient is allergic to penicillin, sulfadiazine (or sulfisoxazole), 1 g daily, or erythromycin, 250 mg orally twice daily, may be substituted. The macrolide azithromycin is similarly effective against group A streptococcal infection. If the patient has not had an immediate hypersensitivity (anaphylactic-type) reaction to penicillin, then cephalosporin may also be used.

Recurrences are uncommon after 5 years following the first episode and in patients over 21 years of age. Prophylaxis is usually discontinued after these times except in groups with a high risk of streptococcal infection—parents or teachers of young children, nurses, military recruits, etc. Secondary prevention of rheumatic fever depends on whether carditis has occurred. Guidelines suggest that if there is no evidence for carditis, preventive therapy can be stopped at age 21 years. If carditis has occurred but there is no residual valvular disease, it can be stopped at 10 years after the acute rheumatic fever episode. If carditis has occurred with residual valvular involvement, it should be continued for 10 years after the last episode or until age 40 years if the patient is in a situation in which reexposure would be expected.

Prognosis

Initial episodes of rheumatic fever may last months in children and weeks in adults. The immediate mortality rate is 1–2%. Persistent rheumatic carditis with cardiomegaly, HF, and pericarditis implies a poor prognosis; 30% of children thus affected die within 10 years after the initial attack. After 10 years, two-thirds of patients will have detectable valvular abnormalities (usually thickened valves with limited mobility), but significant symptomatic valvular heart disease or persistent cardiomyopathy occurs in < 10% of patients with a single episode. In developing countries, acute rheumatic fever occurs earlier in life and recurs more frequently; thus, the evolution to chronic valvular disease is both accelerated and more severe.

DISEASES OF THE PERICARDIUM

ACUTE INFLAMMATORY PERICARDITIS

ESSENTIALS OF DIAGNOSIS

- Anterior pleuritic chest pain that is worse supine than upright.
- Pericardial rub.
- Fever common.
- ESR or inflammatory CRP usually elevated.
- ECG reveals diffuse ST-segment elevation with associated PR depression.

General Considerations
